The examination in 1944 (age 45 yrs) showed a rather large yellow smooth soft and lobulated mass on the right side of the tongue extending from the epiglottis to the deep surface of the right tonsil (see Fig. 3) Nothing else of significance was found in the local or general physical examination On Dec 7 1944 under general anesthesia the tumor was removed by sharp dissection along with both tonsils The tumor had extended between the capsule of the right tonsil and the fossa bed Bleeding was slight and the mass whose dimensions were 4 5x3 5x1 cm was surrounded by a definite capsule and was on the surface of the tongue The pathological diagnosis by Dr Warren C Hunter was submucous lipoma He commented that this was the first time that he had seen a lipoma in this location

The wound healed well and periodic examinations showed no recurrence until June 20 1952 (age 53 yrs) when a discrete mass about 1 cm in diameter with a broad base was found on the right side of the tongue in the vallecular fossa The patient returned for surgery on Feb 7 1953 The tumor was now about the size of an olive and was removed by sharp dissection under local anesthesia A small adjoining mass was also resected

Thoma[1] described the removal of a similar tumor by an extraoral approach The mass was so large that it interfered with talking and prevented the wearing of an upper denture Because the osteoma was so hard it was necessary to remove part of the cortex of the mandible with the specimen The same writer states,[2] "The development (of an osteoma) may occur in any part of the maxilla and mandible and arises from preformed bone, periosteum or retained cartilage cells from the embryonic chondroskeleton Growth is progressive, but slow, and the tumor is benign in character It starts spontaneously and is believed by many to be of traumatic but noninflammatory origin Its growth generally ceases with the termination of general skeletal development "

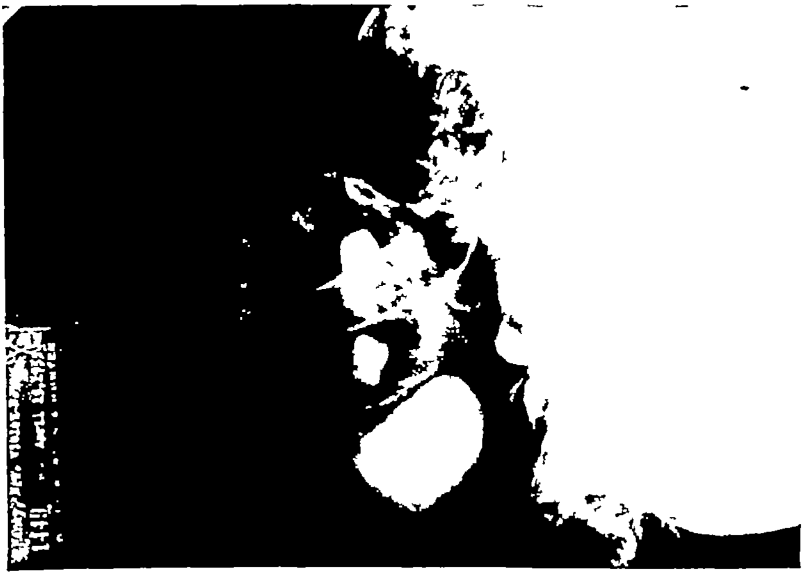

Fig 2 Case 1 Osteoma of Mandible as seen by X-ray

Uhler[3] presented the case of a man with such a large pedunculated osteoma attached to the lower first molar area that the tongue was displaced, making the intake of food difficult The tumor was thought to be the result of a blow to the lower jaw 37 years before Removal was accomplished with a Gigli saw

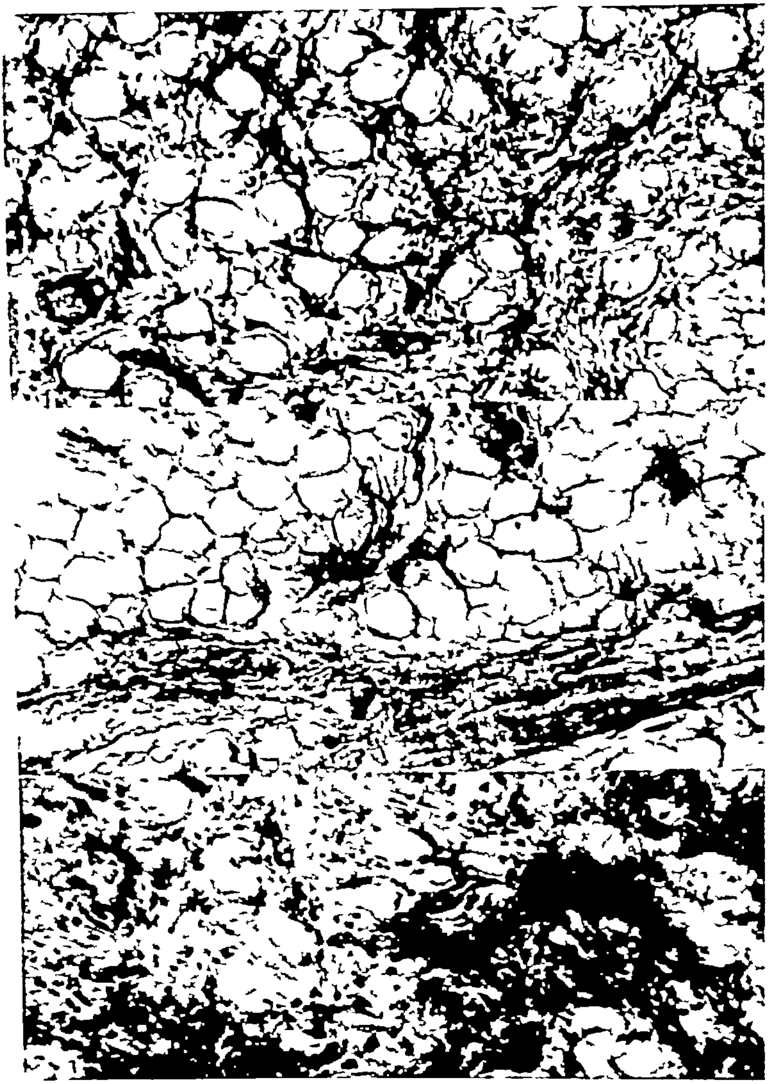

Fig 4 Case 2 Top—Photomicrograph (×160) of a representative portion of the original tumor removed in 1927 Adult-type fat cells are abundant but between these in places are elongated cells with fairly large and very deeply stained nuclei representing the sarcomatous element. Middle—Recurrent tumor of 1944 at this time entirely lipomatous and nonmalignant (×160) Lower—Representative area from the 1953 recurrence now somewhat more sarcomatous than in 1927 but still containing many adult adipose cells (×160)

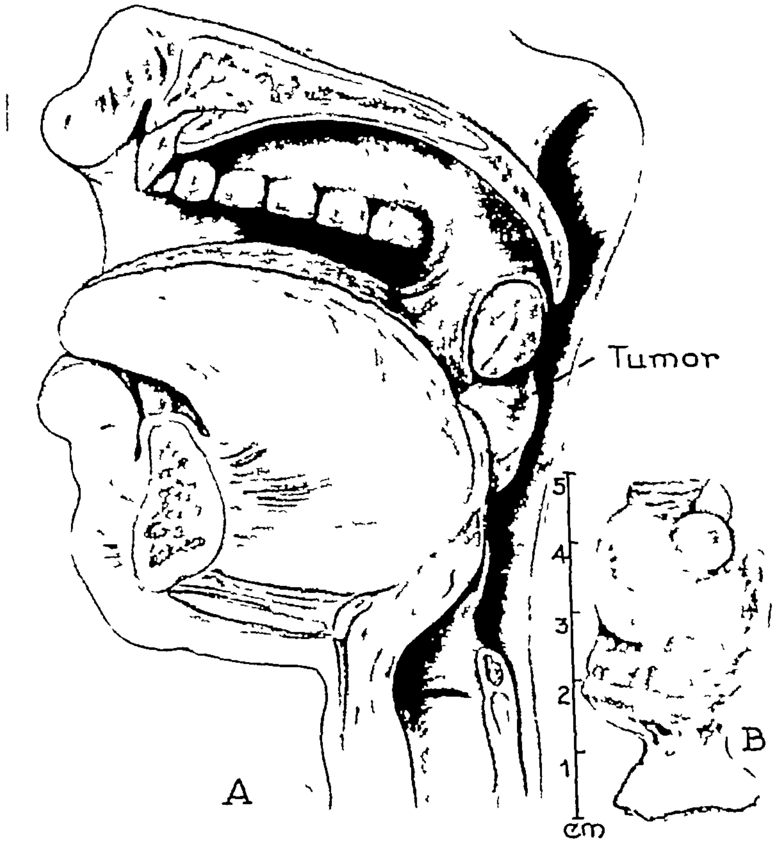

Fig 3 Case 2 Fibro-liposarcoma of dorsum of tongue extending into tonsil fossa

The pathology examination as recorded by Dr Hunter was as follows The pathological diagnosis of the tumor removed in 1927 was adeno myxoma with doubtful malignancy ”

Reviewed in late 1957 the histopathology proved to be identical with that observed in the recurrence of 1953 termed recurrent fibro liposarcoma

In 1944 a mass of yellow tissue divided into two parts by a cleft surrounded by a thin fibrous zone and measuring 4 5x3 5x1 cm was reviewed

Microscopically this proved to be principally fat cells of adult type, together with some mature collagenous type connective tissue Vascularity was not at all excessive There were no lipoblastic cells The pathologic diagnosis was submucous lipoma articular, perineal and mediastinal regions They generally first appear as rounded swellings of spontaneous origin, which grow steadily or rapidly until large or bulky masses result with prominent pressure symptoms They are usually encapsulated until recurrences develop as diffusely infiltrating, highly malignant and metastasizing processes"

Boyd[10] in discussing retroperitoneal liposarcomas says "Microscopically the greater part of the mass consists of adipose tissue, but here and there may be found areas of myxomatous tissue and sarcomatous formation It appears probable that these have developed primarily and that the tumor represents an embryonal type of tissue, rather than that they are due to a transformation of the lipoma"

MIXED TUMOR OF THE NASOPHARYNX

Case 3 Mrs D C M white age 52 In a general physical examination by Dr Eldon W Snow on Feb 10 1957 a swelling of the left tonsil area was noted It appeared as a fullness of the soft palate and posterior pillar which pushed the tonsil forward and medially The mass did not appear to change in size and on Oct. 27 1957 was explored by Dr Snow Upon removal of the normal tonsil the tumor immediately protruded through the posterior pillar It appeared to be of the consistency of cartilage which fragmented easily and was readily separated from the surrounding tissue A large fragment was removed for biopsy and the pathological examination by Dr Warren C Hunter revealed chondrosarcoma

X ray examination by Dr Arthur L Hunter revealed a large discrete opacity about 4 cm. in diameter protruding from the left lateral wall of the nasopharynx beyond the midline with no evidence of bone destruction X ray examination of the thorax was normal Otolaryngological examination showed the soft palate and left posterior pillar to be pushed forward by a large mass covered with normal mucosa protruding into the nasopharynx from the left side It extended almost to the midline and compressed the Eustachian orifice No other significant abnormality was found

Definitive surgery was carried out by the writer on Nov 21 1957 Under general anesthesia, the left external carotid artery was ligated below the lingual branch A tracheotomy was performed to facilitate anesthesia, and the hypopharynx was completely packed off A vertical incision was made through the left side of the soft palate beginning in the tonsil fossa and extending upwardly to the posterior edge of the hard palate Tumor tissue with a definite capsule was immediately encountered It was soon found that the tumor extended into the surrounding muscles extensively By sharp and blunt dissection the large neoplasm with a wide margin of surrounding normal muscle was removed in many pieces with a minimum of bleeding The largest fragment measured 5x4x3 cm In order to remove the tumor completely it was necessary to resect large portions of the left internal pterygoid muscle the palatine muscles and the posterior pillar The resulting cavity was bounded above by the Eustachian cartilage (not involved by tumor) and

In 1953, the specimen consisted of two tissues, one both smooth and rough surfaced, very soft white to red and measuring 1 3x1x0 5 cm, the other smooth everywhere soft, white to faintly pink and having dimensions of 3x2 5x1 5 cm The cut surfaces proved to be white to faintly yellow

Over a part of the larger tissue was a covering of stratified squamous epithelium along with underlying aggregates of lymphocytes The mass consisted of connective tissue and of fat and mingling with the latter were a good many cells of varying size and with hyperchromatic nuclei The cytoplasm lacked demonstrable vacuolization in the paraffin sections, yet their form otherwise and in a background of adipose tissue gave the impression that this growth must be considered as a recurrent fibroliposarcoma, and such was the pathological diagnosis Since all of the material had been embedded there was nothing available for fat staining (see Fig 4)

In a written consultation on this patient, Dr Simeon T Cantrell of Seattle, Wash, stated that he had never seen a similar tumor on the tongue, and that it was one of the very rare forms of mesenchymal sarcoma which has considerable radio-sensitivity He suggested that this patient should not be radiated unless the tumor should recur

At the present time there is no evidence of local recurrence or metastasis Obviously this tumor had a low degree of malignancy, as shown by its long duration and its recurrence at one time as a lipoma

A patient with a simple lipoma on the anterior surface of the tongue has been reported by Braunstein [6]

Saunders[7] in reporting a lipofibroma of the larynx presents an extensive bibliography on the subject of lipoma of the larynx Several of the cited cases of primary laryngeal lipoma showed extensions of the tumor to the epiglottis and valleculae One tumor originated on the left aryepiglottic fold and was diagnosed as myxolipoma with sarcomatous changes All of these tumors were removed surgically

Knowles and Hugill[8] have reported the case of a 12-year-old child who had a primary liposarcoma in the submucosa of the naso-pharynx The patient died with metastasis to the lungs, liver and brain

Lipomas are commonly seen in many parts of the body and are usually of no major consequence Ewing[9] states that "Liposarcomas are most frequent in the intermuscular, peri-

Boyd[11] states that a mixed tumor has two components, the first of which is the epithelial cell and the second, the spindle or stellate cell, separated by abundant intercellular mucoid material He states that in places this material may closely resemble or be identical in appearance with cartilage It was considered very fortunate that this tumor was of the mixed type rather than a chondrosarcoma Wirth and Shimkin[12] report a chondrosarcoma of the nasopharynx, which was very extensive and had a fatal outcome in spite of extensive surgical removal

Mixed tumors commonly arise in the major salivary glands, and also occasionally in aberrant salivary glands widely scattered over the whole of the oral mucosa If the tumor is completely removed by the first operation, the prognosis is generally considered to be quite favorable, however, "recurrence" may follow incomplete removal In order to be sure of total removal the tissue surrounding the capsule must be resected Malignant changes are uncommon The author observed in 1946 the removal by Dr Louis Clerf of a large mixed tumor of the nasopharynx by a transpalatine approach In reporting 33 malignant tumors of the nasopharynx, Hara[13] includes two mixed salivary gland tumors

In the presently reported case, there was no connection between the nasopharyngeal tumor and the deep lobe of the parotid gland, however, Morfit[14] reported 12 mixed tumors arising from the deep lobe of the parotid and presenting in the lateral pharyngeal wall as a large mass covered with normal mucosa Occasionally also the tumor presented below the horizontal ramus of the mandible The pharyngeal prominence is to be distinguished from an aneurysm or a large carotid body tumor External removal of the large parotid mass was recommended

Sonnenschein[15] has described two mixed tumors in the soft palate These were surgically removed and are rare in this location

MALIGNANT LYMPHOMA OF THE TONSIL

Case 4 Mrs K L white age 60 consulted her family physician on July 3 1957 because of a sore throat of two weeks duration His exam the base of the skull, laterally by the styloid process and carotid sheath, posteriorly by the longus capitis muscle, and anteriorly by the remains of the soft palate

The post operative course was uneventful except for trismus which has gradually improved

The pathological report by Dr Hunter of the original biopsy was The portions of tissue first seen had the color, consistency and cutting qualities of hyalin cartilage Sections contained nothing other than apparent cartilage and because of the atypical character of the nuclei the initial diagnosis was chondrosarcoma

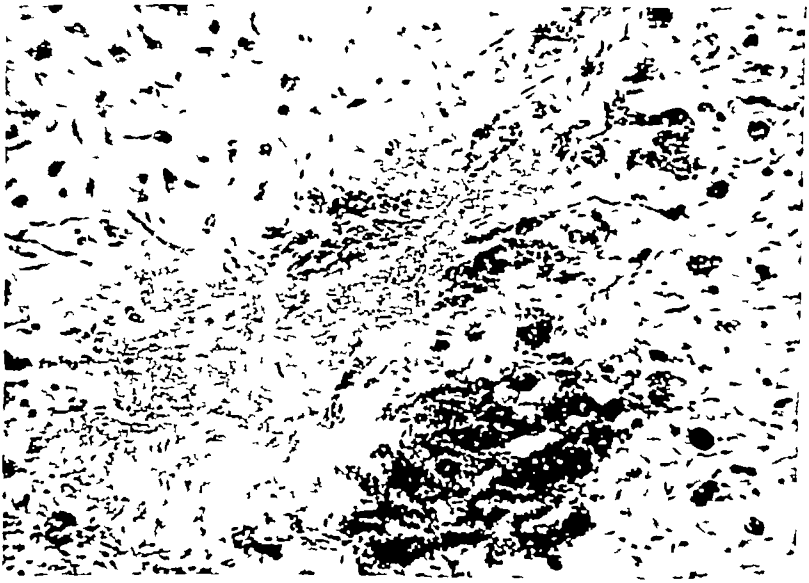

Fig 5 Case 3 Mixed salivary gland tumor (X160) this field contains many nests of epithelial cells relatively little matrix and no cartilage whereas the biopsy consisted entirely of atypical cartilage

The largest of the masses, removed on Nov 21 1957, appeared to be a partially encapsulated lobulated white tissue measuring 5x4x3 cm, cut with the consistency of cartilage and was white to yellow

Microscopically the growth consisted in large part of bluish pink to violet staining material rather poor in cells of apparent epithelial nature occurring in solid strands, and as small alveoli These had some resemblance to the alveolar epithelium of a serous type of salivary gland Mucus was not a component of the cells or the lumens of the alveoli None of the cells appeared to be of squamous type Embedded in surrounding connective tissue in close association with skeletal muscle and entirely away from the tumor were some lobules of a salivary gland of mucous type, unassociated with neoplasm

In view of the structure of the whole tumor as contrasted with the fragments making up the earlier biopsy the original diagnosis of chondrosarcoma was changed to mixed tumor of aberrant salivary gland" (see Fig 5) showed the soft palate and right pillars to be grossly normal with a gray membrane lining a normal appearing fossa In the right side of the neck, anterior to the sterno-cleidomastoid muscle was a freely movable smooth mass of rubbery consistency measuring about 10 cm in greatest diameter The remainder of the examination including an X-ray of the chest was negative X ray therapy was administered in divided doses to the throat and neck. The tumor responded well and examination on Oct. 3 1957 showed the tonsil fossa to be well healed and the mass in the neck to have completely disappeared

Malignant lymphomas of the throat and cervical lymph glands are rather common, and are usually considered to be best treated by irradiation

CARCINOMA OF THE TONSIL

Case 5 Mr M. O white, age 57 sought consultation because of a mass in his neck He stated that for several months he had visited various physicians in a large clinic because of a sore throat. He was told that he had an infection and was given various antibiotics which gave no relief Eventually the left side of his neck began to swell and an incision into this mass showed squamous cell carcinoma

Examination by the writer showed that a fungating tumor about 5 cm. in diameter occupied the left tonsil fossa. The soft palate and pillars were indurated and fixed and moderate trismus was present. The entire left side of the neck was greatly swollen and indurated The patient appeared to be in good general health otherwise

At that time he had already begun a course of cobalt radiotherapy under a competent physician For that reason, he was advised to continue the treatment, and that if the lesion in the tonsil was controlled radical surgery of the neck should be considered His further progress is not known.

Obviously, the prognosis in a patient such as this is discouraging

Early and small carcinomas of the tonsil can sometimes be completely removed by tonsillectomy If the tumor is more advanced, irradiation therapy is usually employed If the metastasis in the cervical lymph glands is not too far advanced, radical neck dissection is usually the best treatment if the primary lesion can be controlled

SUMMARY

The records of five patients having tumors in a tonsil or in the surrounding structures are presented The diagnostic and treatment problems are discussed and the literature is reviewed

ination revealed the right tonsil to be enlarged and displaced medially An enlarged anterior cervical lymph gland was present on the same side Because it was thought to be a peritonsillar abscess, an incision was made above the tonsil, but no pus was found Under antibiotic therapy, the tonsil decreased somewhat in size On Aug 13, 1957, the tonsil was removed and found to be extremely large

The pathological report by Dr Jeff Minckler was as follows The tonsillar tissue is submitted in three pieces ranging from 2 5 to 3 5 cm in their greatest dimensions The epithelial surface is identified on the larger specimen The surfaces are moderately fragmented and on sectioning much destruction of the tonsillar tissue is identified The entire tissue is mottled pale pink to red Nothing suggestive of a neoplasm is encountered

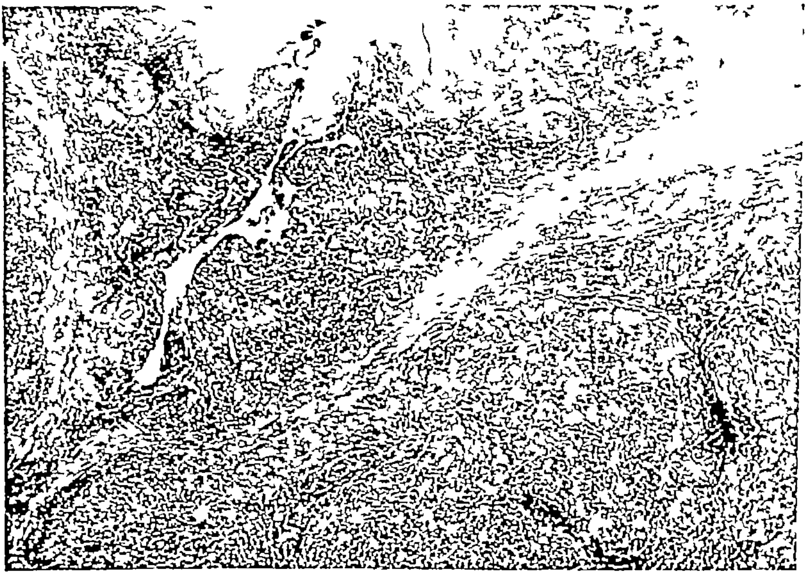

Fig 6 Case 4 At a 40X magnification the contrast between normal tonsil just below the epithelium of the crypt and the malignant lymphoma occupying the lower part of the field is quite evident

Microscopically the architectural pattern of the tonsil is altered by what is interpreted as a neoplastic process of the lymphoma group The predominant pattern is that of large follicle-like structures without distinct germinal centers composed of relatively uniform medium sized cells that have somewhat ill defined cytoplasmic outlines with suggestive tailed processes attached There is slight to moderate mitotic activity in these fields In selected areas there is somewhat more dense cellularity with somewhat larger darker staining cells and more apparent mitotic change There appears to be local infiltration of the capsular surfaces

Diagnosis Malignant lymphoma (lymphosarcoma) of the right tonsil (see Fig 6)

The otolaryngological examination by the writer on Aug 16 1957

SINUS SYMPTOMS ORIGINATING FROM MODERN FLIGHT[*]

LT COL STANLEY H BEAR,

USAF (MC)[†][‡]

With the advent of a new era in aviation, man is ever attaining higher altitudes and traveling at faster speeds In so doing, he is encountering physical problems which interfere with his best performance and well-being One of the vital problems is the involvement of the sinuses due to barotrauma, a condition more commonly known as aerosinusitis

Aerosinusitis is an acute or chronic inflammation of one or more of the nasal accessory sinuses produced by a barometric pressure difference between the air or gas inside the sinuses and that of the surrounding atmosphere It is commonly characterized by congestion and inflammation of the lining structures Mucosal or submucosal hemorrhage may occur[1]

There are two general types of aerosinusitis which may develop the non-obstructive, which is due to the collection of mucous secretions in the ostei, or the obstructive type, which has three degrees depending upon the severity Most chronic cases will fall into the latter group and are usually of the third degree

During the past two years, I have examined, in our clinic, 48 cases of aerosinusitis of the chronic obstructive type An evaluation has been made of the incidence, predisposing factors producing the physiological disturbances, signs and symptoms, pathology, X-ray findings, treatment and sequelae

The incidence of aerosinusitis is difficult to evaluate in

been properly briefed on the awareness of difficulty in flight, such as making slower descent and the use of the Valsalva maneuver, especially in cases of Eustachian tube involvement, however, the Valsalva maneuver is of little benefit in sinus obstruction and will not lessen the degree of symptoms Several fliers with more than 1,000 hours in conventional aircraft experienced symptoms on their very first jet flight In two instances, symptoms occurred during every descent in jet aircraft, yet they never experienced any difficulty in flying slower conventional aircraft

There are two main factors which tend to produce difficulty in flight These are a rapid change in barometric pressure, plus a predisposing factor which interferes with the air or gaseous change between the environment or nasal cavity and that of the sinus cavity The pressure change at the various altitudes is noted on the following table [5]

TABLE I

Altitude Based on United States Standard Atmosphere
(From Armstrong)

Altitude (Feet)	Pressure (mm Hg)
0	760
5 000	632 30
10 000	522 60
20 000	349 10
30 000	225 60
40 000	140 70
50 000	87 30

In general, on ascent from sea level to 5,000 feet, there is a decrease in barometric pressure from 760 mm Hg to 632 30 mm Hg, one-sixth atmosphere, and on ascent to 18,000 feet there is a decrease to 360 mm Hg, or one-half atmosphere The change is reversed on descent, therefore, it is especially noted that the greater differrential pressure change is noted at the lower altitudes This effect is more pronounced as the speed or rate of change is increased and greatly altered if a predisposing factor in any way interferes with this change Proetz[6] states that a reduction of one-fifth atmosphere (152 mm Hg) pressure is ordinarily well tolerated by the mucosa, any group of cases We were unable to correlate the incidence, because the cases were referred for final disposition after failing to respond to primary treatment The exact number of acute cases, before becoming chronic, was undetermined Campbell[2] reported on 35,000 simulated flights in the altitude chamber, where a direct control of all cases was able to be made, and found an incidence of 1 9 per cent McGibbon[3] noted 18 cases in 1000 chamber flights, or incidence of 1 8 per cent

One large airline during a one-year period, noted a major discomfort in its passengers from all causes due to air travel, averaged about eight or nine per 1,000[4] The incidence of sinus and ear distress reported varied from 0 5 to eight per 1,000 passengers carried, and it was felt that this rate would have been higher if all passengers who experienced sinus or ear distress had reported it Unfortunately, the number of flights made in pressurized aircraft was not differentiated from those in unpressurized aircraft

To our knowledge, there has been no report made on the incidence of aerosinusitis resulting from jet aircraft flight Of the 48 individuals we examined, 38 experienced symptoms of aerosinusitis in pressurized jet aircraft Of the remaining ten cases, six occurred in pressurized conventional aircraft for a total of 44 cases in pressurized aircraft There were four cases occurring in unpressurized conventional aircraft

What are the factors producing this change? It was interesting to note that of the 48 aircrew members, there was no direct correlation with the flying time The minimum number of hours flown by any of the pilots was approximately 50, and the maximum number of hours was over 5,000, when the symptoms became incapacitating There were four cases occurring in the 0-500 hour group, eight cases in the 500-1,000 hour group, 13 cases in the 1,000-1,500 hour group, 16 cases in the 1,500-3,000 hour group, and seven cases occurring in personnel with more than 3,000 hours of flying time

The four cases which developed in the 0-500 hour group all occurred during the flight training period in unpressurized conventional aircraft In all instances the individuals had between 12,000 feet and ground level Some occurred at an altitude of less than 5,000 feet The condition seemed to be aggravated by the rate and duration of the pressure change

There are many predisposing factors which, in combination with a rapid barometric pressure change, either on ascent or descent, will produce an acute obstruction to the sinus passage with resulting aerosinusitis The more common, in decreasing order of occurrence, are

TABLE II

Predisposing Factors in Etiology of Aerosinusitis

Deflection of Nasal Septum (More than 50%)	23
Hypertrophy of middle turbinate with encroachment of middle meatus and nasofrontal duct orifice	14
Nasal allergy	10
Upper respiratory infection	7
Polyps in middle meatus	7
Mucocele	2
Septal spur	1
Hypertrophic rhinitis	1
No abnormal finding at examination	1
Cyst on floor of maxillary sinus	1
Vasomotor rhinitis	1
Osteoma over sinus orifice of nasofrontal duct	1

In some cases it was noted that more than one factor was prevalent, such as allergy and nasal polyps, or deflection of the nasal septum with encroachment of the middle turbinate on the nasofrontal duct, thus, the total on the above chart will, in some instances, have more than one etiologic factor It is important to note that deflection of the septum was high in over two-thirds of the cases This resulted in the impingement of the middle turbinates laterally over the opening of the nasofrontal duct with encroachment on the duct orifice This was a significant finding in nearly 50 per cent of the cases The one case of osteoma was located at the orifice of the superior part of the nasofrontal duct and caused almost complete collapse of the mucosa lining the duct This acted as a suction valve on descent and would obstruct the orifice, producing severe symptoms Nasal allergy and polyps were present in seven of the cases They were obstructing the middle meatus in all instances The case of vasomotor rhinitis but when in much excess of this may be expected to be followed by hemorrhage, either mucosal or submucosal Behnke[7] found that if a sinus opening is obstructed and an increased pressure of one to two pounds transmitted to the body tissues and circulating blood, an area of relatively decreased pressure is produced in the air spaces This results in a cupping action in the cavity and a vascular congestion of the mucous membrane Tension is produced on the cells of the living membrane, and the blood vessels distributed in tissue surrounding the occluded space Pain is present in and around the involved area, associated with congestion and hemorrhage

Today most modern pressurized aircraft fly at a cabin altitude of approximately 8,000, and those of future jet operations will be at or near this altitude on long flights There is only a slight difference on ascent or descent of selected cabin altitude from that of the plane, therefore, from 8,000 feet to ground level, pressurization will have little beneficial effect on the individual crew member or passenger At the present time C A A Regulations allow a maximum rate of change of cabin altitude equivalent to approximately 300 feet per minute[8] This applies to both ascent and descent In future jet aircraft operations there are times when a faster rate of descent may be produced through loss of pressurization, faulty pressurization valves, instrument approaches, or in cases of fuel starvation Any one of these factors will necessitate a more rapid rate of barometric pressure change, and added to a predisposing intrinsic factor in the passenger or crew member, sinus symptoms will likely result

It is worthy to note at this point that there is a difference in the pressurization between military jet aircraft and those of anticipated commercial design At lower levels, the altitude of pressurization is approximately 12,000 to 13,000, rather than 8,000 feet, and the differential pressure at high altitudes is usually the maximum of 5-plus pounds per square inch, while the commercial planes are designed for 8-plus pounds per square inch for operation

In all the cases in our series, there were only a few occurring above 15,000 feet cabin altitude The majority occurred sinus and four with both frontal and maxillary sinuses involved The fourth major symptom was that of a feeling of pressure over the involved sinus, and occurred in seven cases The fifth predominant symptom or sign was evidence of a delayed bleeding, *usually of old blood, occurring 24 or* more hours after primary involvement This was noted on expectoration upon arising in the morning, or on blowing the nose, when blood-streaked mucous would be present The lesser symptoms are noted on the Table above

This discussion does not include the ethmoids and sphenoid sinuses, because no case of aerosinusitis occurred where only

TABLE III

Subjective Symptoms Experienced with Reference to Involved Sinus

	Frontal	Maxillary	Frontal and Maxillary
Sharp pain from descent	23	7	2
Sharp pain from ascent	0	1	0
Pain from ascent and descent	3	0	4
Generalized headache	2	0	3
Pressure over sinus	3	2	2
Nasal obstruction	4	3	2
Bleeding (delayed)	4	0	2
Blurring of vision	3	0	0

Swelling of upper eyelid	1	0	0
Rhinorrhea	0	1	1
Plugged ears	3	0	1

the ethmoid and sphenoid was primarily involved When there is severe involvement of either maxillary or frontal sinuses there may be associated involvement of the ethmoid sinus, but it is not felt to be the cause of the primary symptom complex This was also the finding of other authors[2,3] As previously noted, the frontal sinus was most frequently involved, next, the frontal and maxillary, with the maxillary sinus the least involved Campbell and McGibbon[2,8] also found the frontal sinus to be the most frequently involved, while Wright, in his series, found the most frequent site of involvement to be the maxillary[9] The reasoning for greater involvement of the frontal sinus is based on the greater length of the nasofrontal duct and its tortuous path and small caliber was in a cadet in training period, and was aggravated by an emotional problem On flying, his nose would completely obstruct, causing pain in sinus He was recommended for psychiatric evaluation and elimination from flying duties

The above conditions were present even in a select group of individuals Aircrew members were given rigid acceptance physical examinations, however, in most instances the deformities were acquired or developed during their career In addition, most pilots had been indoctrinated in the preventive medical aspects of flying and proper care of themselves during flight The average air passenger is not as well indoctrinated in active and preventive measures that can be performed while flying Many prospective passengers may have a nasal allergy of sufficient degree to be symptomatic on descent, active sinus pathology, upper respiratory infection, nasal obstruction of one sort or another, or a marked degree of apprehension and anxiety All of these act as predisposing factors, and when subjected to a rapid change of descent will produce aerosinusitis of one degree or another On ascent, the predisposing condition is basically intra-sinus, or in the osteum or duct of the sinus, while on descent the difficulty present is in the nasal cavity or surrounding structures in the area of the duct orifices leading into the sinus, as noted in the previously mentioned causative factors From these findings one is able to deduce whether the difficulty will be encountered on ascent or descent, or both

There are many symptoms produced by aerosinusitis, but the predominant symptom in most cases is pain located over the involved sinus It is described as being sharp, lancinating in character, non-radiating and occurring most often during descent The frontal sinus was involved in 23 instances, the maxillary sinus in seven, and both frontal and maxillary in two instances (see Table III)

The second most common symptom was that of nasal obstruction This occurred in nine cases and was almost equally divided, with involvement of either the frontal or maxillary sinus There were seven cases of pain on both ascent and descent, with three associated with involvement of the frontal orifice This results in free bleeding from the mucosa surface or submucosally, producing submucosal hematoma This was noted in four of our cases Campbell was able to demonstrate the same findings in his experiment with a dog in an altitude chamber

The treatment of aerosinusitis usually falls into one of two categories the acute phase, and the chronic or persistent type The acute stage is treated conservatively with treatment initiated as soon as possible after symptoms occur Treatment consists in the use of vasocontrictor sprays and packs, steam inhalation, antibiotics prophylactically, and anodynes for control of discomfort In severe cases, applicators of 5 per cent cocaine and 1 per cent ephedrine are placed directly in the middle meatus at the opening of the nasofrontal duct of the side involved Depending on the time interval following initiation of the first symptoms, most cases will respond to conservative management It is worthy of mention that the longer the interval before treatment is begun, the more difficult it is to obtain patency of the involved sinus

TABLE IV

of opening The opening of the maxillary sinus is larger and may have accessory openings Von Diringshofer[10] states that more involvement is expected in individuals with large frontal sinuses, but in one of our cases with severe frontal pain there was only a small frontal cell and no development of the frontal sinuses

X-ray examination is an important phase in the evaluation of aerosinusitis When possible they should be taken immediately as well as several days later if symptoms and signs persist It has been noted in cases where there is either mucosal or submucosal bleeding that definite delineation of the area involved may not be demonstrated until the bleeding is organized into a hematoma One of the most difficult X-ray diagnoses to make is submucosal hemorrhage It is very helpful to have previous X-ray films to help differentiate from polypoid hypertrophy or polyps The latter is uncommon in the frontal sinus, otherwise, the clinical history must be evaluated to rule out the presence of nasal polyps and allergy This was the opinion of Coche[11], also in four of our cases of bleeding with hematoma found on X-ray The views used in routine evaluation are Caldwell, Waters, and lateral views When indicated, laminograms are beneficial in making a differential diagnosis (see Table IV)

There were two cases in which more than one finding was made The pathology of aerosinusitis varies, depending on the etiologic factor and the degree of intra-sinus or naso-frontal duct changes The histologic structure of the mucosa is a continuation of the nasal respiratory mucosa with slight variations The submucosa is thinner and tends to blend with the fibrous periosteum of the underlying bony sinus wall The epithelium is a thinner cuboidal-like, stratified ciliated structure The resulting sinus mucosa changes can vary from thickening of the mucosa either inflammatory or polypoid, or there can be presence of fluid, blood, mucous, or purulent secretions in the chamber of the sinus In some cases, mucoceles will be present while others have osteoma in the cavity covered with a very thin mucosa Probably the most marked change is that noted in rapid changes of barometric pressure with the complete occlusion of the sinus partial turbinectomy of the anterior third of the middle turbinate because of polypoid hypertrophy encroaching on the opening of the nasofrontal duct There was one case of vasomotor rhinitis which was due to an emotional disturbance, and it was recommended that the individual have psychiatric evaluation and be eliminated from flying duties

As a group, chronic cases of aerosinusitis must have treatment directed to the precipitating factor, and in most instances the condition can be corrected only by surgical or allergic management It is easy to ascertain that conservative management will be of little avail where these conditions exist Many of the predisposing factors would not require surgical intervention if the individual were not flying, however, when required to fly either as passenger or aircrew member, surgical correction is necessary to alleviate the condition

Of the 48 cases, there were three cases which were entirely unsuccessful following treatment two of these cases showed marked nasal polyposis and polypoid hypertrophy of the turbinates and an underlying allergic condition The individuals were unable to fly without repeated bouts of aerosinusitis The other case was that of the vasomotor rhinitis, for which no treatment was indicated as it was felt to be due to an emotional basis There were three cases in which the individuals were able to fly, but at intermittent intervals would still experience symptoms, usually not to the degree of incapacitation from flying duties Two of these cases were allergic rhinitis with polyposis, while the third case was that of recurrent upper respiratory infection This individual is still undergoing treatment to determine the etiology of his infection. The remaining 41 cases have been returned to flying duty and have experienced no difficulty in most cases, and minimal symptoms in a few cases which did not interfere with duty performance All cases were followed for a minimum of one year, however, due to loss of contact and follow-up in some cases the incidence of recurrence may have been slightly higher One case has recently been discharged from the hospital following frontal sinus surgery for submucosal hemorrhage and obstruction to the nasofrontal duct He has

In our series, almost all the cases were of a chronic nature, having been referred when conservative management failed, or when there was a recurrence of the condition at frequent intervals Following is a table showing the various treatments utilized in the 48 cases of our series

In several cases, more than one procedure or combined procedures were necessary to correct the condition In 20 cases, conservative management was used which consisted of antibiotics when indicated, vasoconstrictors and steam inhalation, or minor surgical manipulation to produce a patent osteum of the involved sinus The conservative treatment was mainly combined with infraction of the middle turbinate which was necessary in 13 cases, and in cases of post-polypectomy to maintain normal drainage, however, there were 19 cases in which it was necessary to perform a submucous resection (Killian type) In all but seven of these cases, the obstruction was located in the region of the middle turbinate, and in several cases following resection, infraction of the middle turbinate was combined in the treatment Four cases of frontal sinusotomy, by the Lynch approach, were necessary to remove the frontal sinus pathology and obtain a patent nasofrontal duct Allergic management was utilized in five cases with fair results In one case of an antral cyst, an antral window was performed with curettement of the cyst Two cases of recurrent purulent infection of the sinus were treated by irrigation, one was of the frontal sinus, the other, of the maxillary sinus Two cases were surgically treated by

MANAGEMENT OF SINUSITIS IN CHILDREN *

CLIFFORD F LAKE, M D ,†
Rochester, Minn

Sinusitis, either alone or associated with some other inflammatory process in the respiratory tract or related areas, occurs frequently in childhood Although this fact has been demonstrated and reported many times in the past, it seems that in this age of antibiotics its re-emphasis is indicated

Dependence on antibiotics alone, and especially on short courses of them, during acute respiratory tract infections may only modify or mask associated acute sinusitis

Failure to examine the nose and nasopharynx completely when possible, or to obtain roentgenologic views of the paranasal sinuses, often causes failure in diagnosis Birdsall[1] stated that nasal sinus infection in children is common, but is often overlooked because of its usually insidious onset, the lack of definite symptoms, and the difficulty of examining the affected parts

From the ages of four or five most children who are co-operative can be given satisfactory nasal examination Children this old frequently will be co-operative on nasopharyngeal examinations with the small to medium-sized mirrors A brief explanation of what is about to happen, and a demonstration of quiet rhythmical breathing often will convert a skeptical child into a most co-operative youngster If the tongue depressor and nasopharyngeal mirror are introduced simultaneously, the number of satisfactory nasopharyngeal examinations will be increased This method of introducing the instruments relieves the child of the "double jeopardy" of separate instrumentations

not been returned to flying duty, but exhibits a patent duct at the present time and will be given trial indoctrination in the altitude pressure chamber to see whether his results have been successful before returning to full flying duties

In all cases of aerosinusitis, treatment is directed to removing the etiologic factor as well as the existing condition

several days before attempting therapy directed to the nose Antihistaminic drugs are of particular value in cases with a history of vasomotor or allergic rhinitis

Treatment directed to the nose usually is a matter of personal choice Prolonged use of vasoconstrictors often produces the familiar rebound phenomena Application of argyrol packs to the middle meatus and in the nasal chamber, followed by gentle suction, may prove of value in the removal of purulent secretion from the nose and sinuses In some children lavage of the maxillary sinus via the natural ostium can be carried out after the acute edematous stage has subsided

In an instance of acute ethmoiditis with external manifestations, as is found occasionally in a young child, surgical drainage may be necessary, however, if seen in the early stages this situation will usually respond to antibiotic treatment

Heat applied to the area over the involved sinus or sinuses may afford some relief of pain, however, sometimes it may exacerbate the pain Increasing the humidity in the patient's bedroom and making him comfortable are beneficial in his general care

During his course of treatment the patient should be reexamined for conditions which may have influenced the onset of the sinusitis or the application of therapeutic measures Enlarged adenoids, septal deflections, and allergic changes in the nasal mucosa are commonly occurring factors predisposing to acute sinusitis

The status of the patient's general health should be investigated Whatever general measures are necessary to improve it should be carried out, also it may be necessary to remove enlarged adenoids or a septal deflection to gain final resolution of the disease

Roentgen therapy has been used successfully in the treatment of acute or subacute sinusitis in the past Laing[4] reported treatment with Roentgen therapy in 900 cases of subacute sinusitis in children, 639 of whom were cured during

Obviously the anatomic development of the paranasal sinuses in accord with age has an effect on the sites in which infection may develop In older children the roentgenologic views are particularly helpful in localizing the site of infection Maresh,[2] in a study of routine roentgenograms of the sinuses of 100 children who were followed from birth to maturity, observed many variations in the size and shape of antrums, ethmoid cells, and frontal sinuses

DIAGNOSIS AND SYMPTOMATOLOGY

Sinusitis should be included in the differential diagnosis when symptoms of prolonged rhinorrhea, coughing, frequent sniffling, or throat clearing are present A history of recurrent respiratory infections, otitis media, secretory otitis, and sore throats should suggest the possibility of the presence of sinusitis Wishart[3] stated that the most frequent complaint in an otherwise healthy child in whom sinusitis is discovered is repeated head colds

In cases of small children the history obtained from the parents and the objective findings on examination, with the findings from roentgenologic examination in some instances, usually will suffice in making the diagnoses Older children often can contribute to their history, and should be encouraged to do so Frequently such children describe their symptoms accurately, especially when pain is present in acute sinusitis or in a flare-up of chronic disease

In the history, allergy affecting either the patient or his family should not be overlooked

MANAGEMENT OF ACUTE SINUSITIS

The best basis for management of acute sinusitis in children is consideration of the child as a whole and the severity of his infection A culture of the nasal secretions should be made and tests of sensitivity to antibiotics performed The child's reaction to obtaining the material for culture from his nose may indicate the degree of co-operativeness to be expected in carrying out local treatment If the infection is severe enough to warrant the use of antibiotics one may wait sinuses and ethmoids, particularly the left antrum. Skin tests were made which showed sensitivity to cat hair cattle hair goat hair, house dust, mixed feathers pyrethrum and giant and small ragweed

A diagnosis of allergic rhinitis and sinusitis was made The treatment consisted of giving the child an antihistaminic drug for two weeks, after which he was re-examined The nose then appeared to be normal with no evidence of any unusual discharge New roentgenograms showed marked clearing of the paranasal sinuses

Comment This case is an example of sinusitis superimposed on hay fever, and illustrates the improvement which occurred from the use of an antihistaminic prescription during the recession of the hay fever season Further care in regard to the allergic manifestations was advised

Case 2 A seven-year-old girl was registered at the clinic Nov 8 1957 She had had pneumonia approximately two months prior to her registration After five days in the hospital and two weeks at home for recovery she had returned to school, but after two days in school left otitis media developed To combat this ear infection she had been given antibiotics for a few days (The exact type of antibiotic and the number of days that it was given could not be determined at the clinic) Approximately a week later the patient developed a sore throat and a course of penicillin had been administered

On Oct. 30, the child had been seen in consultation by an oto-rhino-laryngologist A diagnosis of sinusitis had been made nasal irrigations had been carried out and she had seemed to improve On Nov 6 however she complained of a sore throat again and her trip to the clinic followed

She was first examined in the Section of Pediatrics Only normal findings resulted from general examination a roentgenogram of the lungs blood counts urinalysis and electrophoresis of serum protein

The child was examined in the Section of Otolaryngology and Rhinology, and her eardrums were found to be intact although the left showed slight infection from the recent acute otitis media Her hearing of tuning forks seemed normal The nose looked clear on examination, and no pus was visible on anterior rhinoscopy The turbinates were only slightly congested Roentgenograms of the child s sinuses showed involvement, particularly of the antra and especially on the left. The tonsils had been removed and the nasopharynx contained only a minimal amount of lymphoid tissue A culture of the nasal secretion was negative

It was thought that this patient's disorder was sinusitis the diagnosis depending largely on the history and on the appearance of the roentgenograms of the sinuses A two week trial of antibiotics was prescribed and the patient was advised to return at its conclusion

She did return at that time On examination her nose appeared normal and in roentgenograms her sinuses seemed clear The child was feeling well.

Comment This is a case of recurring upper respiratory infection, sore throats, and otitis media, in which a diagnosis of sinusitis was made largely on the history and roentgenographic findings The response to a two-week course of an one series of treatments, however, with the knowledge of risks involved in exposure to radiation I prefer not to use it for children

MANAGEMENT OF CHRONIC SINUSITIS IN CHILDREN

Adequate treatment may include several types of therapy, and the physician should not limit himself to an inflexible routine, rather, he should avail himself of all procedures, and use them as the situation demands, to restore the paranasal sinuses to their normal physiologic state

The treatment of chronic sinusitis follows the same principles in using antibiotics and intranasal therapy which were mentioned in the treatment of acute sinusitis Lavage of the maxillary sinus via its natural ostium can be accomplished in many older children

If surgical treatment is necessary it usually can be done intranasally, except for most instances in which external manifestations exist

The patient's general health should be evaluated A search for predisposing factors should be made, and their eradication accomplished, and again, the history of allergy in the patient or his family should not be overlooked The rather special problem of chronic sinusitis, associated with bronchiectasis, is not within the scope of this presentation, but the possibility of a co-existing bronchiectasis must be ruled out in all cases of chronic sinusitis

REPORT OF CASES

Case 1 An 11 year-old boy was registered at the Mayo Clinic on Sept 26 1957 His complaint was that sneezing, itching of the eyes, and nasal discharge had persisted for one month After a general examination in the Section of Pediatrics an ear, nose, and throat examination was requested

In the Section of Otolaryngology and Rhinology, examination of the ears revealed no abnormalities Examination of the nose showed much thick, sticky mucoid discharge on both sides particularly on the left some of which was yellowish and obviously mucopurulent The turbinates were moderately congested on both sides Pus was demonstrated coming from the natural ostium of the left antrum The tonsils had been removed There was a thick mucoid discharge in the nasopharynx, along with some mucopurulent material

Roentgenograms of the sinuses showed thickening about the maxillary rhinitis on the paternal side of the family The child had been taking an antibiotic of an undiscoverable type for 11 days prior to her admission for examination.

On examination of the ears the tympanic membranes were intact with very slight redness on the right The nasal septum was straight There was mucopus on both sides of the nose The tonsils were of size 2 on the basis of 1 to 4 The nasopharynx was examined with a mirror and a good view was obtained it was noted that an adenoid blocked most of the choana. On roentgenograms of the sinuses both antra were diffusely cloudy A culture of the nasal secretions was reported as showing usual flora

The patient was given penicillin for ten days At the end of that time the nose looked clear and no discharge was noted on examination of the nasopharynx Roentgenograms showed clearing of the paranasal sinuses

Arrangements were made for removal of the tonsils and adenoids this was done June 15 1956 After the operation the child got along well and was dismissed June 21, 1956

The child was observed a year later during the course of a common cold, however the cold cleared in eight days without complications or recurrence of sinusitis

Comment This case is an instance in which an enlarged adenoid obstructing the choana seemed to play an important part in the persistence of the patient's nasal symptoms and sinusitis

SUMMARY AND CONCLUSIONS

The occurrence of sinusitis in childhood deserves re-emphasis A short course of antibiotics may only modify or mask an acute sinusitis during the course of an upper respiratory infection Examination of the nose and nasopharynx should be complete when at all possible The value of roentgenograms and the history obtained from the parents and the child is great

The foregoing diagnostic principles and a discussion of the management of acute and chronic sinusitis in children have been illustrated in reports of four cases

antibiotic was excellent, and the roentgenograms which were taken at the end of this treatment illustrated marked clearing within the sinuses There was no history of allergy in the family of the patient

Case 3 A six year old boy was registered at the clinic Nov 28, 1956 He had had persistent nasal obstruction for at least a year or so Infections of the upper part of the respiratory tract had been frequent and he had had pneumonia in 1952 There was no history of a definite allergic background but the patient's mother had had mild vasomotor rhinitis

In the general examination nothing out of the ordinary was found except mild obesity He was referred to the Section of Otolaryngology and Rhinology Our examination revealed the tympanic membranes to be intact, but they appeared slightly dull and his hearing seemed to be reduced very slightly through the entire range in both ears An audiogram showed very slight bilateral conductive deafness On nasal examination the nasal airways seemed to be open, however, mucus was pooled on the nasal floor, and when this was removed the adenoid could be seen obstructing the choana The tonsils were enlarged (grade III, on a basis of 1 to 4 with one being slightest), and combined tonsillectomy and adenoidectomy was advised The operation was carried out Nov 30 1956, and large masses of adenoid, and the tonsils were removed

The patient then got along very well until three weeks later when he developed an upper respiratory infection On examination a large amount of pus was observed in each nasal passage A culture of the discharge was reported as showing usual flora Tetracycline (achromycin) was prescribed, and the child's nose cleared nicely after a ten days' trial

The patient was again seen on January 23 1957, with a report that a cough had developed two days previously, and he had coughed most of the night prior to his examination His case was followed for several weeks, but the situation did not clear, and a culture again was made of the nasal secretions, this time showing many Hemophilus influenzae organisms Electrophoresis of serum protein gave findings within normal limits Roentgenograms of the sinuses showed cloudiness throughout all of them The patient was given a preparation of streptomycin with dihydrostreptomycin (distrycin) 500 mg twice daily for ten days and therapy directed to the nose was begun with shrinkage and suction and application of argyrol packs to the middle meatus on each side This was carried out for two weeks, after which the nose was clean the child was breathing freely and roentgenograms of the sinuses showed marked improvement, there being only a minimal amount of thickening in the left antrum Clinically the child was well

The case has been followed since and during one more upper respiratory infection the boy has gotten along well, with no further recurrences of his sinusitis

Comment This case illustrates the need in many instances of treatment to the nose as well as antibiotics in order to clear a sinusitis

Case 4 A 4½ year old girl was registered at the clinic May 3 1956 A history of repeated prolonged colds worse in the Winter months was obtained She had less difficulty during the Summer and her symptoms were not related to the hay fever season There was a history of allergic nasion, the chisel may force the ends of the fractured bones into the lumen of the sinus, causing frontal sinusitis

FRONTAL SINUS RELATIONSHIPS

At the *nasal notch* of the frontal bone, the floor of the frontal sinus is normally at the level of the glabella, but in some cases, it may extend as far down as the middle-third of the nasal bones (over-developed sinus), or it may stop short of the glabella (under-developed sinus)

OVERDEVELOPED FRONTAL SINUS

When the frontal sinus extends beyond the glabella, its floor is attached directly to the inner surfaces of the nasal bones, which in this instance become part of the anterior wall of the sinus (see Fig 1)

Thus, manipulations of the nasal bones at the nasion may injure the frontal sinus A natural protection is given by the fact that the periosteum, which covers the posterior surface of the anterior wall of the frontal sinus, is tough and loosely attached Its toughness gives it a good deal of resistance to cutting by sharp instruments, and its looseness renders it easily detachable at the slightest pressure These two favorable conditions form a very valuable protection against accidental entry into the lumen of the sinus when an ostectomy is performed

X-ray studies will give valuable information about the size and extent of the frontal sinus and its relationship to the nasal bones

UNDERDEVELOPED FRONTAL SINUS

When the frontal sinus is not well-developed, it will stop short of the glabella, and a block of compact bone will be found where the sinus is normally located At the nasion this block of compact bone fuses with the nasal bones, the frontal processes of the maxillae, the bony nasal septum, the frontal spine and the nasal notch of the frontal bone, to form a huge block of solid bone, which will make the ostectomy a difficult procedure

ANATOMICAL OBSERVATIONS FOR RHINOPLASTIC SURGERY *

ROMEO A LUONGO, M D ,
and
ROMEO A LUONGO, JR , M D ,
Philadelphia, Pa

ANATOMIC RELATIONSHIPS AT THE NASION

The squama of the frontal bone projects downwards, at the midline, to form the *nasal part* The lower margin of the nasal part, which is beveled, rough, uneven, and serrated, is called the *nasal notch* The *upper margins* of the nasal bones and of the frontal processes of the maxillae imbricate, like shingles, upon the beveled portion of the nasal notch

From the center of the nasal notch, the *nasal process* projects downwards and forwards underneath the upper margins of the nasal bones and the frontal process of the maxillae The *frontal spine* extends below farther than the nasal process itself, and it becomes fused with the perpendicular plate of the ethmoid posteriorly, and with the septal crests of the nasal bones anteriorly to give the bridge of the nose a solid support

This type of construction makes infracturing difficult and inadvisable Out-fracturing is the procedure to be chosen

If, to complete an osleotomy, a chisel is used to fracture at the nasion, the surgeon should bear in mind that this technique may cause fractures of the sloping edges of the nasal notch, of the frontal spine, of the perpendicular plate of the ethmoid, destroying the main support of the nasal bridge, and the impact of the chisel may even be transmitted to the cribriform plate, furthermore, when the frontal sinus extends below the fronto-nasal suture line, which is located at the

THE USE OF ANTIBIOTIC-STERIOD COMBINATIONS AS NEBULIZING AGENTS IN THE TREATMENT OF LARYNGEAL CONDITIONS

A Preliminary Report *

BERNARD L SILVERBLATT, M D ,

Pittsburgh, Pa

The treatment of disease entities affecting the larynx is predominantly surgical Except for antibiotics in the acute infectious reactions and streptomycin in tuberculous laryngitis, other therapeutic measures have failed to produce the enthusiastic results portrayed by their author Thus podophyllin, hormonal agents as theelin, adrenalin, etc , are seldom prescribed today Limitations of vocal abuse, smoking and alcohol, persist as standard directives to the patient with hoarseness

For almost two years, we have been using antibiotic steriod combinations in the treatment of many of our laryngeal problems This combination has been used in nebulization form, both as a primary therapeutic agent and as an adjunct to surgical procedures We feel that the combination has rational and merit for usage I would stress, however, that they are not "cure-alls "

ANALYSIS OF THE PROBLEM AND RATIONAL OF THERAPY

Standard textbooks list[1] better than 50 specific diseases of the larynx Standard nomenclature increases this to better than 150 diagnoses This discrepancy is partially due to our own inadequacies in standardizing nomenclature for disease entities, thus a clinical entity may be diagnosed on the basis of the etiology, the pathologic picture, the anatomic deformity or disability, and with the name of an author

---

*Read at the meeting of the Eastern Section American Laryngological Rhinological and Otological Society Inc. Philadelphia, Pa Jan 9 1958

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication Feb 27 1958

cus pre-lacrimalis) This landmark is important, because it indicates the posterior limits of rhinoplastic surgery

Posterior to this groove are found the following vital structures the lacrimal sac, the naso-lacrimal duct, the orbital contents, the agger nasi cells, the middle turbinate, the cribriform plate and the naso-frontal duct

SUMMARY

1 The frontal sinus may be over-developed and extend downwards beyond the glabella, past the fronto-nasal suture line, reaching as far down as the middle of the nasal bones The nasal bones themselves will then become part of the anterior wall of the frontal sinus, and the floor of the sinus will be attached directly to the inner surfaces of the nasal bones

2 The frontal sinus may be under-developed and stop short of the glabella In this instance, a solid block of compact bone will be found where the sinus is normally located X-ray studies will determine the relationship of the frontal sinus to the nasal bones

3 The nasal notch of the frontal bone is beveled, at the expense of the outer layer, to form a suitable bed for the imbrication of the upper edges of the nasal bones and of the frontal processes of the maxillae The frontal spine extends further downward from the center of the nasal notch, to become fused with the septal crests of the nasal bones and with the bony septum, to give the nasal bridge greater support This construction makes infracturing impracticable

4 The pre-lacrimal groove (sulcus pre-lacrimal) is one of the most important landmarks of the nasal pyramid It is located between the inner orbital rim and the postero-lateral margin of the nasal pyramid It runs parallel to the inner orbital rim, and it is semi-lunar in shape It can easily be felt by digitation This groove indicates the posterior limits for rhinoplastic surgery There are no vital structures anterior to this groove, they are all posterior to it

2054 Locust Street

CLINICAL RESULTS

Antibiotic-steroid nebulization has been utilized in the clinical management of all of these conditions The antibiotic to combat the infectious factor in the etiology of many of these conditions, or the secondary infection that may co-exist, the steroids to act as the blocking or anti-inflammatory agent for the stereotyped reaction that occurs in response to nonspecific irritation In its action it also controls fibrosis of healing

ACUTE LARYNGITIS

Case 1 Young male employed in recapping automobile tires developed hoarseness when the overhead ventilator broke down and he was subjected to the inhalation of concentrated chemical irritants, symptoms had persisted for one week Examination revealed a diffuse redness of the larynx with edema of the mucosa Nebulization therapy was recommended Report of the referring laryngologist 48 hours after therapy was "improved voice with marked clearing of the local reaction'

ACUTE LARYNGITIS

Case 2 Young male railroader was seen in consultation because of hoarseness and painful difficult swallowing, four weeks prior he had been injured and exposed to chemical fumes when a Diesel engine exploded Treatment during his two weeks of hospitalization consisted of penicillin and confinement in an oxygen tent, at this time the mucosa of the hypopharynx and larynx was red and edematous there were residual areas of ecchymosis and ulceration in the nasopharynx One week after nebulization therapy was started the voice had improved and pain and difficulty in swallowing had subsided In another week all symptoms had subsided and the physical findings had returned to normal

Both cases represent specific therapy for a reversible process

The contact ulcer has usually been a chronic difficult problem to treat

Case 1 Music teacher with hoarseness for two weeks failed to show improvement under a regime of therapy prescribed by her home town laryngologist Examination of the larynx showed a diffuse edematous ulceration with exudate on the right vocal cord and a concave ulceration of the right arytenoid One week after nebulization there was 75 per cent improvement the edema and exudate had subsided leaving only the concave ulceration of the vocal process, this was larger than on the original examination Two weeks later healing was complete, voice rest had not been insisted upon

Case 2 A similar result was obtained in a female patient with hoarseness for two months excessive talking and smoking had been part of an unusually active social program there was a large ulceration of the right vocal process Two weeks after therapy the process was 50 per

If we analyze the laryngeal diseases, however, we find that they can be classified into six categories *1* Congenital Defects, *2* Infections, *3* Toxic, *4* Traumatic, *5* Paralysis, neuromuscular and systemic disturbances, *6* Tumors

Of these, congenital defects and paralysis can be eliminated from this discussion The others may be considered, since they have a common factor in that they represent an inflammatory reaction, using the term inflammatory as a nonspecific reaction to injury whether due to infection, allergy, irritation or trauma The inclusion of tumors depends upon these factors *1* Many of the so-called benign tumors of the larynx are actually non-neoplastic in origin, *2* Malignant tumors are of unknown etiology and steroids, and antibiotics have been used to control neoplastic activity in other parts of the body, *3* Nebulization might be a useful adjunct in the postoperative healing program

The pathologic response to inflammation in the larynx is the same as elsewhere in the body, differing only in the symptomatology of the local anatomy The inflammatory reaction takes place in the subcutaneous connective tissue[2,3] This reaction leads to progressive changes, described from the gross appearance, as redness, edema, hyperplasia, fibrosis or hypertrophic changes with keratosis For simplicity we can diagram this gross pathologic picture and coordinate it with our clinical diagnosis as follows

GROSS APPEARANCE		CLINICAL DIAGNOSIS
Redness ↓ Edema	Reversible	Laryngitis ↓ Contact Ulcer Hyperplasia Polyp ↓ Vocal Nodule Papilloma
Fibrosis ↓ Metaplasia	Irreversible	Pachydermia Hyperkeratosis Leukoplakia Cancer

was started and endoscopic removal performed in February and April There was no recurrences at the last examination in November

HYPERKERATOSIS AND LEUKOPLAKIA

Nebulization has been used both as a primary therapeutic agent and also as a postoperative adjunct in these cases The progress of therapy can be observed in the routine examination of the patient We feel that we have been able to reverse the process in cases with early surface changes, and prevent recurrence in those cases requiring endoscopic removal

TUMORS

Nebulization has been utilized in the postoperative care of patients with carcinoma *in situ* removed under direct laryngoscopy

METHOD OF THERAPY

A No 40 DeVilbiss nebulizer is prescribed for home use by the patient The preparation of choice has been cortisporin This is a suspension of aerosporin, neomysin and hydrocortisone in an aqueous vehicle Therapeutically this formula combats infection due to susceptible organisms, and relieves symptoms caused by an inflammatory process The incidence of tissue sensitivity to the components is low While other preparations may be equally effective, we believe that a suspension offers the advantage of a greater concentration and more prolonged action

The patient is instructed in the method of nebulization and treats herself four times daily with 6 to 8 inhalations at each procedure Therapy is decreased to an "as needed regime," with improvement in symptoms and local findings

SUMMARY

An analysis and rational for the use of cortico-steriod-antibiotics combination in various disease entities of the larynx has been presented The clinical results observed in the treatment of various laryngeal diseases with cortisporin cent improved in spite of continuation of her social activity Because of her apprehension, therapy was continued along with limited voice use One week later the voice and local findings were normal, and there has been no recurrence to date

Case 3 S K, age 42, was a salesman with hoarseness for two years, a laryngoscopy had been performed twice previously for removal of a tumor Our examination revealed the presence of a large pea sized granuloma of the right vocal process A recurrence developed after laryngoscopic removal Nebulization therapy was prescribed The patient was not seen again for three months At this time the voice was good and laryngeal examination revealed complete healing with only a small epithelized nodule at the site of the previous granuloma

LARYNGEAL POLYP

The laryngeal polyp is basically a localized edematous reaction It is referred to by clinicians and pathologists in varying descriptive terminology Nebulization has been used as the primary agent in many cases, with a satisfactory reversal of the process and improvement in the voice In other cases treatment has been used as a postoperative adjunct to prevent irreversible granulation We feel that there have been benefits in both situations

PAPILLOMA

Papilloma has been a problem, especially in children, because of its tendency to recur Improvement with antibiotic therapy has been controversial We feel that the antibiotic steroid combination has served to abort the process when used as a postoperative adjunct

Case 1 R M, age five years, was first seen in 1954 A tracheotomy had been performed at the age of two years, and endoscopic removal of papilloma performed repeatedly Laryngeal findings at this time were described as a diffuse growth of papillomas in the larynx and extending into the upper segment of the trachea During 1954 and 1955 we continued to remove papillomas every three months Nebulization therapy was added to his regime in April, 1955 There was complete arrest of the recurrence, so that in October, 1955, the tracheostomy was closed There was no recurrence at the last examination in September, 1957 Age at this time was seven years

Case 2 A. B, age three years was first examined in 1955 with hoarseness due to a diffuse growth of laryngeal papilloma over both cords Endoscopic removal was performed at three-month intervals until February, 1957 when nebulization therapy was started Papillomas were removed in July, 1957, and there has been no recurrence to date Patient is now five years old

Case 3 J H, age three years had papillomas removed on three occasions prior to our examination in February, 1957 Nebulization therapy

THE ROUTINE BLEEDING AND CLOTTING TIME TESTS THEIR MEDICOLEGAL STATUS *†

RUSSELL FLETCHER, M D ,

San Rafael, Calif

The reason for presenting a paper on this controversial subject is to review briefly the history of the tests and the reasons why these obsolete "screen" tests are so extensively employed The modern diagnosis of hemorrhagic disease leaves no doubt that these tests are not accurate, they are not reliable, and actually they may constitute a danger or a menace to the patient and to the physician by inducing false security if he relies upon these tests alone to determine preoperatively whether or not a patient will bleed

THE HISTORY OF THE BLEEDING AND CLOTTING TIME TESTS

These tests have been done for 40 years Bailey[1] in 1922, and Hunt[2] in 1927, each made surveys of several hundred hospitals in the United States in which a large percentage used the tests routinely They found that most of the hospitals and physicians who had stopped using the tests did so because they were not reliable Hunt stated that it was not necessary to have tests done if a proper history and physical examination had been done Shepeard[3] in 1948, stated that the tests were "a vestigial remnant of yesteryear," and the *Journal of the American Medical Association*,[4] in 1955, commented on his article as follows "There have been numerous reports relating experience from Nose and Throat Departments that show bleeding and clotting time estimates are not practical as tests predicting hemorrhages during and after a tonsillectomy Normal results are not a guarantee of freedom from hemorrhage, and abnormal results have been ob-

ANNUAL OTOLARYNGOLOGIC ASSEMBLY UNIVERSITY OF ILLINOIS

The University of Illinois College of Medicine Department of Otolaryngology announces its Annual Otolaryngologic Assembly from September 29 through October 5, 1958 The Assembly will consist of an intensive series of lectures and panels concerning advancements in otolaryngology, and evening sessions devoted to surgical anatomy of the head and neck and histopathology of the ear, nose and throat Interested physicians should write direct to the Department of Otolaryngology, 1853 West Polk Street, Chicago 12, Ill information, as well as the fact that practically all physicians concede that the tests are of very little value, why are these tests done in so many hospitals, either optionally on the part of the physicians, or are required by hospital regulations? In a rough survey of the hospitals of the San Francisco Bay area, over 50 per cent of them require these tests preoperatively In Portland, Ore, seven of the eight hospitals have the tests done

REASONS GIVEN FOR CONTINUING THE TESTS

1 An occasional physician "thinks that the tests might be helpful sometime" (rarely is there a physician found who is convinced of this fact) *2* Some physicians believe that having the tests done reassures the patient *3* Many physicians, when asked why they continue the test, answer "why worry or fuss about eliminating the tests which cost the patient such a trivial or paltry sum" ($2 00 in the San Francisco Bay area), and they add, "anyhow, most patients have insurance" Although economics should never be a consideration in this problem, it is one of the chief arguments of the proponents for continuing the tests A few facts might be brought out regarding this If it is not reliable and not necessary, it is wasteful, no matter how cheap it is or who pays for it

In Marin County, with a population of 30,000, the three hospitals in this county did 5,446 operations in 1957 At $2 00 per test, this amounts to $10,892 As Marin County is approximately 1 per cent of the State of California, this total would be $1,089,200 for the State If this amount is wasted by requiring an unnecessary test, it is not trivial or paltry One of the health insurance companies in California that does 10 per cent of the health insurance in this State, handles about 90,000 operations per year, therefore, it is self-evident that elimination of such unnecessary tests would be a material saving to all insurance companies *4* The tests have been done for so many years that physicians are hesitant to discard "such time-honored tests," which is chiefly due to inertia The fact that any test has been done routinely by a large number of physicians in any community was a strong medico-served without subsequent bleeding Dependence upon bleeding and clotting time tends to lead to a false sense of security The history and physical examination are much more important, *and if such an examination suggests a bleeding* tendency, then a thorough study is indicated "

There are some statements in the literature, and in text books, which claim in the same sentence that "although the tests are not reliable, their omission "might have disturbing medicolegal consequences" Some text books have stated that the tests were of value in anticipating hemorrhage pre-operatively (These indefinite statements and inferences in the literature, are the points that a lawyer grasps in order to convince a jury that one was negligent if the tests were not done) This is illustrated by our experience in Marin County this past year The surgeons voted unanimously to eliminate the tests pre-operatively, however, the pathologists, who direct all the hospital laboratories, strongly argued that, although they "conceded that the tests are of somewhat limited value," they felt that such statements and inferences as noted above in the literature were of sufficient value for the lawyer to accuse and perhaps convince a jury that there was negligence if the tests had not been done on a patient that subsequently hemorrhaged The result was that the hospital made it obligatory to have the tests done pre-operatively on every patient

The following are a few of the outstanding hospitals and clinics that do not have tests done pre-operatively the Massachusetts Eye and Ear Infirmary, the Children's Hospital in Boston, the hospitals in Baltimore, the University of Michigan Hospital, the Mayo Clinic, the University Hospital in Iowa City, and Stanford Hospital in San Francisco All of these hospitals had routinely used the tests for years, but abandoned them because they were not reliable

In a letter from the legal department of the American Medical Association,[5] dated Dec 13, 1957, it was stated that they knew of no court decision based upon the use or non-use of these tests

Why are These Tests Still Continued? In spite of the above all in-patients about to undergo surgery is a sensible one, and that it should not be changed *unless substantial medical evidence is available* as to the *unreliability* and *futility* of *the tests",* therefore, it is up to the medical profession to show "substantial medical evidence as to the unreliability and futility of the tests"

This evidence is available from three national authorities on hemorrhagic diseases *1* The most concise and graphic presentation of this evidence is given in a letter from Louis K Diamond, M D ,[c] who is Associate Professor of Pediatrics at Harvard Medical School, and who is in charge of the Blood Clotting Laboratory at Children's Hospital in Boston He made the following brief survey *Survey of children referred to the Blood Clotting Laboratory of Children's Hospital of Boston in the past four years*

Group I Patients who had had a routine pre-T and A bleeding and clotting time determination in a hospital laboratory where one or both tests were found to be prolonged beyond normal limits and, therefore, were referred to us for more elaborate tests which we found to be entirely normal, nine patients, most of whom later had T and A without any bleeding disturbance

Group II Patients who had a definite history of bruising in the past and when explored, frequently a history of bleeding in relatives, but normal bleeding and clotting times had been determined by routine methods, 14 patients, nine of whom had hemophilia of varying degrees and five Christmas disease

Group III Patients who bled following surgery, in whom a routine bleeding and clotting time was said to be normal, five patients, of whom four had hemophilia and one Christmas disease

Group IV Patients who bled following surgery in whom a good bleeding and clotting time test, even using venous blood, and supervised by our own laboratory, showed normal values, and yet following T and A in seven cases and dental extraction in one case, there was moderate to severe hemorrhage In two cases blood loss was sufficient to require transfusion legal argument for continuing the test This point is very well covered in the next paragraph, under *"Medicolegal Status"*

5 *The Mediolegal Status* The chief reason why physicians and hospitals have continued this routine pre-operative test is the medicolegal threat or intimidation that failure to have had the tests done might be grounds for negligence if a lawsuit were instigated because a patient hemorrhaged On the Pacific Coast we are particularly aware of malpractice suits This is reflected in the high rates for malpractice insurance The rates given by the American Academy of Ophthalmology and Otolaryngology shows that Oregon has the highest rate in the nation, which is about twice as high as California, and Washington which, in turn, are three times as high as the rates in Texas, Pennsylvania or New Hampshire, and twice as high as New York

What is the accepted or customary practice in the community in which you practice? A letter from the legal department of the American Medical Association to me,[5] dated Dec 13, 1957, outlines the requirements very well and states in part, as follows "To comply with legal requirements, a physician must meet the standards of good medical practice in any service he furnishes a patient These standards are based on what other reputable physicians in the community, or in similar communities, would or would not do in the care of similar cases One of the tests applied, so far as the use of a particular medical or surgical technique is concerned, is the *general reliability and acceptance of such technique* If the value of a particular technique is of such a degree that a substantial number of reputable physicians in the community would utilize it in a given situation, then the failure of a physician to utilize it in the same or similar situation would be a difficult factor to explain in a subsequent malpractice suit It may not constitute negligence *per se*, but the jury would certainly regard such factor with respect Whether or not bleeding and clotting time tests enjoy the degree of acceptability described above, I cannot say *That must be decided by the medical profession* I believe a hospital regulation urging routine bleeding and clotting time tests on all in-patients about to undergo surgery is a sensible one, and that it should not be changed *unless substantial medical evidence is available* as to the *unreliability* and *futility* of *the tests"*, therefore, it is up to the medical profession to show "substantial medical evidence as to the unreliability and futility of the tests"

This evidence is available from three national authorities on hemorrhagic diseases *1* The most concise and graphic presentation of this evidence is given in a letter from Louis K Diamond, M D ,[6] who is Associate Professor of Pediatrics at Harvard Medical School, and who is in charge of the Blood Clotting Laboratory at Children's Hospital in Boston He made the following brief survey *Survey of children referred to the Blood Clotting Laboratory of Children's Hospital of Boston in the past four years*

Group I Patients who had had a routine pre-T and A bleeding and clotting time determination in a hospital laboratory where one or both tests were found to be prolonged beyond normal limits and, therefore, were referred to us for more elaborate tests which we found to be entirely normal, nine patients, most of whom later had T and A without any bleeding disturbance

What is the accepted or customary practice in the community in which you practice? A letter from the legal department of the American Medical Association to me,[5] dated Dec 13, 1957, outlines the requirements very well and states in part, as follows "To comply with legal requirements, a physician must meet the standards of good medical practice in any service he furnishes a patient These standards are based on what other reputable physicians in the community, or in similar communities, would or would not do in the care of similar cases One of the tests applied, so far as the use of a particular medical or surgical technique is concerned, is the *general reliability and acceptance of such technique* If the value of a particular technique is of such a degree that a substantial number of reputable physicians in the community would utilize it in a given situation, then the failure of a physician to utilize it in the same or similar situation would be a difficult factor to explain in a subsequent malpractice suit It may not constitute negligence *per se,* but the jury would certainly regard such factor with respect Whether or not bleeding and clotting time tests enjoy the degree of acceptability described above, I cannot say *That must be decided by the medical profession* I believe a hospital regulation urging routine bleeding and clotting time tests on hemorrhagic studies are not indicated in the case of patients who are not bleeding at the time, or who have a personal and family history negative for abnormal bleeding, and no signs of abnormality at the time of physical examination"

He further states "On patients whose history or physical examination indicates a bleeding tendency, then special hemorrhagic tests *by experts* are indicated" He stated that "a surgeon would not be considered negligent if he did not perform routine pre-operative tests for bleeding and clotting time" He also states "in the past, the finger tip method was an accepted and standard practice and afforded the surgeon, the laboratory director, and the hospital administration a degree of medicolegal protection which comes from the performance of the usual and customary procedures Such procedures will not, in the light of present knowledge, continue to be accepted" There are so many interesting and pertinent facts in this article by Dr Diggs, that it would take too long to review them in this paper It is, therefore, strongly recommended that everyone read this excellent article by Dr Diggs

CONCLUSIONS

1 The routine bleeding and clotting time tests are not reliable, authorative medical evidence is herewith presented (It has also been the experience of many clinicians)

2 The tests are dangerous and a menace to the patient and to the physician by inducing a false sense of security

3 The safest practice for the patient, as well as the physician, is to take a careful history of bleeding in the patient and the family, and to make a good physical examination If these show any bleeding tendency, then special hemorrhagic studies *by an expert* are indicated

a A physician with such a patient will not be guilty of negligence if the routine tests were not done pre-operatively and the patient subsequently bled

b A physician with such a patient who relied on the routine bleeding and clotting tests *alone* and did not have special

2 The second authoritative evidence is given by Paul Aggeler, M D,[7] Associate Clinical Professor of Medicine at University of California Medical School, and Head of the Blood Clotting Research Laboratory at Children's Hospital in San Francisco He states that "numerous cases falling into all four categories listed by Dr Diamond have been extensively investigated in his laboratory During the past three years alone, 28 patients whose bleeding and venous blood clotting time were normal, were nevertheless proven by more detailed methods to suffer from well defined clotting disorders (hemophilia, P T C deficiency, P T A deficiency, hypoproconvertinemia and fibrinogenopenia) In about one-third of these patients tooth extraction, tonsillectomy, and even major surgery had been performed, with hemorrhagic complications in every instance In several cases, because of the false assurance afforded by normal bleeding and clotting times, the operation had been done without further investigation, despite the surgeon's complete awareness of the bleeding history In 20 years' experience in this field Dr Aggeler can recall not a single instance in which a bona fide hemorrhagic disorder was discovered solely by the use of routine pre-operative bleeding and clotting times He has seen many cases, however, where false positive results have lead to still further useless and expensive investigations"

3 The third source of evidence that these tests are not reliable, is the article "Diagnosis of Hemorrhagic Diseases—Evaluation of Procedures" Part I appears in the December, 1957, *California Medicine,* and Part II in the January, 1958, issue by L W Diggs, M D, who is Professor of Medicine at the University of Tennessee College of Medicine, and Director of Department of Medical Laboratories, University of Tennessee, City of Memphis Hospitals, who was the guest speaker at the California Medical Association meeting in May, 1957, in Los Angeles This paper discusses in detail the importance of a careful history and physical examination, and states that "they are more reliable than laboratory tests for the prediction of the tendency to bleed at the time of surgical operation, and failure to obtain a history of bleeding episodes may be catastrophic" He also states that "Routine pre-operative

THE TREATMENT OF POLYPOID LARYNGITIS *†

GERSON LOWENTHAL, M D ,

Cincinnati, Ohio

The term polypoid laryngitis designates a localized or diffuse non-specific inflammatory tumor of one or both vocal cords, involving the epithelium and the subepithelial space of Reinke This space is a very thin layer of loose connective tissue between the epithelium and the elastic and muscular tissue of the vocal cords [1] It extends from near the anterior commissure to the vocal process of the arytenoid and to the stria arcuata, superior and inferior,[2] which is the transition point between the squamous and the columnar epithelium above and below It has a scarce arterial supply but a rich venous plexus The epithelium is much thinner, only two or three layers, at the free edge and upper surface of the cord, while there are 10 to 20 layers of stratified squamous epithelium over the remainder of the cord [3] This explains why the inflammatory lesions may be restricted to this space, and why they occur most commonly along the phonating edge and upper surface of the cord

The most common inciting factors for polypoid laryngitis are considered to be the trauma of vocal abuse[4] or the irritation produced by smoking [5,6] These lesions nearly always produce hoarseness, tiring of the voice, occasionally pain or discomfort in the throat, and rarely, respiratory embarrassment Psychologically there is usually apprehension on the part of the patient over the implications of the symptoms

Clinically, the lesions may be placed in two groups localized and diffuse Either of these may be acute, due to sudden vocal strain, or chronic, due to repeated trauma to an unresolved process In the localized, the tumor may be a pedun-

hemorrhagic tests by an expert, might be accused of negligence

4 Since the tests have been proven to be so unreliable, they should not be required pre-operatively on surgical patients

5 "If it is medically sound, it will stand up legally!"[9]

POST GRADUATE COURSE
UNIVERSITY OF ILLINOIS

The next postgraduate course in Laryngology and Broncho-esophagology to be given by the University of Illinois College of Medicine is scheduled for the period October 27 through November 8, 1958, under the direction of Dr Paul H Holinger

Interested registrants please write to Department of Otolaryngology, University of Illinois College of Medicine, 1853 West Polk Street, Chicago 12, Illinois

neoplasm, benign or malignant, not only in gross appearance but also in mode of onset and in production of symptoms" They feel that with few exceptions all benign tumors should be removed

Although the definition, clinical appearance, etiology, histopathology and location may be variable or controversial,

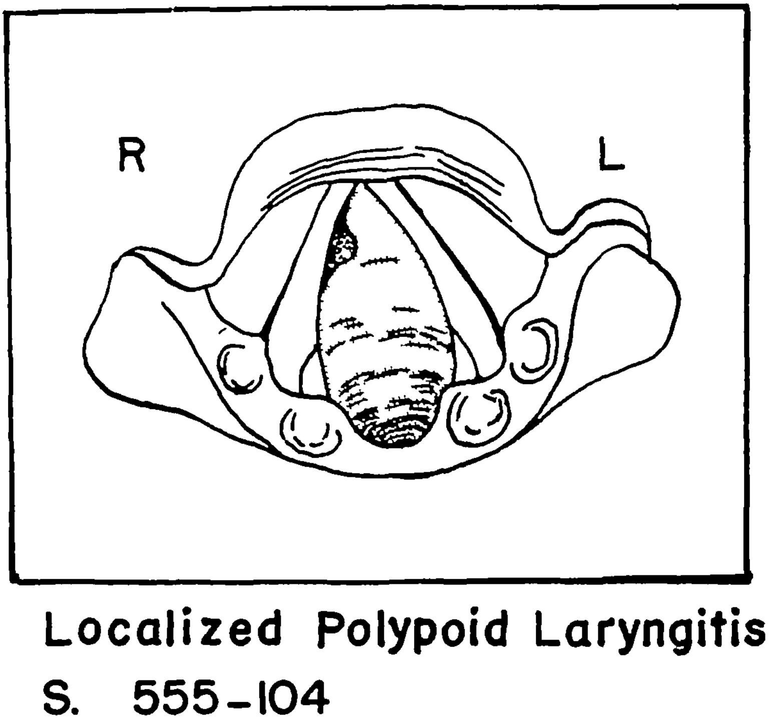

Fig 2 Most common location on cord—the anterior half (View by indirect laryngoscopy)

there is relative unanimity with regard to treatment This paper will concern itself primarily with the surgical treatment

Treatment is divided into three phases first, the medical or "expectant" phase A careful survey of the mouth, ears, nose and throat, and a thorough medical examination to rule culated or sessile mass arising from the free edge or upper surface of the cord, near the junction of the anterior and middle thirds, rarely in the posterior third Occasionally the lesion may be found in the anterior commissure, and infrequently in the posterior commissure It may vary in color from a pale glistening gray to a pink, yellow or purple In consistency it may vary from soft, almost gelatinous, to rather firm and nodular In the diffuse, the swelling involves the anterior half or two-thirds or more of one or both cords The color may vary from a pearly gray to a dusky pink This type may also be flabby or somewhat firm

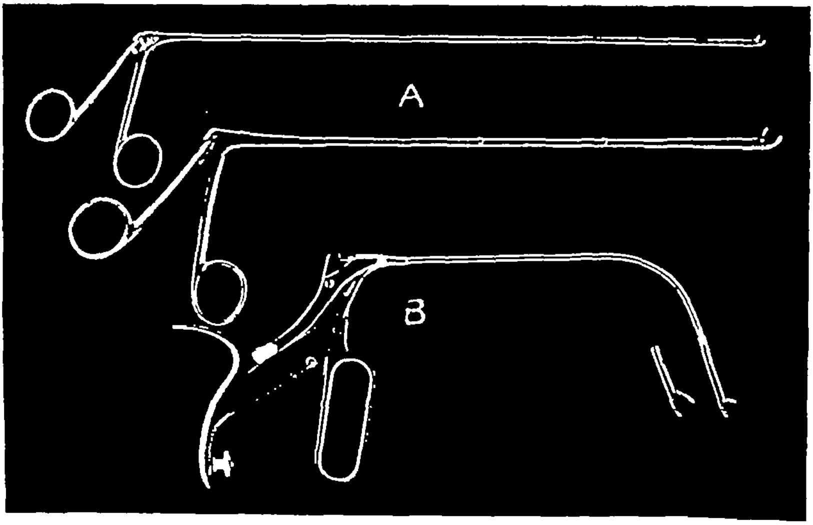

Fig 1 Instruments used in surgical treatment of polypoid laryngitis A Jackson Laryngeal Cup Bite Forceps Angular Jaw 2-4 mm (Direct Laryngoscopy) B Curved Laryngeal Forceps (Universal Handle) 3-4 mm (Indirect Laryngoscopy)

Histologically, the localized and the diffuse lesions frequently cannot be differentiated and show varying degrees of congestion, edema, thrombosis and hyalinization, described by Friedberg and Segall[3] (see Fig 4)

New and Erich,[2] in their monumental paper on benign tumors of the larynx, state that "Inflammatory tumors may bear an exact similarity to almost any type of laryngeal

Chlorophenol If the lesion is reversible within a few weeks, no further treatment may be necessary

The second phase is surgical treatment, which is essentially an excisional biopsy (see Fig 3), with gentle, precise, superficial removal of the lesion It is well recognized that following this principle without damage to the underlying elastic membrane, there appears to be complete regeneration of the cord with normal appearance and function This has been demonstrated by Jackson, Tucker,[11] Lore,[10] Holinger[12] and others[13] Jackson[15] states that it is better to leave a convex edge of the lesion on the cord, even if this should allow a little of the basal tissue to remain, rather than to remove too much tissue, leaving a concavity If necessary, a secondary procedure can be done In polypoid lesions with a suggestion of hyperkeratosis or leukoplakia, biopsies must be taken from various areas in the larynx and carefully labeled as to the site of origin of each specimen Thus, early or *in situ* carcinoma can be localized[14]

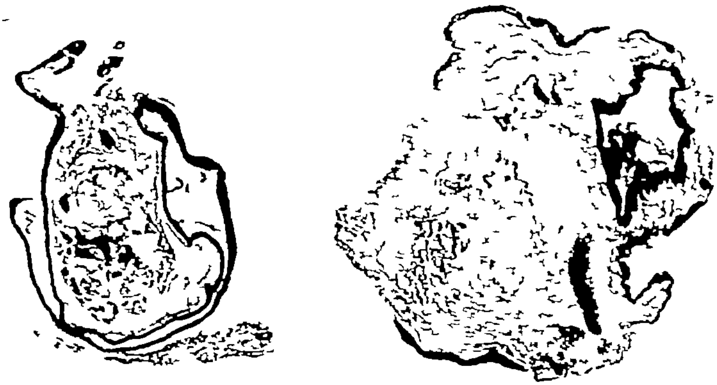

Fig 4 Localized Polypoid Laryngitis Photomicrograph of specimen shown in Fig 3 demonstrating congestion edema thrombosis and hyalinization of the loose subepithelial connective tissue

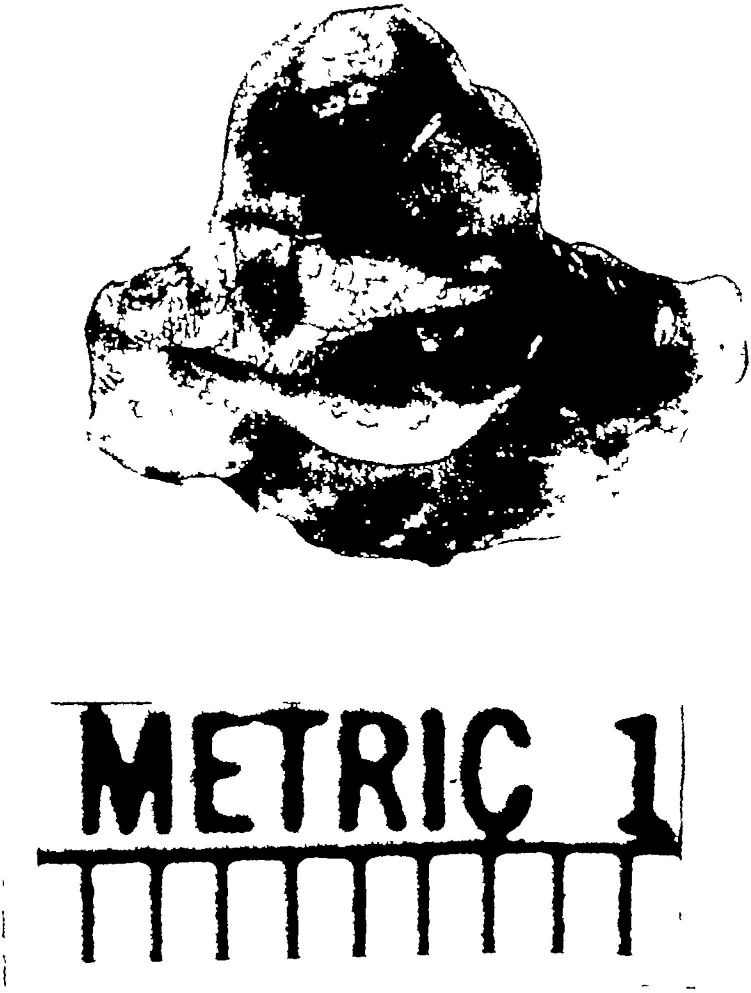

Fig 3 Localized Polypoid Laryngitis Photograph of a lesion remove from position shown in Fig 2

out local or pulmonary, or other systemic disease, is important[6] Elimination of the inciting causes such as vocal abuse, smoking, and alcohol ingestion, are mandatory Voice re-education is required in many cases Specific medical therapy has not been available, although recently steroids have been used by Brodnitz[9] Some symptomatic relief may be obtained from a bland intratracheal instillation such as Mono-P-three-minute intervals, and the patient is encouraged to expectorate the excess Some of the anesthetic is applied to the upper gum to reduce the discomfort of the laryngoscope later

Cocaine hydrochloride, 5 cc of 10 per cent solution, is freshly prepared in the operating room from a measured amount of crystals This is instilled into the laryngopharynx and larynx by the drop method Using a laryngeal syringe with a curved tip, several drops are placed into the valleculae and into each piriform sinus The patient is instructed to breathe quietly while the tongue is being held, after which he expectorates the excess and the procedure is repeated One cc is then instilled over the cords with the patient saying "A" or "E" for a few moments This is also repeated in a few minutes Rarely is more than 3 or 4 cc of the solution required

The combined technique is used most often First, by indirect laryngoscopy the lesion is removed by evulsion with a double cupped biting forceps The patient is usually unaware that this maneuver is different from the instillation of the anesthetic Depending upon the size of the lesion, a large or small tip is used Most, if not all, is removed by this technique

Secondly, a direct laryngoscopy with a Jackson or Holinger anterior commissure laryngoscope, using the Andrews chest support, or more recently, the Lewy[1-] holder, is performed with the patient in the supine position, placing a folded blanket under his shoulders Direct laryngoscopy allows closer inspection of the lesion, and permits trimming of small, loose fargments of mucosa with a small angulated cupped forceps

Multiple and diffuse lesions are removed except when the anterior third of both cords are involved, (see Figs 2, 3, 4), then, the more severely involved side only is operated upon The polypoid cord on the other side is compressed or pinched with-the double cupped forceps in two or three areas to reduce the edema This may be a form of superficial scarification (see Fig 5) It was noted that in a number of patients a subsequent procedure on the second cord was obviated by this thesia, or by suspension[10] laryngoscopy under general anesthesia Rarely, an external approach with tracheotomy may be necessary for removal of a large growth[16] The surgical treatment in the series of cases analyzed was by indirect laryngoscopy, direct laryngoscopy, and most frequently by a combination of the two, under local (topical) anesthesia The operation is simple, orderly, and relatively easy on the patient For a successful procedure it is necessary to secure the cooperation of the patient, and to obtain good anesthesia

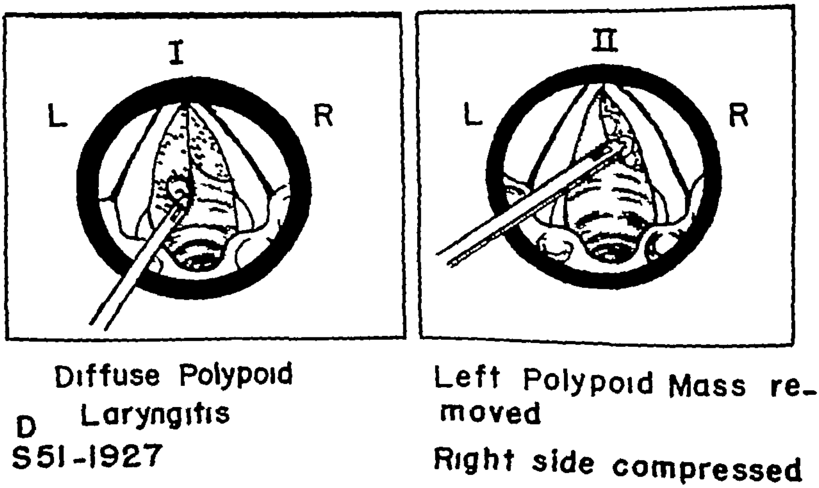

Fig 5 Diffuse Polypoid Laryngitis Bilateral Histologically these lesions are similar to the one shown in Fig 4 I and II—Steps in the surgical treatment (Direct laryngoscopic views)

Since the lesions under discussion occur most frequently in adults, this can usually be accomplished

Premedication consists of seconal or nembutal, grains $\frac{3}{4}$ to grains $1\frac{1}{2}$, taken at bedtime the night before surgery and repeated one hour pre-operatively Morphine sulfate, grains 1/8 to grains 1/6, and scopalomine, grains 1/300 to grains 1/200, are given hypodermically one-half hour pre-operatively

The mouth, oropharynx and hypopharynx are sprayed with 2 per cent pontocaine solution two or three times at about to remove further tissue In one instance there was a recurrence of a lesion on the same cord three years later The second lesion, however, occurred at the junction of the middle and posterior thirds, whereas the original was at the junction of the anterior and middle thirds The lesions also varied somewhat, the first being a polyp and the second a cyst In nine patients with bilateral diffuse polypoid degeneration of both cords, only three required operation on the second side after use of the compression (scarification) technique In one, with only slight diffuse involvement of the second cord, the compression technique was not necessary, and this patient also made a good recovery

SUMMARY AND CONCLUSIONS

1 The particular structure of the subepithelial space of Reinke predisposes to the formation of laryngeal polyps on the vocal cords

2 In the series presented, as in other series, the most common benign tumors are inflammatory, and of these the localized polyps are the most frequent

3 Treatment is divided into three phases the medical or "expectant", the surgical, wherein under local (topical) anesthesia, combined indirect or direct laryngoscopy is performed in all cases, the post-surgical, with removal of the initial predisposing factors and voice correction therapy if required

4 In diffuse polypoid involvement of both cords, the larger lesion is removed The smaller lesion is compressed (superficially scarified) in two or three areas with a double cupped forceps This frequently obviates the need for surgery on the second cord

5 In general, the prognosis in these lesions is good Recurrences are uncommon

REFERENCES

1 Waldapfel, R Pathology of the Subepithelial (Reinke s) Layer of the Vocal Cord *Ann Otol Rhinol and Laryngol*, 49 647 659 Sept 1940

2 Ash Col. J F and Schwartz Leo The Laryngeal (Vocal Cord)

technique *Tschiassny[18] states that scarification is an old treatment and attributes the idea to Hajek Waldapfel[1] reported the use of "simple, superficial scarification of flabby tissue" in such a case, with complete resolution of the lesion without visible scar formation

1940

The third phase is post-surgical This consists of complete vocal rest for a period of 10 to 14 days, followed by a regime of sparing the voice for a period of several weeks and by voice correction therapy, if indicated This phase also includes the removal of the factors which predisposed to the lesion initially At the conclusion of the third phase the cords appear to be well healed and the voice returns to normal Recurrences are uncommon

The case histories reviewed for this paper are of patients over 20 years of age who failed to respond to the medical or "expectant" treatment described in phase one and, therefore, required surgical intervention This group consisted of 62 adult private patients operated upon for benign laryngeal tumors during the past ten years It is interesting to note that even in this small series there was a general distribution of lesions comparable to the vastly larger series reported by New and Erich,[7] and by Holinger[12] Polypoid tumors predominated in the small group, as they did in the larger series Thirty-five of the lesions were polypoid tumors, of which 26 were localized polyps and nine showed diffuse polypoid degeneration of both cords Six were papillary tumors, six were *multiple papillomata*, *there were three* angiomas, one hemangioma, two granulomas, three amyloid tumors, one leukoplakia, two cysts, two thrombosed varices and one vocal nodule In six instances other than the papillomata there were multiple localized lesions, sometimes of different types

In spite of the variation of diagnoses of these benign tumors and of their neoplastic and non-neoplastic character, the treatment of this entire series was essentially the same Following surgery the cords healed well and appeared normal, and the voice returned to normal within a period of several weeks In only two cases was it necessary to go back a second time

---

*He suggests that diffuse lesions be known by the descriptive term 'subepithelial chronic edematous corditis

SUBCOMMITTEE ON HEARING IN CHILDREN

The American Academy of Ophthalmology and Otolaryngology, through its Subcommittee on Hearing in Children of the Committee on Conservation of Hearing, has been conducting a long-term nationwide study of problems relating to the conservation of hearing in children The specific aims are to develop the most efficient case-finding methods and to use these methods in estimating the magnitude of the problem in the country, to study state laws and review current practices and facilities for rehabilitation of hearing impaired children, to help develop methods for medical and surgical rehabilitation standards, and ultimately to use the Subcommittee findings in assisting professional workers to improve and enhance programs in hearing loss

In the second year of operations, a full-time Executive Director has been engaged, and offices established at the Graduate School of Public Health, University of Pittsburgh An initial study is being conducted in Pittsburgh to identify early medical signs and symptoms which may indicate danger of hearing impairment, to measure the psychological, social and other effects of such impairment and to develop efficient and economical methods for the testing of hearing in children The Pittsburgh study is a cooperative effort among the following The Subcommittee on Hearing in Children, the Graduate School of Public Health and the School of Medicine of the University of Pittsburgh, the Pittsburgh Board of Public Education, and the Allegheny County Department of Health.

The members of the Subcommittee on Hearing in Children are Dr John E Bordley, Baltimore, Dr Victor Goodhill, Los Angeles, Dr Hollie E McHugh, Montreal, Dr S Richard Silverman, St Louis, and Dr Raymond E Jordan, (Chairman) Pittsburgh An advisory committee of consultants from the University of Pittsburgh includes Dr Samuel M Wishik, Dr Leo G Doerfler, and Dr Isidore Altman Grants from the United States Children's Bureau through the Pennsylvania Department of Health and from the National Institutes of Health are providing financial support

AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Erling W Hansen, 90 So Ninth St., Minneapolis, Minn
Executive Secretary Dr William L Benedict Mayo Clinic, Rochester, Minn
Meeting Palmer House, Chicago Ill

AMERICAN BOARD OF OTOLARYNGOLOGY

Meeting Palmer House Chicago Ill

AMERICAN BRONCHO ESOPHAGOLOGICAL ASSOCIATION

President Dr Walter Hoover, 605 Commonwealth Bldg Boston, Mass
Vice-President Dr Walter P Work, 384 Post St. San Francisco, Calif
Secretary Dr F Johnson Putney 1719 Rittenhouse Square Philadelphia, Pa.
Treasurer Dr Verling K. Hart, 106 W 7th St., Charlotte, N C

AMERICAN LARYNGOLOGICAL ASSOCIATION

President Dr Harry P Schenk 326 S 19th St., Philadelphia 3, Pa.
Secretary Dr James H. Maxwell, University Hospital Ann Arbor Mich

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, INC

President Dr Gordon Hoople 1100 E Genesee St. Syracuse 10 N Y
President Elect Dr Theo E Walsh 640 So Kingshighway St. Louis 10 Mo
Secretary Dr C Stewart Nash 700 Medical Arts Bldg Rochester 7, N Y
Place The Homstead Hot Springs, Va., March, 1959

AMERICAN MEDICAL ASSOCIATION, SECTION ON LARYNGOLOGY, OTOLOGY AND RHINOLOGY

Chairman Dr Gordon D Hoople Syracuse N Y
Vice-Chairman Dr Kenneth L. Craft, Indianapolis Ind.
Secretary Dr Hugh A. Kuhn Hammond Ind
Representative to Scientific Exhibit Walter Heck, M.D San Francisco Calif.
Section Delegate Gordon Harkness M.D Davenport, Iowa
Alternate Delegate Dean Lierle M.D Iowa City, Iowa.

PROGRAM OF THE SEVENTH INTERNATIONAL CONGRESS OF BRONCHOESOPHAGOLOGY

Meeting Place—Kyoto University, Kyoto, Japan

Friday, September 12th, 1958

8 00 P M -10 00 P M —Reception (Party) Shimomura House in Kyoto

Saturday, September 13th

8 00 A M —Inaugural Session (in Kyoto University Hall)

9 00 A M -12 00 M —First Scientific Session

12 00 M -2 00 P M —Luncheon (Reception The Place not decided)

2 00 P M -6 00 P M —Sightseeing in Kyoto

8 00 P M —Banquet, Miyako Hotel

Sunday, September 14th

8 00 A M -11 30 A M —Second Scientific Session

11 30 A M -12 00 M —Closing Ceremony

12 00 M —Departure for sightseeing in Nara

1 00 P M —Luncheon, Nara Hotel

2 00 P M -6 00 P M —Sightseeing in Nara

7 00 P M —Return to Kyoto

ASOCIACION DE OTO-RINO-LARINGOLOGIA DE BARCELONA, SPAIN

Presidente Dr J Abello
Vice-Presidente Dr Luis Suñe Medan.
Secretario Dr Jorge Perelló 319 Provenza, Barcelona.
Vice-Secretario Dr A. Pinart.
Vocal Dr J M Ferrando

BALTIMORE NOSE AND THROAT SOCIETY

Chairman Dr Walter E Loch, 1039 No Calvert St., Baltimore, Maryland.
Secretary-Treasurer Dr Theodore A. Schwartz.

BUENOS AIRES CLUB OTOLARINGOLOGICO

Presidente Dr K. Segre
Vice-Presidente Dr A. P Belou.
Secretario Dr S A. Aranz.
Pro-Secretario Dr J M. Tato
Tesorero Dr F Games
Pro-Tesorero Dr J A Bello

CANADIAN OTOLARYNGOLOGICAL SOCIETY
SOCIETE CANADIENNE D'OTOLARYNGOLOGIE

President Dr Robert T Hayes, 42 Cobourg St. St. John N B
Secretary Dr Donald M. McRae, 324 Spring Garden Rd., Halifax N S

CENTRAL ILLINOIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr G C. Otrich Belleville, Ill.
President-Elect Dr Phil R. McGrath Peoria, Ill.
Secretary-Treasurer Dr Alfred G Schultz, Jacksonville, Ill.

CHICAGO LARYNGOLOGICAL AND OTOLOGICAL SOCIETY

President Dr Stanton A. Friedberg 122 So Michigan Ave., Chicago 3 Ill.
Vice-President Dr Maurice Snitman, 408 So 5th Ave., Maywood Ill.
Secretary-Treasurer Dr Fletcher Austin 700 No Michigan Ave., Chicago 11 Ill.
Meeting First Monday of each Month, October through May

CHILEAN SOCIETY OF OTOLARYNGOLOGY

President Dr Enrique Grünwald S
Vice-President Dr Agustin Estartus
Secretary Dr Marcos Chaimovich S
Treasurer Dr Benjamin Kapkan K.
Director Dr Alberto Basterrica A.

DALLAS ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Ludwig A. Michael 3707 Gaston Ave. Dallas Tex.
Vice-President Dr Hal W Maxwell.
Secretary Treasurer Dr Edward A. Newell 1511 No Beckley Dallas 8 Tex.

AMERICAN OTOLOGICAL SOCIETY, INC

President Dr Moses Lurie, Boston, Mass
President Elect Dr R. C Martin
Secretary Dr Lawrence R Boies, University Hospitals, Minneapolis 14, Minn
Place The Homestead, Hot Springs, Va., 1959

AMERICAN OTORHINOLOGIC SOCIETY FOR THE ADVANCEMENT OF PLASTIC AND RECONSTRUCTIVE SURGERY

President Dr Joseph Gilbert, 111 E 61st St, New York, N Y
Vice President Dr Kenneth Hinderer, 402 Medical Arts Bldg, Pittsburgh, Pa
Secretary Dr *Louis Joel Feit, 66 Park Ave, New York 16, N Y*
Treasurer Dr Arnold L Caron, 36 Pleasant St, Worchester, Mass

AMERICAN RHINOLOGIC SOCIETY

President Dr Russell I. Williams, 408 Hynds Bldg, Cheyenne, Wyo
Secretary Dr Robert M Hansen, 1735 No Wheeler Ave, Portland, Ore
Annual Clinical Session Illinois Masonic Hospital, Chicago, Ill, October, 1958
Annual Meeting October, 1958, Chicago, Ill (Definite time and place to be announced later)

AMERICAN SOCIETY OF FACIAL PLASTIC SURGERY

President Dr Trent W Smith, 327 East State St., Columbus 15, Ohio
Secretary Dr Samuel M Bloom, 123 East 83 St., New York 28, N Y
Meeting New York, July 16, 1958, December 3, 1958, place to be announced

AMERICAN SOCIETY OF OPHTHALMOLOGIC AND OTOLARYNGOLOGIC ALLERGY

President Dr Joseph W Hampsey, Grant Bldg, Pittsburgh 19, Pa
Secretary Treasurer Dr Daniel S DeStio, 121 S Highland Ave, Pittsburgh 6, Pa.
Annual Meeting Palmer House, Chicago, Ill, October 16 17, 1958

ASSOCIACAO MEDICA DO INSTITUTO PENIDO BURNIER—CAMPINAS

President Dr Lech Junior
First Secretary Dr Franco do Amaral
Second Secretary Dr J M Queiroz Abreu
Librarian Treasurer Dr Souza Queiroz
Editors for the Archives of the Society Dr Guedes de Melo Filho, Dr Antonio de Almeida and Dr Gabriel Pôrto
Meetings Twice every month, first and third Thursday, *8 30 P M*

ASOCIACION DE OTORRINOLARINGOLOGIA Y BRONCOESOFAGOLOGIA DE GUATEMALA

Presidente Dr Julio Quevedo, 15 Calle Oriente No 5
First Vice-Presidente Dr Héctor Cruz, 3a Avenida Sur No 72
Second Vice-Presidente Dr José Luis Escamilla 5a Calle Poniente No 48
Secretario-Tesorero *Dr Horace Polanco, 13 Calle Poniente No 9 D*

LOS ANGELES SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Max E Pohlman
Secretary Treasurer Dr Wendell C Irvine
Chairman of Ophthalmology Section Dr Carroll A. McCoy
Secretary of Ophthalmology Section Dr Philip D Shanedling
Chairman of Otolaryngology Section Dr Robert W Godwin
Secretary of Otolaryngology Section Dr Francis O N Morris
Place Los Angeles County Medical Association Bldg 1925 Wilshire Blvd, Los Angeles Calif
Time 6 30 P.M last Monday of each month from September to June inclusive—Otolaryngology Section 6 30 first Thursday of each month from September to June inclusive—Ophthalmology Section.

LOUISIANA MISSISSIPPI OPHTHALMOLOGICAL AND OTOLARYNGOLOGICAL SOCIETY

President Dr Fred D Hollowell Lamar Life Bldg Jackson, Miss
Secretary Dr Edley H Jones 1301 Washington St. Vicksburg Miss
Meeting Edgewater Gulf Hotel Edgewater Park Miss May 15 16 1959

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

Chairman Members serve as chairmen in alphabetical order monthly
Secretary-Treasurer Dr Roland H Myers 1720 Exchange Bldg Memphis, Tenn.
Assistant Secretary-Treasurer Dr William F Murrah, Jr, Exchange Bldg Memphis, Tenn
Meeting Second Tuesday in each month at 8 00 p.m at Memphis Eye, Nose and Throat Hospital.

MEXICAN ASSOCIATION OF PLASTIC SURGEONS

President Dr Cesar LaBoide Mexico, D F
Vice-President Dr M. Gonzales Ulloa, Mexico D F
Secretary Dr Juan De Dios Peza, Mexico D F

MISSISSIPPI VALLEY MEDICAL SOCIETY

President Dr Arthur S Bristow, Princeton Mo
Secretary Treasurer Dr Harold Swanberg Quincy, Ill
Assistant Secretary-Treasurer Dr Jacob E Reisch, Springfield Ill

NETHERLANDS SOCIETY OF OTO RHINO LARYNGOLOGY

(Nederlandsche Keel Neus-Oorheelkundige Vereeniging)

President Dr H. Navis Sonsbeekweg 6 Arnhem.
Secretary Dr W H. Struben J J Viottastraat 1 Amsterdam.
Treasurer Mrs F Velleman Pinto Jac Obrechtstr 66 Amsterdam

NORTH CAROLINA EYE, EAR, NOSE AND THROAT SOCIETY

President Dr J C Peele Kinston Clinic Kinston N C
Vice-President Dr George E Bradord Winston-Salem N C
Secretary Treasurer Dr J D Stratton, 1012 Kings Drive Charlotte 7 N C
Meeting

FEDERACION ARGENTINA, DE SOCIEDADES DE OTORRINOLARINGOLOGIA

Secretary of the Interior Prof Dr Atilio Viale del Carril
Secretary of Exterior Dr Aldo G Remorino
Secretary Treasury Prof Dr Antonio Carrascosa
Pro Secretary of the Interior Prof Dr Carlos P Mercandino
Pro-Secretary of the Exterior Prof Dr Jaime A. del Sel
Pro Secretary of the Treasury Dr Jorge Zubizarreta

FIRST CENTRAL AMERICAN CONGRESS OF OTORHINOLARYNGOLOGY

President Dr Victor M Noubleau, San Salavador
Secretary Treasurer Dr Hector R. Silva, Calle Arce No 84, San Salvador, El Salvador, Central America.

FLORIDA SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Chas C Grace, 145 King St, St. Augustine, Fla ,
President Elect Dr Jos W Taylor, 706 Franklin St., Tampa, Fla
Secretary Treasurer Dr Carl S McLemore, 1217 Kuhl Ave, Orlando, Fla

FOURTH LATIN AMERICAN CONGRESS OF OTORINOLARINGOLOGIA

President Dr Dario
Secretary
Meeting

GREATER MIAMI EYE, EAR, NOSE AND THROAT SOCIETY

President Dr William B Steinman
President-Elect Dr James H Mendel, Jr
Secretary Treasurer Dr H Carlton Howard
Meeting quarterly (March, May, October and December), on the second Thursday of the month, 6 30 P M at Urmey Hotel, Miami

INTERNATIONAL BRONCHOESOPHAGOLOGICAL SOCIETY

President Dr Jo Ono, Tokyo, Japan
Secretary Dr Chevalier L Jackson, 3401 N Broad St, Philadephia 40 Pa., U S A
Meeting Seventh International Congress of Bronchoesophagology Kyoto, Japan, September, 1958

KANSAS CITY SOCIETY OF OTOLARYNGOLOGY AND OPHTHALMOLOGY

President Dr Clarence H Steele
President-Elect Dr Dick H. Underwood
Secretary Dr James T Robison, 4620 J C Nichols Parkway, Kansas City, Mo
Meeting Third Thursday of November January, February and April

RESEARCH STUDY CLUB OF LOS ANGELES, INC

Chairman Dr Orrie E Ghrist, 210 N Central Ave Glendale Calif
Treasurer Dr Norman Jesberg, 500 So Lucas Ave, Los Angeles 17 Calif
Otolaryngology Dr Russell M. Decker, 65 N Madison Ave, Pasadena 1 Calif.
Ophthalmology Dr Warren A. Wilson, 1930 Wilshire Blvd., Los Angeles 57, Calif.
Mid-Winter Clinical Convention annually, the last two weeks in January at Los Angeles Calif

SECTION OF OTOLARYNGOLOGY OF THE MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Chairman Dr J L. Levine.
Vice-Chairman Dr Russell Page.
Secretary Dr James J McFarland.
Treasurer Dr Edward M. O'Brien.
Meetings are held the second Tuesday of September November January March and May, at 6 30 P.M.
Place Army and Navy Club Washington D C

SCOTTISH OTOLARYNGOLOGICAL SOCIETY

President E. A. M. Connal 1 Royal Crescent, Glasgow C 3 Scotland.
Secretary-Treasurer Dr J F Birrell 14 Moray Place Edinburgh
Assistant Secretary Dr H. D Brown Kelly 11 Sandyford Place, Glasgow

SOCIEDAD COLUMBIANA DE OFTALMOLOGIA Y OTORRINOLARINGOLOGIA (BOGOTA, COLUMBIA)

Presidente Dr Alfonso Tribin P
Secretario Dr Felix E Lozano
Tesorero Dr Mario Arenas A.

SOCIEDAD CUBANA DE OTO LARINGOLOGIA.

President Dr Reinaldo de Villiers
Vice-President Dr Jorge de Cárdenas
Secretary Dr Pablo Hernandez

SOCIEDAD DE ESTUDIOS CLINICOS DE LA HABANA.

Presidente Dr Frank Canosa Lorenzo
Vice-Presidente Dr Julio Sanguily
Secretario Dr Juan Portuondo de Castro
Tesorero Dr Luis Ortega Verdes

SOCIEDAD DE OTORRINOLARINGOLOGIA Y BRONCOESOFAGOSCOPIA DE CORDOBA

Presidente Dr Aldo Remorino
Vice-Presidente Dr Luis E. Olsen
Secretario Dr Eugenio Romero Diaz
Tesorero Dr Juan Manuel Pradales
Vocales Dr Osvaldo Suárez Dr Nondier Asis R., Dr Jorge Bergallo Yofre

NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY

President Mr G L. Thompson, 16 Ramshill Road, Scarborough, Yorkshire
Vice-President Mr J H Otty, Frizley Old Hall, Frizinghall Road, Bradford, Yorkshire
Secretary and Treasurer Mr R Thomas, 27 High Petergate, York, Yorkshire

OTOSCLEROSIS STUDY GROUP

President Dr L R Boies, University Hospital, Minneapolis, Minn
Secretary Treasurer Dr Arthur L. Juers, 611 Brown Bldg, Louisville, Ky
Meeting Palmer House, Chicago, Ill

PACIFIC COAST OTO-OPHTHALMOLOGICAL SOCIETY

President H Leroy Goss, M D, 620 Cobb Bldg, Seattle 1, Washington
Secretary-Treasurer Homer E Smith, M D, 508 East South Temple, Salt Lake City, Utah.
Meeting

PAN AMERICAN ASSOCIATION OF OTO RHINO-LARYNGOLOGY AND BRONCHO ESOPHAGOLOGY

President Dr Jose Gros, Havana, Cuba
Executive Secretary Dr Chevalier L Jackson, 3401 N Broad St., Philadelphia 40, Pa., U S A.
Meeting Sixth Pan American Congress of Oto-Rhino-Laryngology and Broncho-Esophagology
Time and Place Brazil, 1958

PHILADELPHIA LARYNGOLOGICAL SOCIETY

President Dr Chevalier L. Jackson
Vice-President Dr John J O'Keefe
Treasurer Dr Joseph P Atkins
Secretary Dr Louis E Silcox
Historian Dr Herman B Cohen
Executive Committee Dr Harry P Schenck, Dr , Benjamin H Shuster, Dr William A. Lell, Dr , William J Hitschler

PITTSBURGH OTOLOGICAL SOCIETY

President Dr Bernard L. Silverblatt, 3500 Fifth Avenue, Pittsburgh, Pa
Vice-President Dr Emory A. Rittenhouse, 203 Masonic Bldg, McKeesport, Pa
Secretary Treasurer Dr John T Dickinson Mercy Hospital, Pittsburgh 19, Pa

PORTUGUESE OTORHINOLARYNGOLICAL SOCIETY

President Dr Albert Luis de Mendonca
Secretary Dr Antonio da Costa Quinta, Avenida, de Liberdale 65, 1° Lisbon

PUGET SOUND ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Clifton E Benson, Bremerton Wash.
President Elect Dr Carl D F Jensen, Seattle, Wash
Secretary Dr Willard F Goff, 1215 Fourth Ave, Seattle, Wash

SOCIEDAD PANAMENA DE OTORRINOLARINGOLOGIA

Presidente Dr Manuel Preciado
First Vice Presidente Dr Alonso Roy
Second Vice-Presidente Dr Carlos Arango Carbone
Secretario Dr María Esther Villalaz
Tesorero Dr Ramòn Crespo

SOCIEDADE PORTUGUESA DE OTORRINOLARINGOLOGIA E DE BRONCO ESOFAGOLOGIA

Presidente Dr Alberto Luis De Mendonca.
Vice-Presidente Dr Jaime de Magalhaes
1.° Secretario Dr Antonio da Costa Quinta.
2 • Secretario Dr Albano Coelho
Tesoureiro Dr Jose Antonio de Campos Henriques
Vogais Dr Teofilo Esquivel.
Dr Antonio Cancela de Amorim
Sede Avenida da Liberdade, 65, 1•, Lisboa.

THE MOTOR ACTIVITY OF THE CRICOPHARYNGEUS MUSCLE *†‡**

JOHN A KIRCHNER, M D ,

New Haven, Conn

Of the many muscles involved in the complex act of swallowing, none has equaled the cricopharyngeus in stimulating the curiosity of the investigator, the interest of the clinician and the respect of the esophagoscopist

First mentioned as a distinct anatomical entity by Valsalva[1] in 1717, the cricopharyngeus was recognized by succeeding anatomists,[2,3,4] who usually included it with the inferior constrictor muscle, as its lower-most or cricopharyngeal portion Its sphincter-like action was recognized in 1823 by Home[5] and later discussed by Mikulicz,[6] 1881, Killian,[7] 1908, and Jackson[8] in 1914 Its relation to the mouth of the esophagus was carefully studied by Elze[9] in 1929, and more recently by Lerche [10]

Its physiological identity has been further demonstrated by studies in comparative[11] and gross anatomy,[12] by roentgenographic demonstration of sphincter action,[13,14] and by the relief of post-poliomyelitic dysphagia following surgical section of the cricopharyngeus muscle [15]

Spasm of the cricopharyngeus muscle and its production by

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication Jan 27 1958

**Recipient of the Harris P Mosher Award 1958 autonomic imbalance is frequently mentioned by clinical authors as a cause of dysphagia, but without much experimental evidence to support it. One of the few basic investigations of this problem was reported by Sjoberg in 1939,[16] involving fluoroscopic studies of the barium-filled esophagus in cats after various combinations of cranial nerve sections in the neck. After bilateral vagotomy, autopsy showed a narrowed condition in both the upper and lower ends of the esophagus, attributed by Sjoberg to spastic contractions during life. Administration of ergotamine tartrate to vagotomized cats to combat sympathetic activity produced relaxation at both the cricopharyngeal and cardiac ends of the esophagus. The parasympathetic action was then simulated in these animals by injection of acetyl-choline, whereupon the cricopharyngeus relaxed and peristaltic waves were seen passing down the esophagus. Sjoberg's conclusion from these findings was that the esophageal ostia are caused to contract by the adrenergic sympathetic fibers, while the cholinergic vagus fibers bring about relaxation.

Further support for this interpretation was furnished by Rogers,[17] who reported relief of severe dysphagia in a woman with a spastic cricopharyngeus muscle on whom he performed bilateral extirpation *of the superior cervical sympathetic* ganglia. One must admire his courage as well as his surgical result, for his operation had very little experimental or clinical evidence to recommend it. Even today a sympathetic supply to the cricopharyngeus is flatly denied by Hollinshead,[18] who states that "the cricopharyngeus muscle, being a voluntary one, is *not innervated by the sympathetic system*, and there seems to be no ready explanation as to why a cervical sympathectomy should relieve spasm of this muscle, as it was reported to do by Rogers."

Although the main vagal branches to the cricopharyngeus have been identified,[19] and a sympathetic as well as a parasympathetic component is generally agreed to exist, there is no definite *mention in modern literature* as to what type of activity (contraction or relaxation) is mediated by the vagus or sympathetic branches to the cricopharyngeus.[20, 21, 22] Nor is it even certain that a specific type of activity is mediated exclusively by one or the other autonomic division as shown by studies on the cardiac end of the esophagus Carlson, for example, showed that the vagus carries both motor and inhibitory fibers to the cardia, and that the splanchnics (sympathetic) also carry both motor and inhibitory fibers to this area, the action depending on the state of contraction of the cardia at the time of stimulation[23]

The purpose of my present study, therefore, is to demonstrate, in each case, the effect of stimulation or interruption of the cervical sympathetic or parasympathetic trunks on the motor activity of the cricopharyngeus muscle

Such experimental conditions simulate the autonomic imbalance said to exist in certain cases of spastic dysphagia The resulting increase or decrease in tonus can then be demonstrated by means of a pressure-sensitive recording device placed in the hypopharynx at the cricopharyngeus level

Pharyngeal pressures during deglutition have been studied and recorded by investigators since the late Nineteenth Century In 1880 Falk and Kronecker measured the pharyngeal pressure generated during deglutition in themselves and in dogs They observed the "squirting" action on liquids and semi-solids exerted by the muscles of the mouth and the pharynx by the use of a "T" tube[24] Kronecker and Meltzer in 1883 reported their observations of the swallowing mechanism in dogs, using small balloons to record intraesophageal motility[25] Meltzer considered the squirting action to be the result of pressure exerted by the mylohyoid muscles, because he was able to eliminate it by sectioning the mylohyoid nerves He reported that this operation made the first stage of swallowing impossible, so that the bolus had to be introduced by the operator into the dog's pharynx in order for the animal to swallow[26] This same investigator, in 1907, added further evidence of the importance of the oral musculature in swallowing by cutting the middle and inferior constrictors of the pharynx in the dog, in addition to removing the muscularis of the cervical esophagus A dog, prepared in this fashion, was still able to swallow normally and could drink from a bowl of milk placed below the level of the head, thus eliminating the effect of gravity[27] Cannon and Moser, in 1898, were the first to use fluoroscopy to study esophageal motility in animals These workers also noted the rapid squirting action of fluids from the pharynx to the level of the heart[28]

Although these experiments contributed much to our knowledge of the motor activity of the pharyngeal and oral musculature, the graphic recording of such motor activity was inexact, and the pressure readings unreliable[29] It was not until 1943, with the development of an electronic device by Wetterer,[30] that a practical means of recording intraluminal pressures was made available Wetterer described the principle of using a differential transformer to construct a miniature manometer, a system having excellent recording properties with a minimum of amplification The device was later modified by Gauer and Gienapp[31,32] in 1950 to fit into the end of a No 8 Cournand catheter for the recording of intracardiac and intravascular pressures This instrument was used by Fyke and Code in 1955 for recording pressure changes in the pharyngoesophageal region during deglutition in normal human subjects[33] Their work showed a definite pressure gradient beginning in the pharynx and traveling down through the cricopharyngeus area into the esophagus during the act of swallowing The high pressure in the cricopharyngeus region remained unchanged throughout most of the act of swallowing, and dropped only momentarily when the pressure wave reached this area

The activity of the individual musculature involved in swallowing was later studied by Doty and Bosma by means of electromyography These workers took electromyographic records from 22 muscles likely to participate in deglutition Their work substantiated that of Fyke and Code, showing a downward progressing contraction wave and an inhibition of the inferior constrictor during the entire course of lead muscle activity[34]

PRESENT STUDY

After controls had been established in the normal dog, the action of the cricopharyngeus muscle was studied under the following conditions

1 Unilateral vagus section above the ganglion nodosum

2 Bilateral vagus section above the ganglion nodosum

3 Faradic stimulation of the vagus and cervical sympathetic trunks

4 Faradic stimulation of the cricopharyngeus muscle

5 Surgical section of the cricopharyngeus muscle

The methods used in studying the motor activity of the cricopharyngeus were the following

1 Observation of the dog's ability to swallow his usual food

2 Endoscopic examination of the soft palate, pyriform sinuses and cricopharyngeus sphincter area with the dog under light general anesthesia

3 Fluoroscopic and roentgenographic studies of the hypopharynx with barium mixtures

4 Pressure changes in the hypopharynx at the cricopharyngeus level during deglutition, using an electronic pressure-sensitive pick-up

These methods are standard and seem self-explanatory except for the last, which requires further explanation

In the beginning of this experiment we were using a Gauer-type pressure capsule attached to the proximal end of a 2 mm polyethylene tube introduced through the mouth to the cricopharyngeus level, and recording the motor activity of the cricopharyngeus by means of a Hathaway oscillograph This gave satisfactory and sensitive responses, as shown by Fyke and Code, but seemed to have certain disadvantages First, if a fold of mucosa came to overlie the end opening (or side opening as was later tried) the pressure determination was interfered with, therefore, the open end was enclosed in a small, partially inflated balloon This, however, was soon abandoned because of distortions produced in the balloon by the contracting cricopharyngeus muscle, with resultant inaccuracies in the reproduction of intraluminal pressures

My chief objection, however, to present techniques of recording pressures at the cricopharyngeus level is that this area is pulled upward during swallowing, so that a recording device introduced to the level of the cricopharyngeus sphincter at rest and kept at this level during swallowing is recording pressure not in the cricopharyngeus segment but in the upper cervical esophagus While there is some evidence that a small polyethylene tube will ride up and down with the cricopharyngeus[35] during deglutition, there seemed enough doubt on this point to have warranted the construction of a pressure-recording device which would respond with equal sensitivity along a 3 or 4 cm distance If such a device were of small diameter and of smooth surface it could be introduced into the pharyngo-esophageal junction behind the cricoid cartilage, allowing the cricoid and cricopharyngeus to ride up and down over it, and recording the motor activity of the cricopharyngeus whether it was elevated or at rest

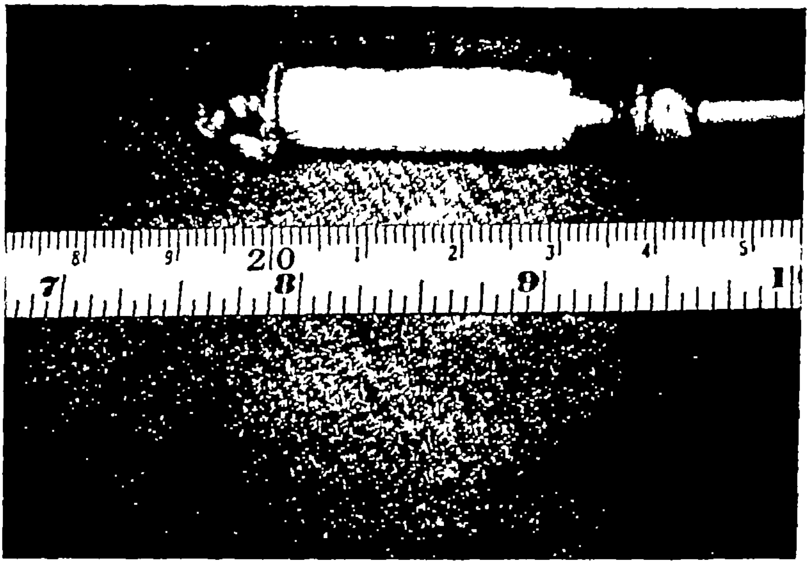

Fig 1 Pressure-sensitive electronic pick-up used in hypopharynx at cricopharyngeus level

For the development of such a recording device I am indebted to Dr Albert Field, Jr , of the Cardiopulmonary section of the Department of Internal Medicine A pressure-sensitive

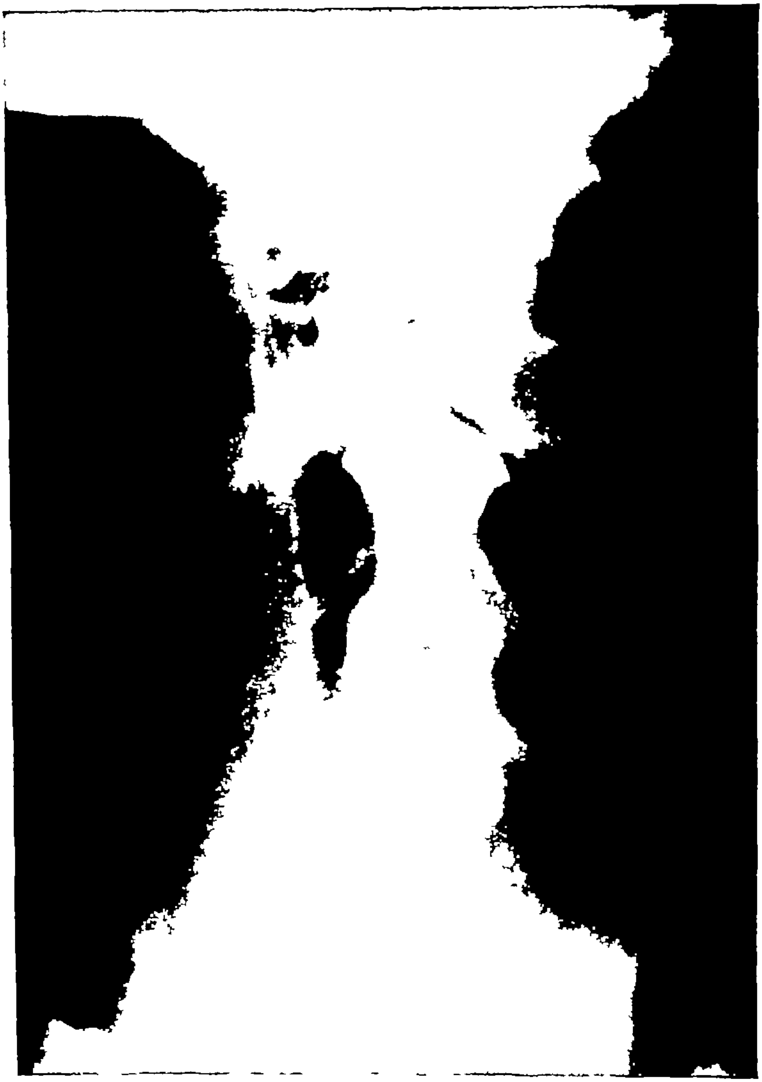

Fig 2 Dog No 1—Normal AP view after barium swallow The trachea deviates to right in supine position in this case but may deviate to left, as seen in other examinations

cording pressures at the cricopharyngeus level is that this area is pulled upward during swallowing, so that a recording device introduced to the level of the cricopharyngeus sphincter at rest and kept at this level during swallowing is recording pressure not in the cricopharyngeus segment but in the upper cervical esophagus. While there is some evidence that a small polyethylene tube will ride up and down with the cricopharyngeus[35] during deglutition, there seemed enough doubt on this point to have warranted the construction of a pressure-recording device which would respond with equal sensitivity along a 3 or 4 cm distance. If such a device were of small diameter and of smooth surface it could be introduced into the pharyngo-esophageal junction behind the cricoid cartilage, allowing the cricoid and cricopharyngeus to ride up and down over it, and recording the motor activity of the cricopharyngeus whether it was elevated or at rest.

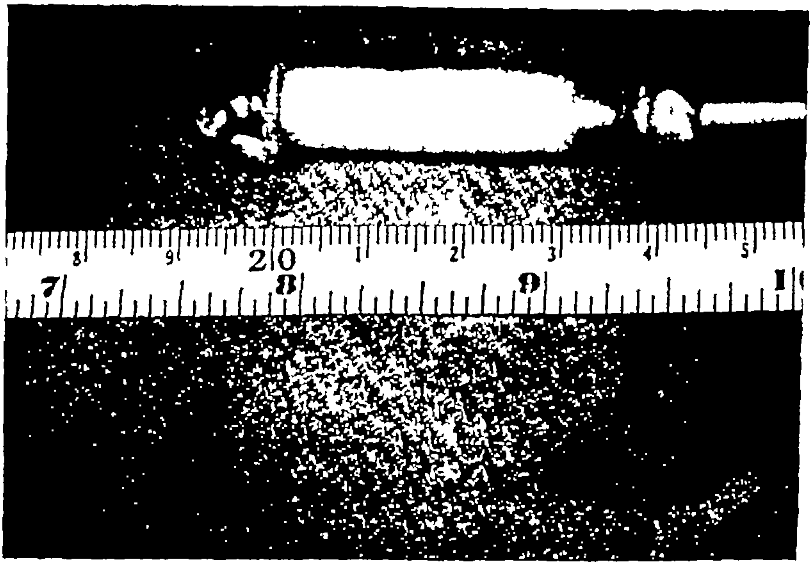

Fig 1. Pressure-sensitive electronic pick-up used in hypopharynx at cricopharyngeus level

For the development of such a recording device I am indebted to Dr. Albert Field, Jr., of the Cardiopulmonary section of the Department of Internal Medicine. A pressure-sensitive

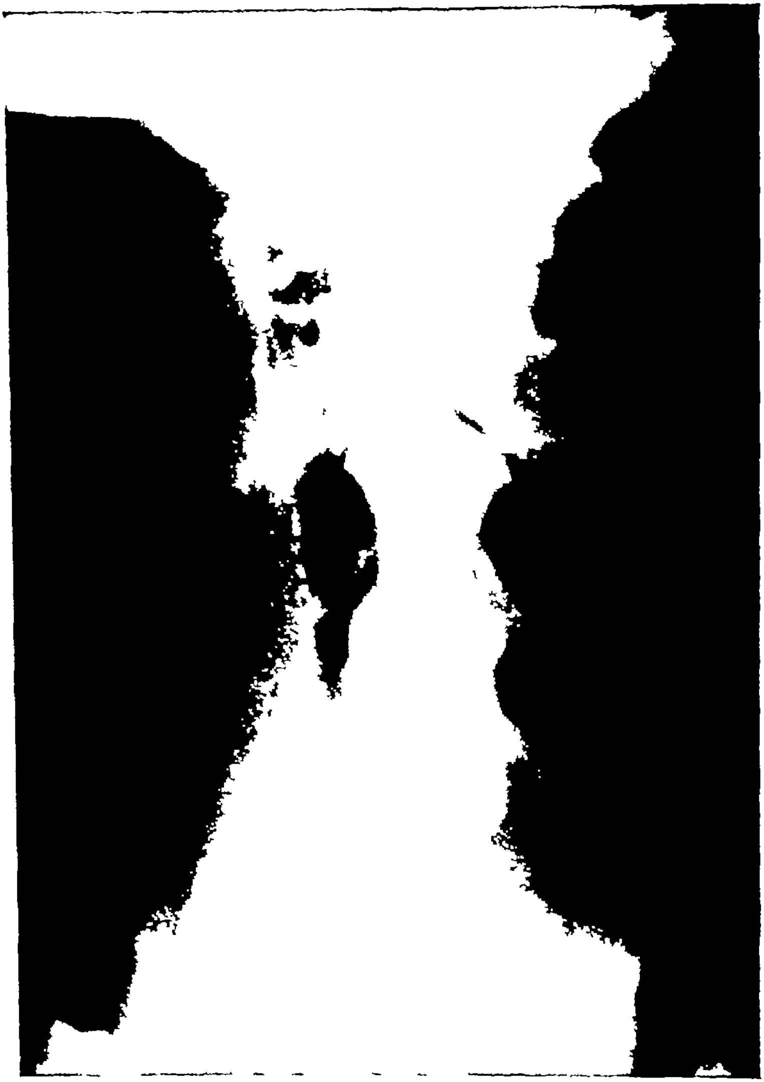

Fig 2 Dog No 1—Normal AP view after barium swallow The trachea deviates to right in supine position in this case but may deviate to left as seen in other examinations

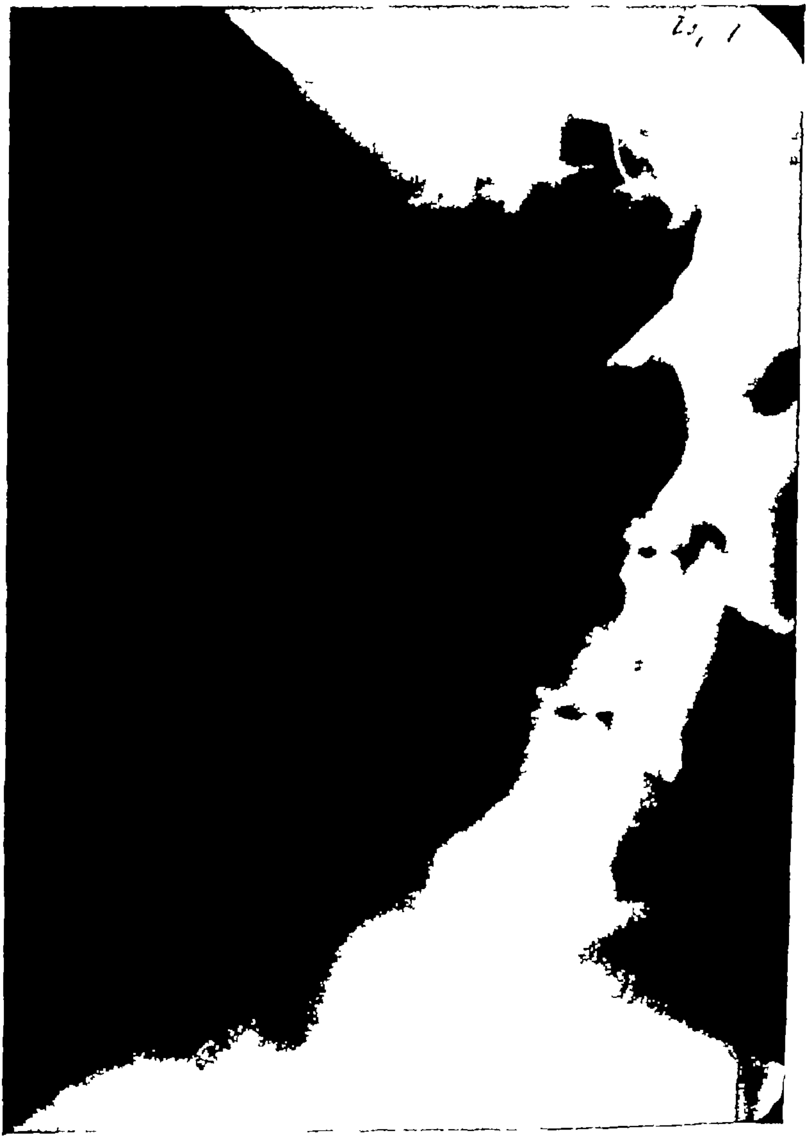

Fig 3 Dog No 1—Normal lateral view after barium swallow A very small amount of barium remains in the valleculae

pick-up was constructed, consisting of a variable capacitance which measures pressure changes by means of variations in a tuned circuit, based on a principle described by Buchtal and Warburg in 1943.[36] It is equally sensitive to pressure at any point along the distance of 3.5 cm., and allows a permanent record to be made by a direct writing electrocardiographic instrument.

The equipment has been checked for performance against a Sanborn pressure capsule and found to be accurate, sensitive

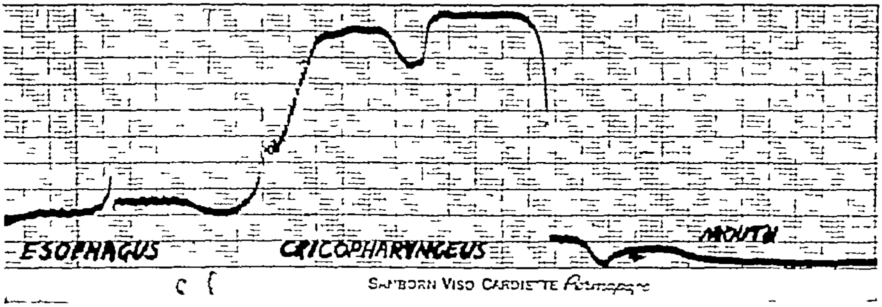

Fig. 4.—High-pressure area encountered at cricopharyngeus as cable is withdrawn from thoracic esophagus.

and brisk in response. Calibrations and other details are described in a separate report.

Because of variations in the base line under different operating conditions, calibrations for exact pressures are not reliable. The calibrations are included, nevertheless, (mm. Hg) to indicate direction of deflections with positive and negative pressure and to indicate approximate pressure ranges. Changes in pressure are, of course, readily demonstrated by the shape of the curves.

NORMAL DOG

Deglutition.—Ate regular diet without difficulty.

Endoscopic Examination.—The soft palate, pharynx, larynx and tongue move normally. A definite annular contraction was seen behind the cricoid cartilage.

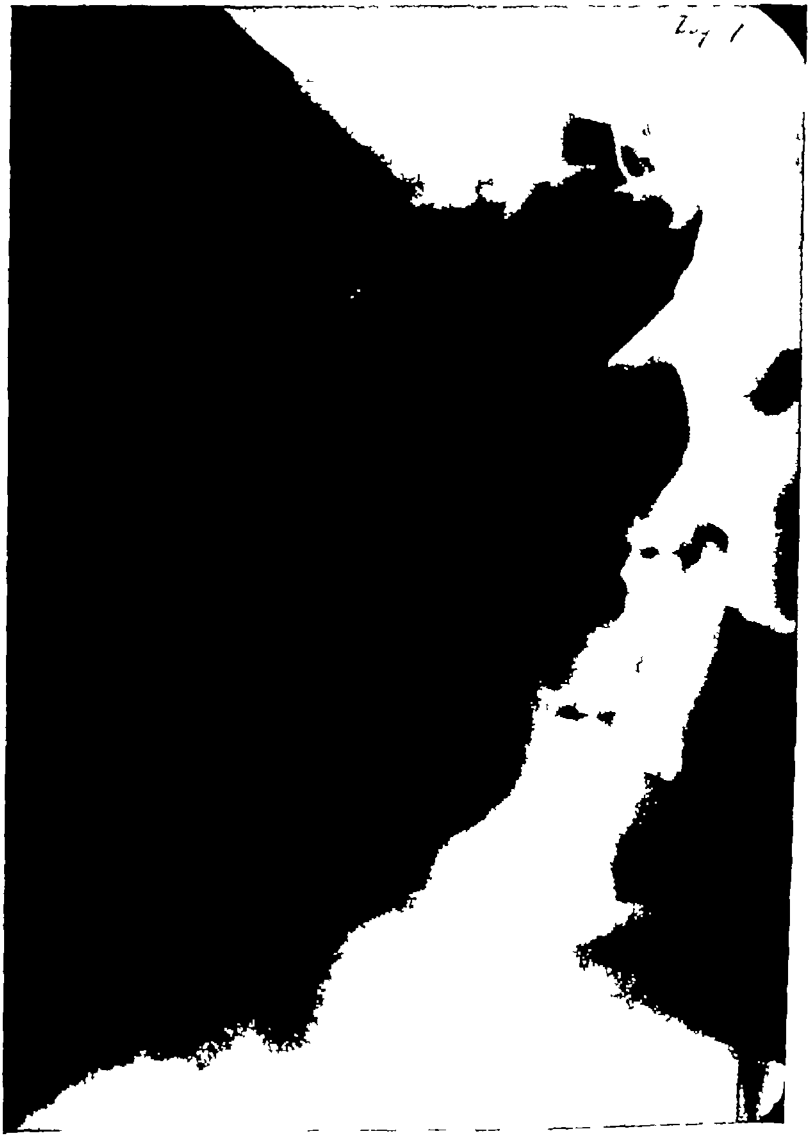

Fig 3 Dog No 1—Normal lateral view after barium swallow A very small amount of barium remains in the valleculae

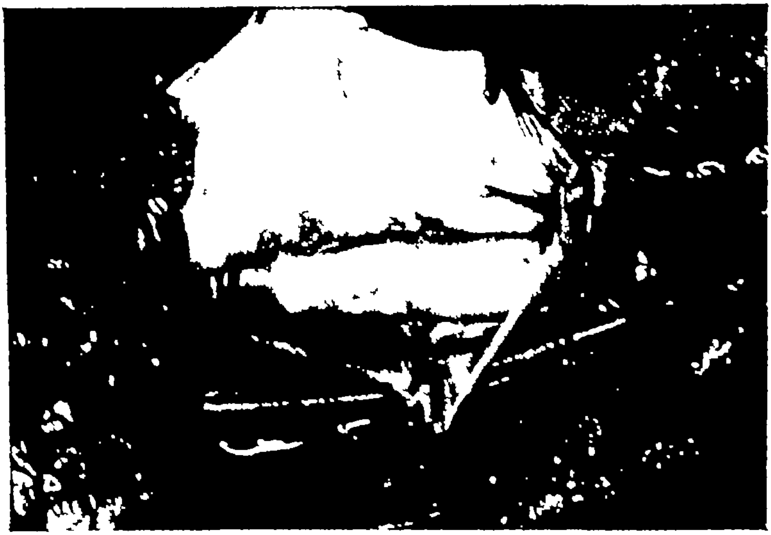

Fig. 6.—Dissected specimen showing pressure pick-up in position at cricopharyngeus level.

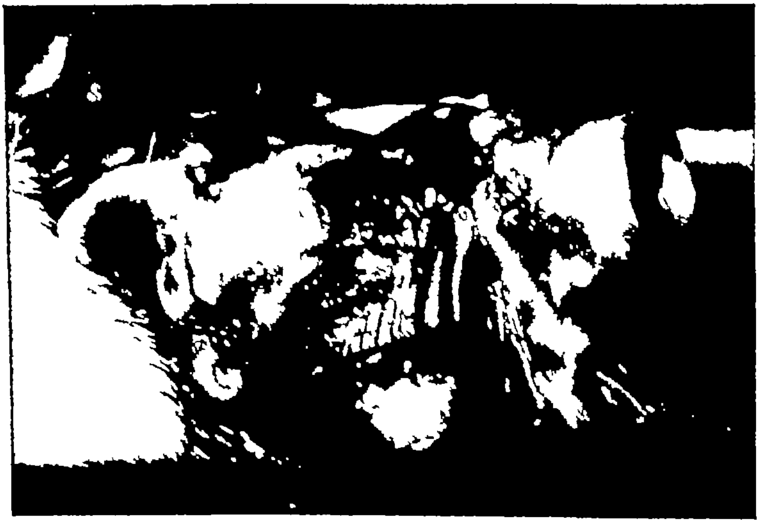

Fig. 7.—Dissected specimen showing cricopharyngeus and thyropharyngeus portions of inferior constrictor muscles. (Operator's finger is in lumen of hypopharynx.)

X-ray Fluoroscopy of a thin barium mixture showed rapid descent of the liquid from the mouth to the level of the heart with no tendency to collect in any of the pharyngeal recesses A normal soft tissue pattern behind the cricoid cartilage was seen on the lateral views (see Figs 2, 3)

Pressure Studies Because of the fact that deep general anesthesia abolishes the swallowing reflex, light nembutal anesthesia was used Pressure readings were made when the deglutition reflex could be stimulated by gently stroking the posterior pharyngeal wall

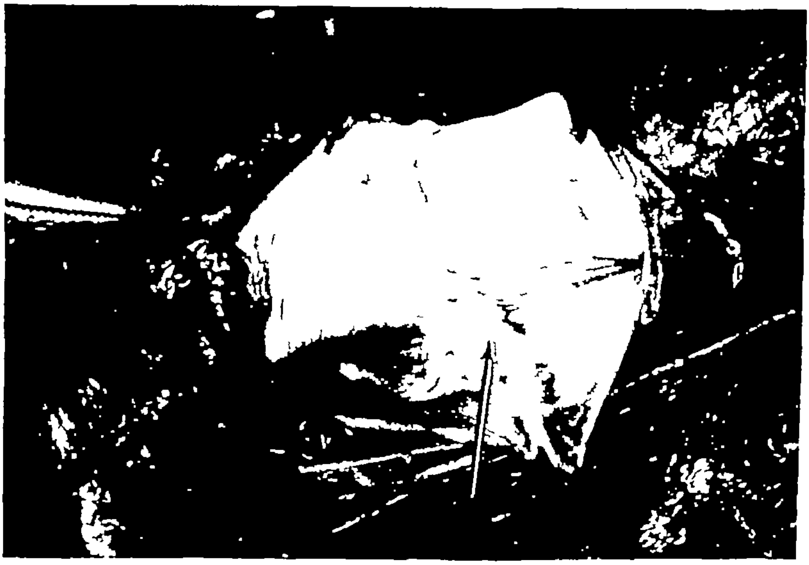

Fig 5 Dissected specimen showing annular fold in hypopharynx behind cricoid cartilage

The pressure capsule was first introduced into the thoracic portion of the esophagus and the recording base line adjusted on the recorder The capsule was then slowly pulled up from the esophagus into the mouth, during which an area of high pressure was encountered in the cricopharyngeal region (see Fig 4) This was a constant finding, whether the dog was in a prone or supine position This high pressure area was found to be 19 5 cm from the upper incisor teeth and corre-

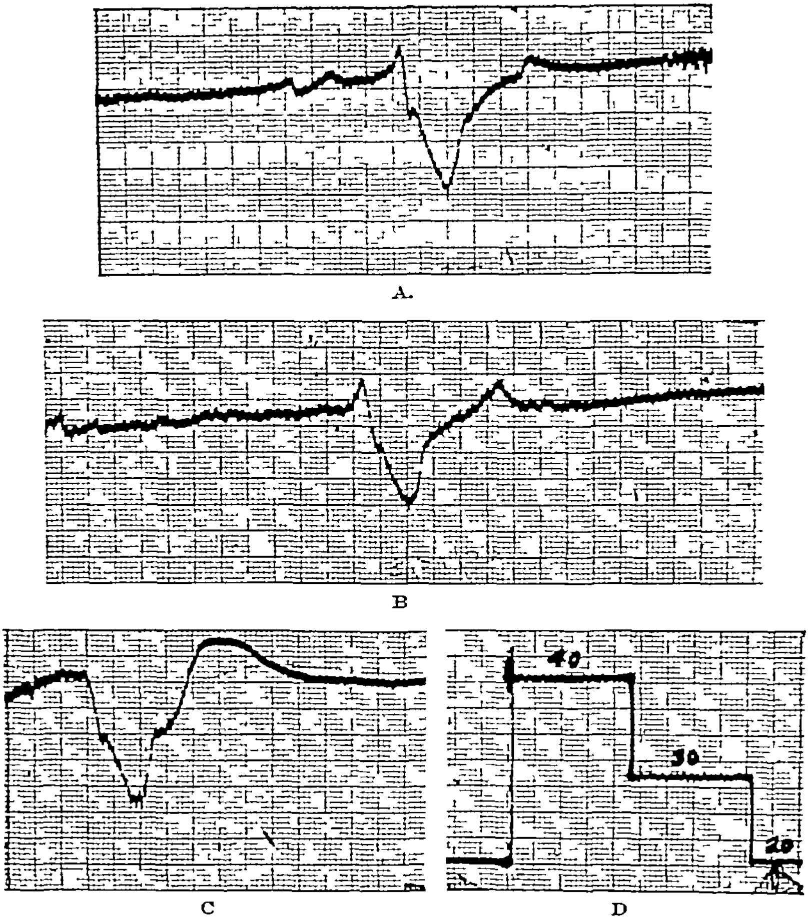

Fig 9 A-B-C—Pressure recordings from cricopharyngeus level during act of swallowing D—Calibration (mm Hg)

nodosum, where it joins the superior cervical sympathetic ganglion The pharyngeal ramus of the vagus, which supplies parasympathetic innervation to the constrictor muscles leaves the vagus trunk cephalic to the ganglion nodosum at its point of emergence from the jugular foramen Whether the sympathetic trunk gives off separate rami to the pharyngeal plexus or to the pharyngeal musculature along its cervical course, as it does in man, I could not determine from the available literature (see Fig 10 for details) sponded almost exactly to the area of annular constriction seen on endoscopic examination (see Fig 5) The mid-point of the recording capsule was introduced to this level for deglutition patterns and other studies in this dog (see Fig 6)

The swallowing patterns shown here illustrate the characteristic curve obtained in all our experimental animals At the beginning of cricopharyngeal activity a small rise in pressure can be seen, probably corresponding to the advancing peristaltic wave Almost immediately the cricopharyngeus undergoes a marked relaxation, followed again by a contraction, which may rise to or above the original base line level (see Fig 9)

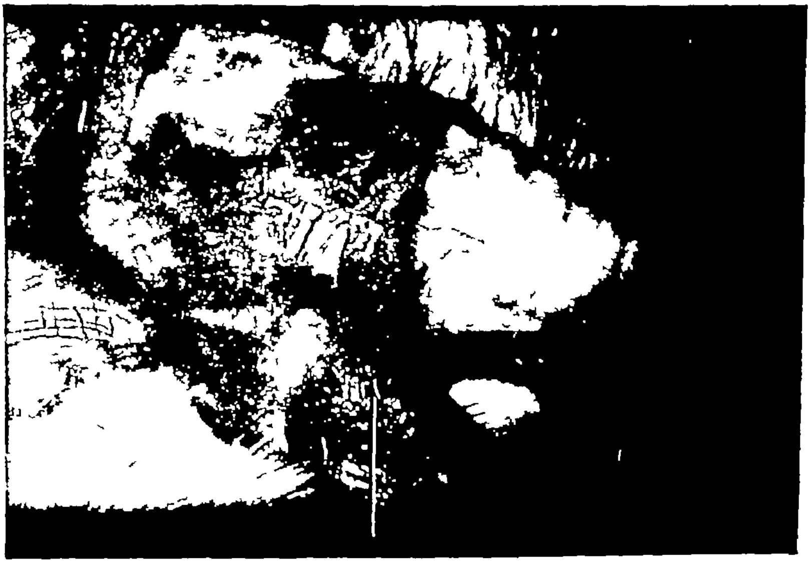

Fig 8 Dissected specimen showing cricopharyngeus portion (arrow) of inferior constrictor separated from thyropharyngeus Pressure determinations were made at cricopharyngeus level

SECTION OF ONE VAGUS NERVE

In the dog the vagus nerve carries with it the sympathetic trunk throughout most of its cervical course The sympathetic joins the vagus opposite the inferior cervical sympathetic ganglion and leaves it again just caudal to the ganglion

X-ray The barium mixture cleared the pharynx easily There was no residual barium in any of the pharyngeal recesses nor were there any changes in the soft tissue patterns (see Figs 12, 13)

Pressure Studies Swallowing patterns show much less relaxation of the cricopharyngeus during swallowing, with a higher positive pressure (see Figs 14, 15)

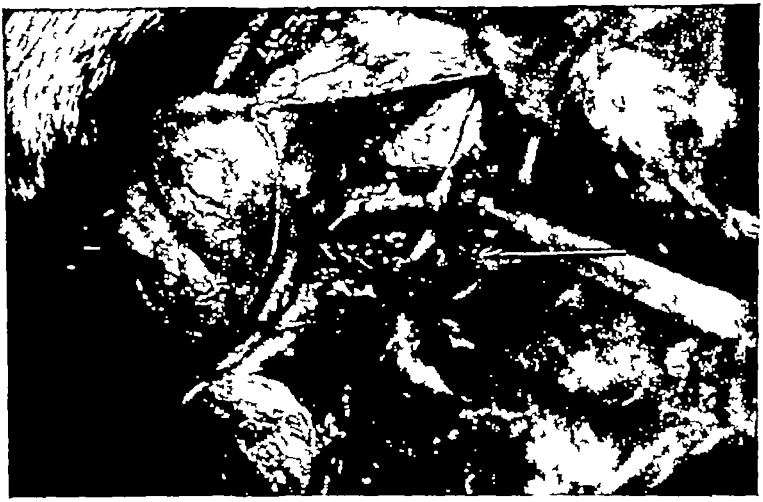

Fig 11 Vagus nerve (arrow) approaching base of skull

DISCUSSION

It is interesting that this dog had no dysphagia, although there was a curtain movement of the pharynx, deviation of the soft palate, and paralysis of the right vocal cord This may be due to the fact that the free portion of the epiglottis of the dog lies above the soft palate, allowing the ingested food and liquids to pass down lateral to the larynx and affording added protection to the laryngeal inlet during the act of swallowing The decreased relaxation of the cricopharyngeus during deglutition following unilateral vagus section may be due to an over-activity of the remaining sympathetic nerve supply I do not believe it is due to a lower starting pressure,

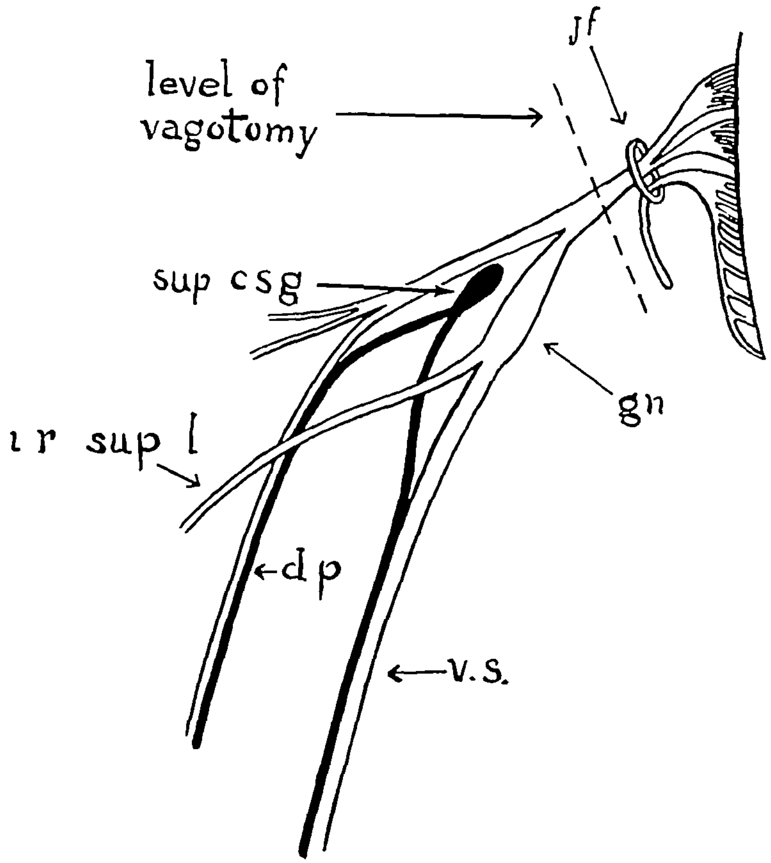

Fig 10 Diagram showing trunks of laryngeal and pharyngeal nerves (from Lemere[19] j f —Jugular foramen g n —Ganglion nodosum v s —Vago-sympathetic trunk d p —descending pharyngeal i r sup l—Internal ramus of superior laryngeal sup c s g —superior cervical sympathetic ganglion Level of vagotomy shown by dotted line

The right vagus nerve was exposed by dividing the muscle which corresponds in the dog to the digastric, then sectioned at its emergence from the base of the skull in order to include the pharyngeal ramus (see Fig 11)

Deglutition The dog continued to eat normally during the entire period of observation of three weeks

Endoscopic Examination The right vocal cord remained motionless in a partially abducted or cadaveric position There was a curtain movement of the pharynx to the left and a deviation of the soft palate to the left

X-ray The barium mixture cleared the pharynx easily There was no residual barium in any of the pharyngeal recesses nor were there any changes in the soft tissue patterns (see Figs 12, 13)

Pressure Studies Swallowing patterns show much less relaxation of the cricopharyngeus during swallowing, with a higher positive pressure (see Figs 14, 15)

Swallow patterns showed complete absence of relaxation of the cricopharyngeus during the act of deglutition (see Fig 22)

DISCUSSION

Section of both vagi produces a condition in which the cricopharyngeus does not relax during the act of swallowing This is probably due to a relative overactivity of the sympathetic supply, and probably explains the dysphagia resulting from nuclear or high cervical lesions of the vagus nerves Paralysis of the remaining constrictor muscles resulting from such lesions undoubtedly contributes to the dysphagia, but does not, in itself, make swallowing impossible, as shown by Meltzer, in cutting the middle and inferior constrictor muscles - The real blockade is produced by the tight cricopharyngeus, whose failure of relaxation, as shown in Fig 22, suggests achalasia as it is encountered at the lower esophageal ostium

STIMULATION OF THE VAGUS AND SYMPATHETIC

In order to eliminate any possible pressures resulting from the rocking of the thyroid on the cricoid cartilages by the cricothyroid muscle during this experiment, the cricothyroideus was first divided bilaterally in a normal dog The vagus nerve was exposed near the base of the skull after dividing the digastric muscle so that the stimulating electrode could be placed between the ganglion nodosum and the jugular foramen The dog was lightly anesthetized with 5 per cent nembutal

X-ray Barium mixture was inserted into the dog's pharynx and the dog made to swallow by stroking the posterior wall of the pharynx The right vagus nerve was then stimulated, but inspection of the neck after the films were taken showed that the electrode had been pulled downward along the vagus so that the entire vagosympathetic trunk had been stimulated AP views show a marked deviation of the trachea to the left, away from the side of vagal stimulation, as one would expect, with relaxation of the supporting musculature on one side While no conclusions are drawn from this finding because a slight tracheal deviation was found pre-operatively, the finding, nevertheless, warrants further investigation (see Figs 23, 24)

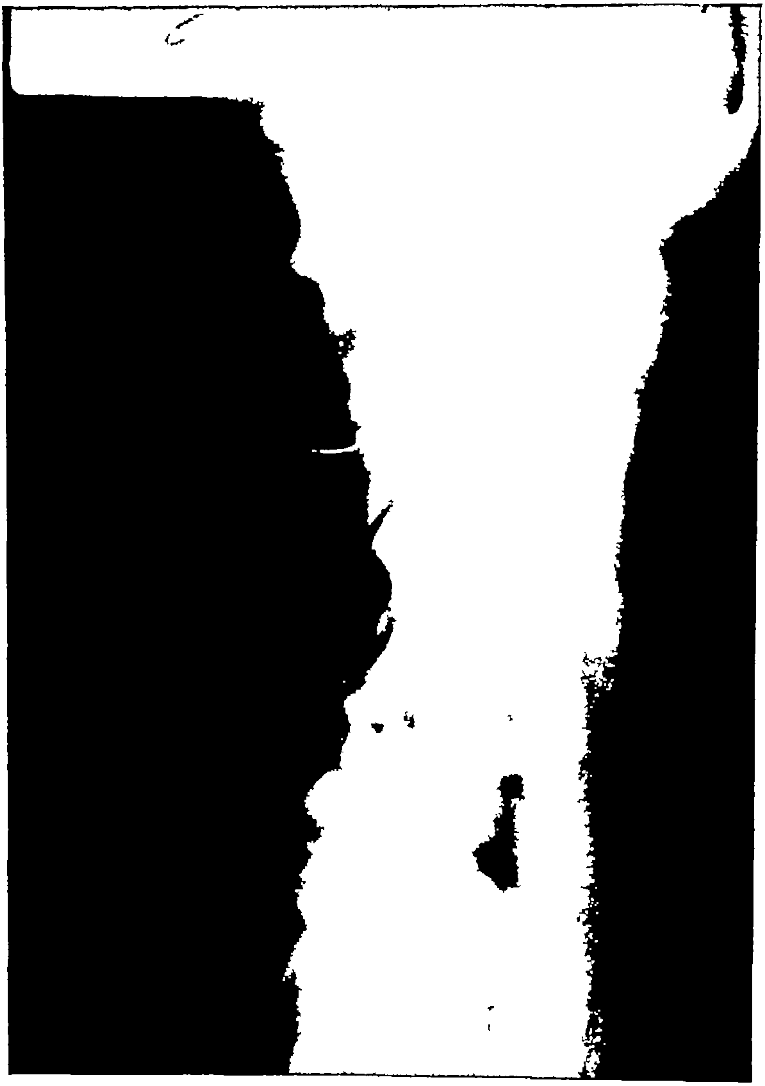

Fig 23 Stimulation of right vagus dog No 2 Tracheal deviation to opposite side is suggestive of relaxation of right constrictor muscle support but inconclusive

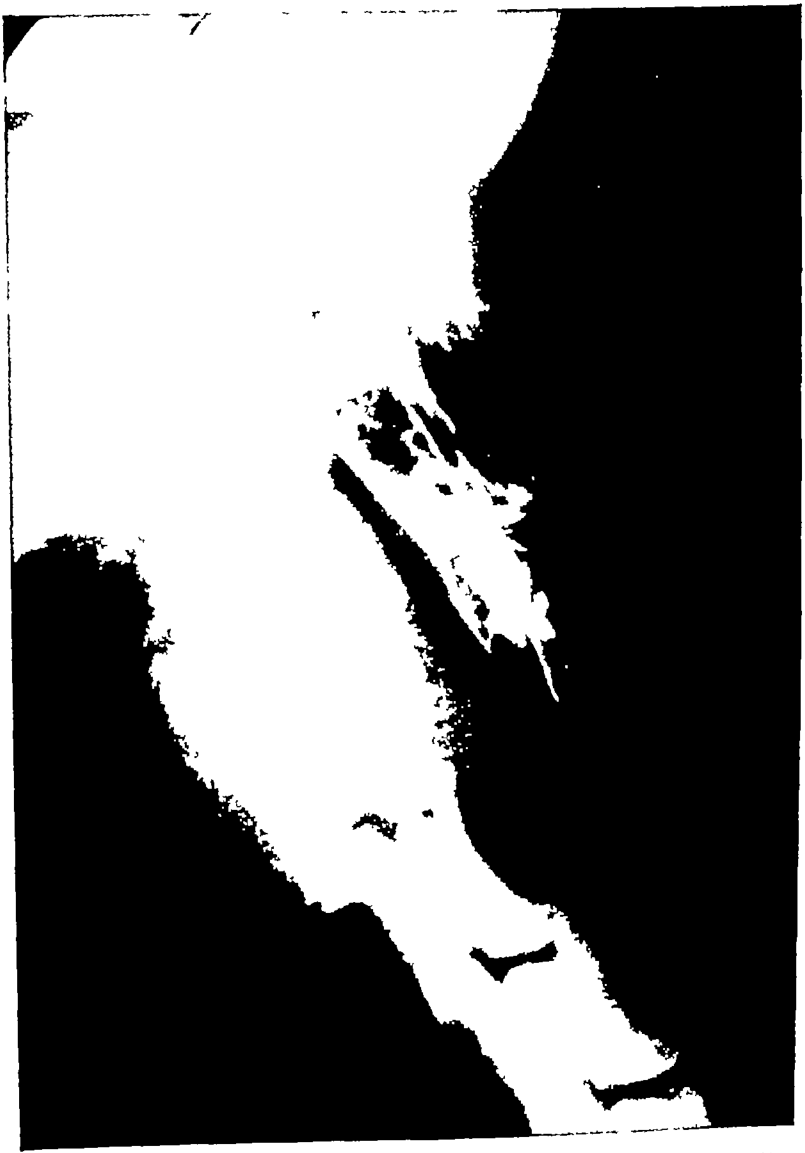

Fig 24 Stimulation of right vagus dog No 2 No significant findings

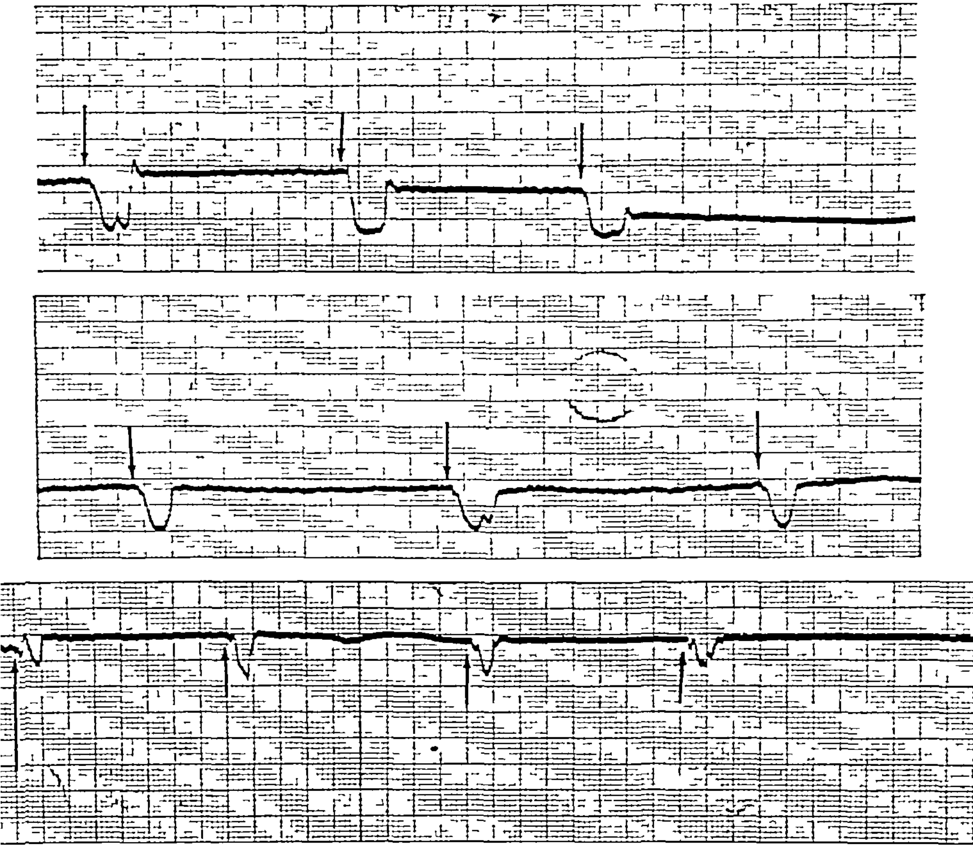

: 25 **Faradic stimulations (arrows) of right vagus Sharp relaxation of cricopharyng**
own.

Pressure Studies The faradic stimulus was adjusted to a low intensity so that vagus stimulation did not produce a swallow or cause noticeable movements of the regional muscles For sympathetic stimulation, it was assumed that the supply to the cricopharyngeus comes from the superior cervical sympathetic ganglion[17] Stimulation of the vagus above the ganglion nodosum produced a sudden sharp drop in the resting pressure of the cricopharyngeus muscle (see Fig 25)

Stimulation at the superior cervical sympathetic ganglion produced a sharp rise in pressure in the cricopharyngeus zone (see Fig 26) Controls were run with finger pressure over

the cricoid cartilage, producing positive deflections (see Fig 27) The faradic stimulator was held near, but not on the nerve, to determine changes due to electrical conditions (see Fig 28) There were none found The stimulator was also applied to the tongue in order to check the effect of movements of adjacent organs There were no significant effects noted (see Fig 29)

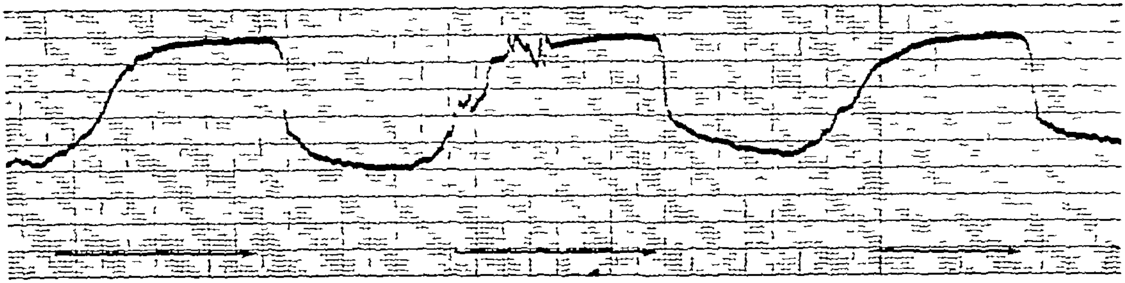

Fig 27 Control finger pressure on cricoid cartilage showing upward deflection with increase in pressure (arrows)

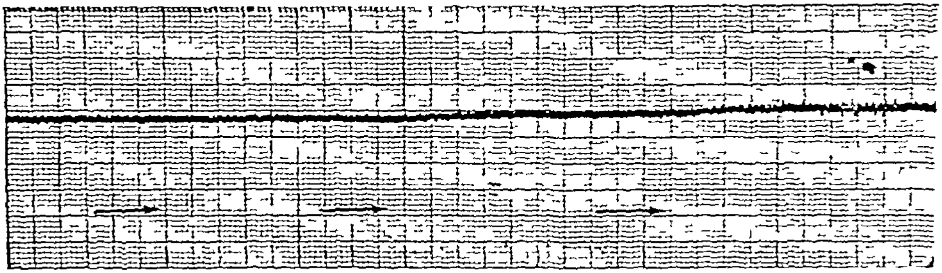

Fig 28 Control Electrode near but not on the nerve

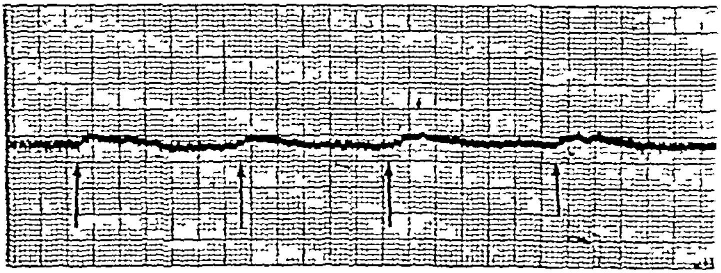

Fig 29 Control Electrode stimulating tongue No significant pressure changes at cricopharyngeus

DISCUSSION

The consistent drop in pressure with vagal stimulation, and the consistent rise in pressure with sympathetic stimulation indicates that only one type of activity is mediated by each of the two autonomic divisions It adds further support to Sjoberg's impression that the sphincteric closure at the crico-

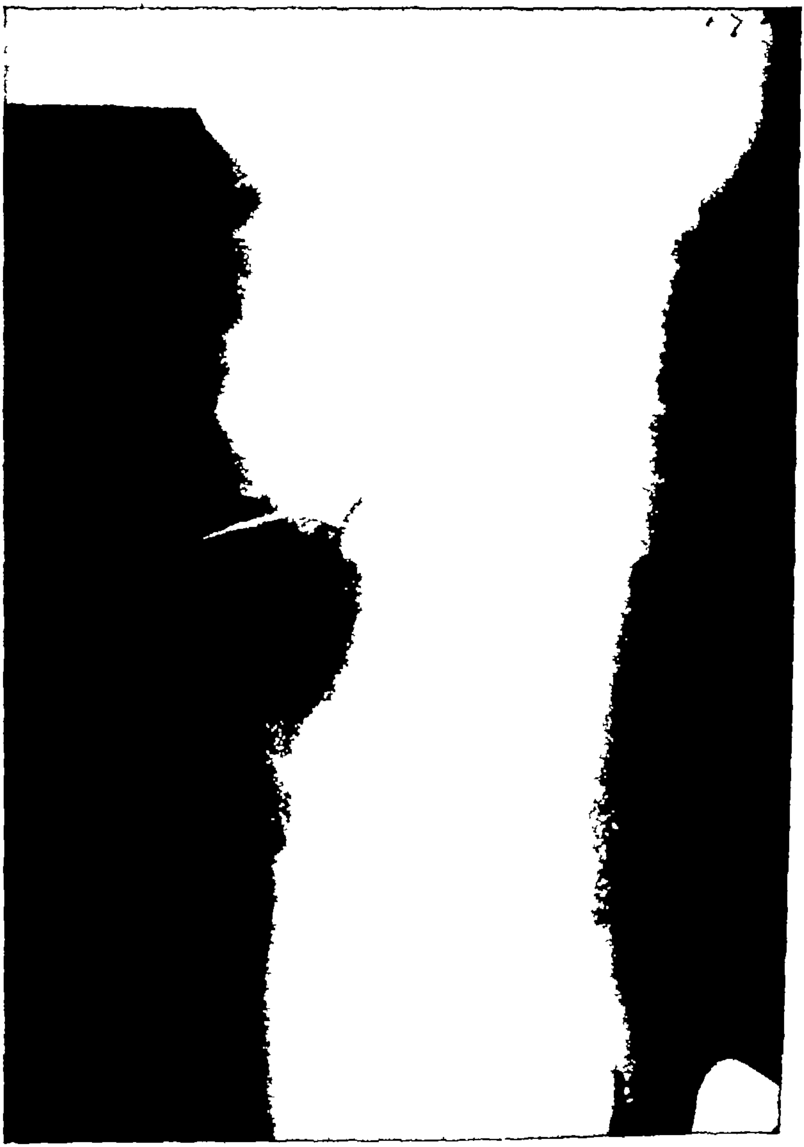

Fig 30 Faradic stimulation of cricopharyngeus muscle Less tracheal deviation but no significant changes

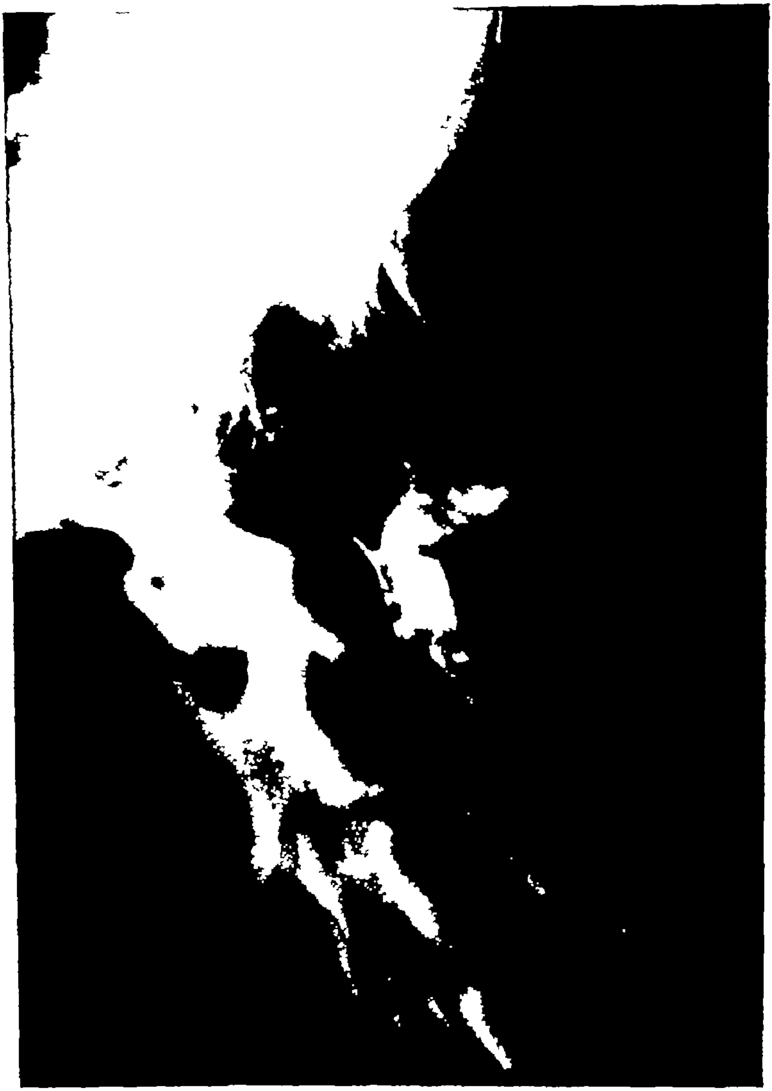

Fig 31 Faradic stimulation of cricopharyngeus No significant changes

pharyngeus following bilateral vagotomy is due to unopposed sympathetic activity, and that this condition may occur clinically

STIMULATION OF THE CRICOPHARYNGEUS

Stimulation of the cricopharyngeus muscle itself produced no appreciable change on X-ray examination from the normal resting stage There appeared to be a slight tilt of the thyroid cartilage on the cricoid, but it is not definite enough to be conclusive (see Figs 30, 31)

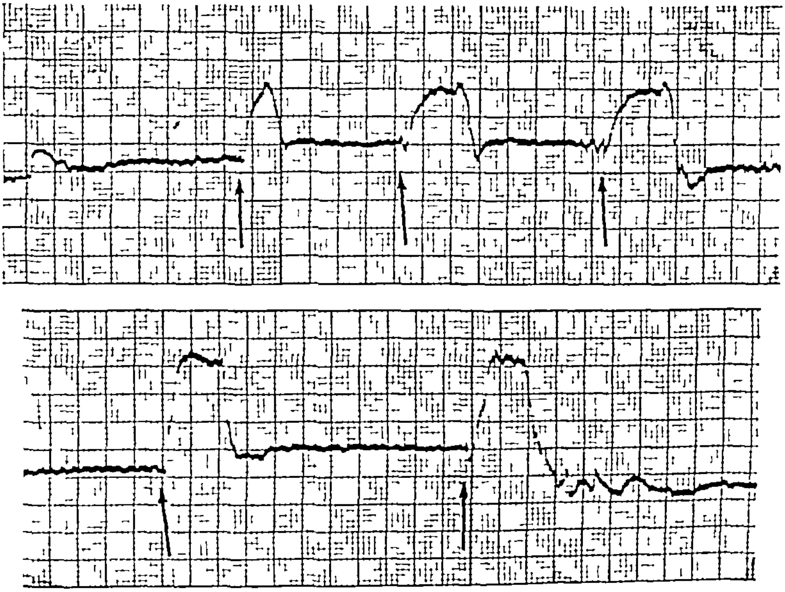

Fig 32 Faradic stimulation of cricopharyngeus muscle Sharp increase in pressure

Pressure Studies Pressure readings during stimulation of the cricopharyngeus muscle show definite contractions with each stimulus (see Fig 32)

SECTION OF THE CRICOPHARYNGEUS

In order to determine whether the thyropharyngeus portion of the inferior constrictor has any tonic action in holding the larynx back against the vertebrae the cricopharyngeus action was eliminated by dissecting the cricopharyngeus off both sides of the cricoid at its points of attachment

Deglutition The dog exhibited no dysphagia over an observation period of one month The right vocal cord was found to be abducted immediately postoperatively, but its action had returned to normal when it was examined about three weeks later

Endoscopic Examination There was no collection of food or saliva anywhere in the pharynx, and the annular area noted in the normal dog was found again to be present behind the cricoid cartilage

X-ray Swallowing performed normally No changes in the soft tissue pattern of the pharynx or hypopharynx There is no change in the position of the larynx as compared to its distance from the posterior wall (see Figs 33, 34)

Pressure Studies Faradic stimulation of the vagus supply to the inferior constrictor muscle produced only a barely noticeable drop from resting pressure (see Fig 35)

DISCUSSION

Complete separation of the cricopharyngeus from the cricoid cartilage is compatible with normal deglutition Endoscopic examination shows the annular constriction found prior to surgery Photomicrographs prepared from this area show that the ridge is composed chiefly of mucous glands (see Figs 36, 37, 38) Stimulation of the vagus after sectioning the cricopharyngeus produced practically no change in the resting pressure in this area, showing that the upper or thyropharyngeus portion of the inferior constrictor has little or no tonic action in supporting the larynx Comparison of pressure readings before and after sectioning the cricopharyngeus shows that this muscle is normally in a state of tonic contraction

SUMMARY

1 The motor activity of the dog's cricopharyngeus muscle was studied during its resting state and during deglutition

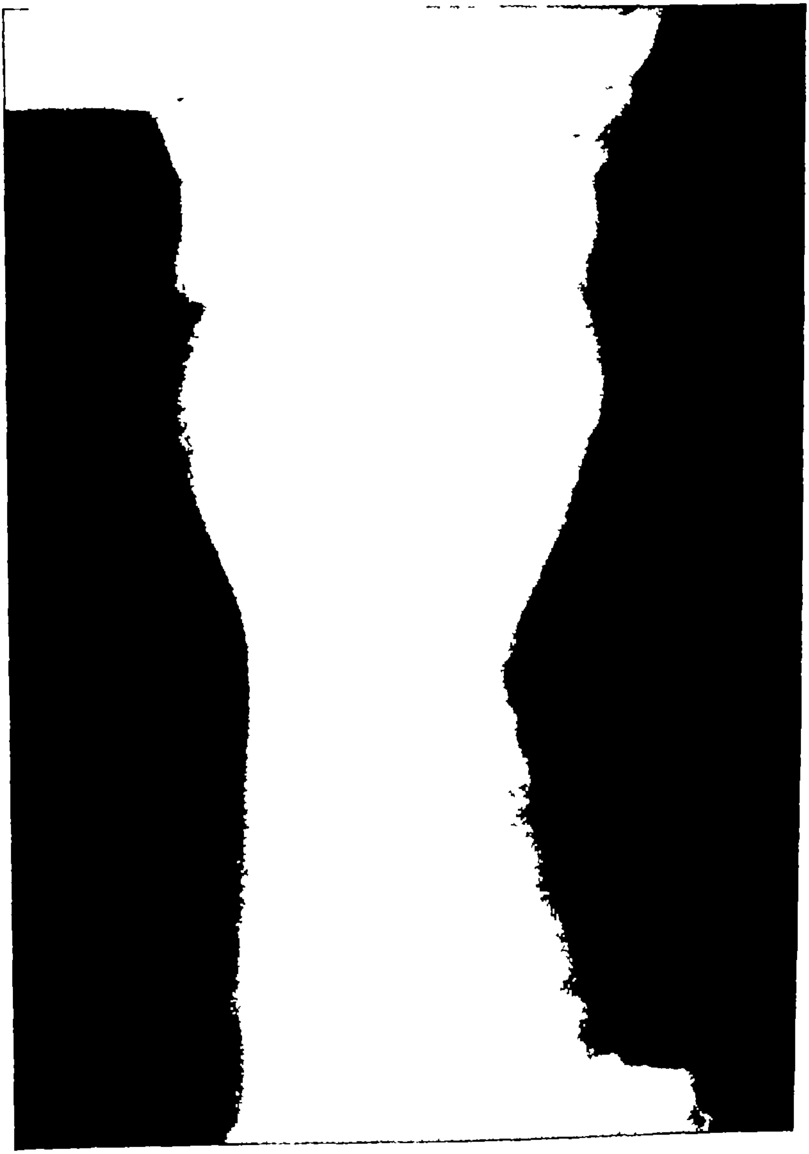

Fig 3 Following section of cricopharyngeus and thyropharyngeus bilaterally No significant changes

Fig 34 Following section of cricopharyngeus and thyropharyngeus No significant changes.

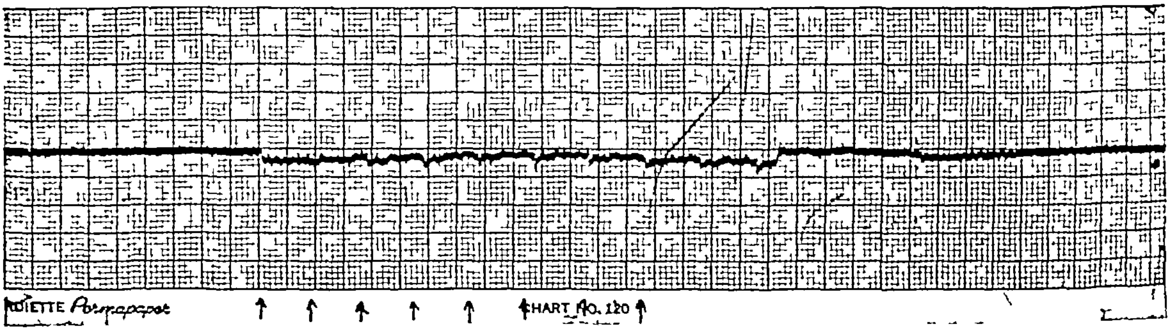

Fig 35 Faradic stimulation of vagus following section of cricopharyngeus muscle The usual drop in pressure is not seen

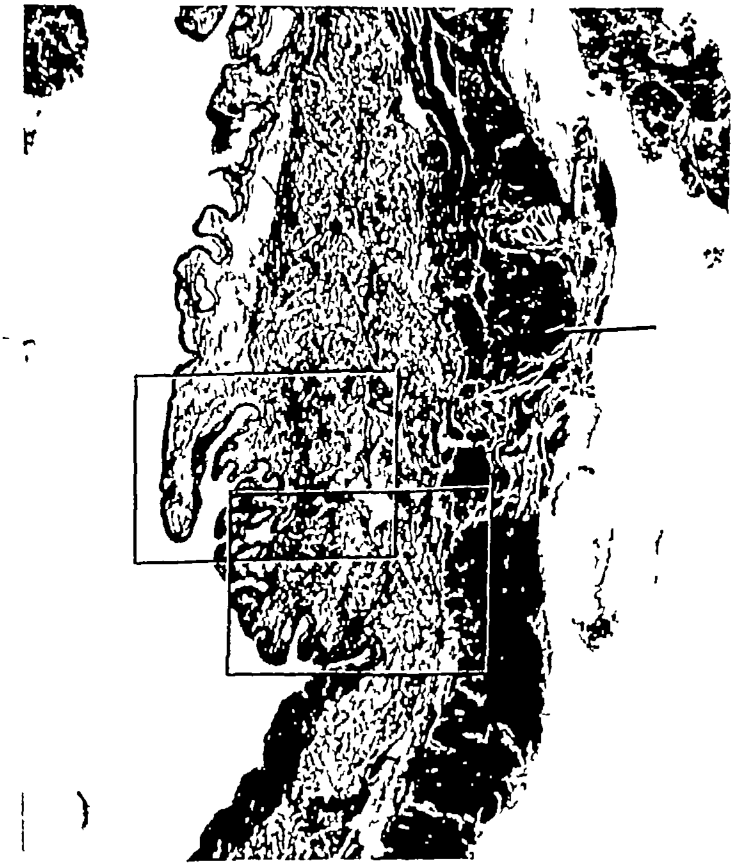

Fig 36 Saggital section of wall of hypopharynx at level of cricopharyngeus (arrow) and annular fold (×12) See Fig 5

2 By sectioning or stimulating each of the two major components of the nerve supply to the cricopharyngeus muscle various states of autonomic imbalance were produced and their effects observed by four methods

A Observations of the dog's ability to swallow food and liquids

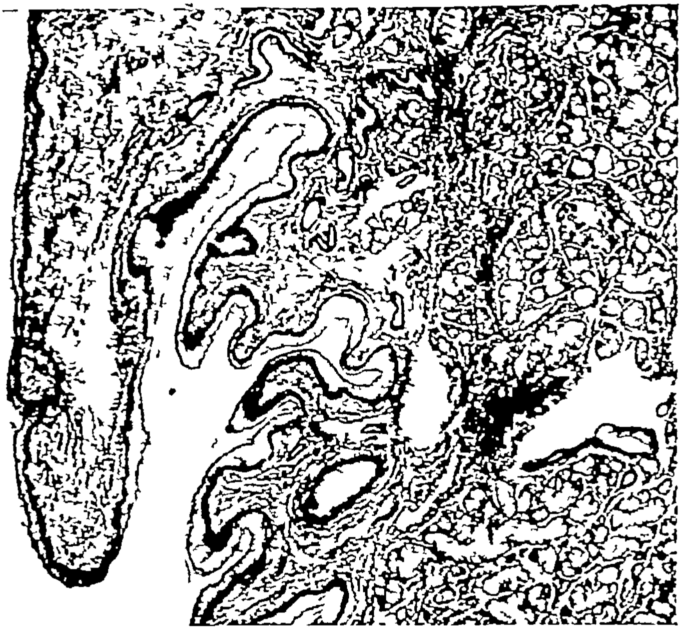

Fig 37 Saggital section through hypopharyngeal fold (upper square in Fig 36) (×38)

B Endoscopic appearance of the pharynx, larynx and hypopharynx

C Radiologic studies of the hypopharynx

D Intraluminal pressure recordings from the cricopharyngeus sphincter area using a newly developed electronic cable

3 Controls were established for the pressure recordings by the following means

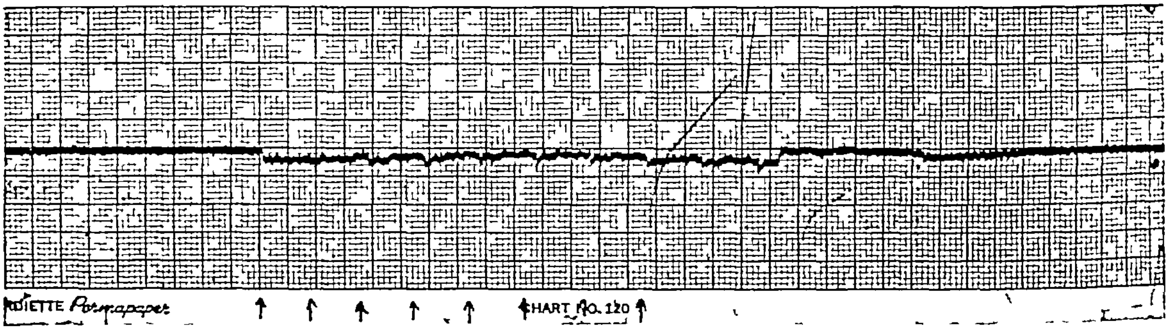

Fig 35 Faradic stimulation of vagus following section of cricopharyngeus muscle The usual drop in pressure is not seen.

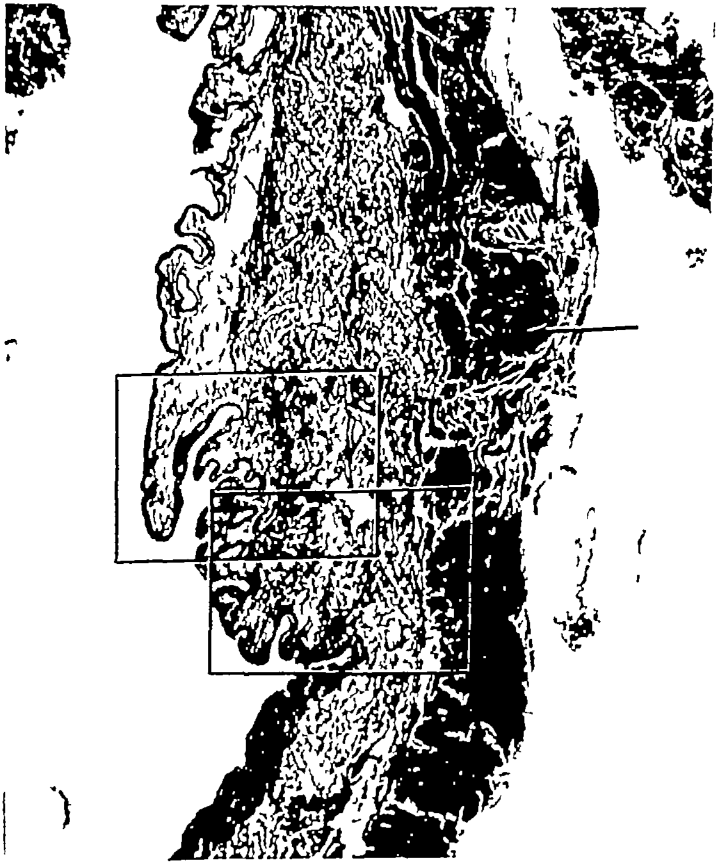

Fig 36 Saggital section of wall of hypopharynx at level of crico-pharyngeus (arrow) and annular fold (×12) See Fig 5

2 By sectioning or stimulating each of the two major components of the nerve supply to the cricopharyngeus muscle various states of autonomic imbalance were produced and their effects observed by four methods

A Observations of the dog's ability to swallow food and liquids

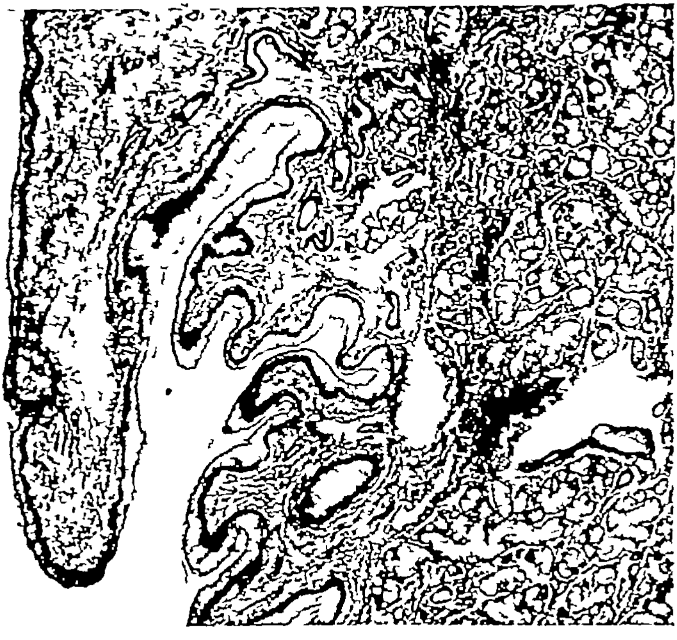

Fig 37 Saggital section through hypopharyngeal fold (upper square in Fig 36) (X38)

B Endoscopic appearance of the pharynx, larynx and hypopharynx

C Radiologic studies of the hypopharynx

D Intraluminal pressure recordings from the cricopharyngeus sphincter area using a newly developed electronic cable

3 Controls were established for the pressure recordings by the following means

A Manual pressure on the cricoid cartilage with the recording capsule in position

B Faradic stimulation of adjacent muscles

C Application of the stimulator near to but not on the nerves in order to determine changes due to electrical conditions

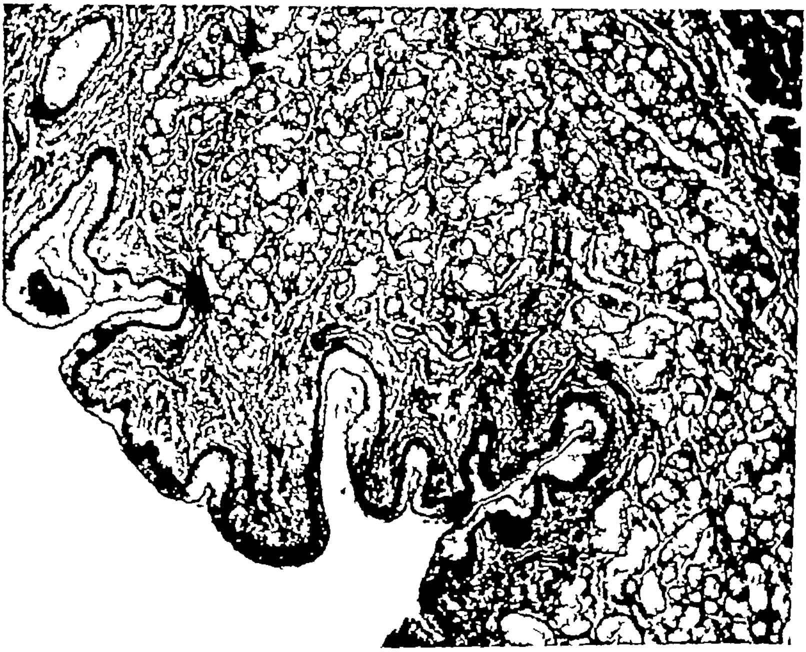

Fig 38 Saggital section through hypopharyngeal fold (lower square in Fig 36) showing large masses of mucous glands (×38)

RESULTS AND CONCLUSIONS

1 The cricopharyngeus muscle was found by pressure recordings to be in a constant state of tonus during its resting stage

2 During normal deglutition the muscle first relaxes then contracts to a pressure level equal to or higher than its resting pressure

3 Unilateral vagus section at base of skull diminishes slightly the relaxation phase of the muscle during swallowing but does not produce dysphagia in the dog

4 Bilateral vagus section at base of skull abolishes the relaxation phase and produces severe dysphagia during the dog's remaining hours of life

5 Faradic stimulation of the vagus branch to the cricopharyngeus produces a sharp relaxation of pressure

6 Stimulation of the superior cervical sympathetic ganglion produces a sharp rise in pressure

7 Relaxation is mediated by the parasympathetic fibers, contraction is mediated by the sympathetic

8 Dysphagia may result from increased tonus in the cricopharyngeus as a result of sympathetic overactivity in lesions affecting the vagus nerves between the nucleus ambiguus and the ganglion nodosum Surgical treatment of this condition would require division of either the muscle itself, or its sympathetic nerve supply

A DEVICE FOR INTRA-ESOPHAGEAL AND OTHER INTRA-LUMEN PRESSURE RECORDING

ALBERT S FIELD, JR ,*

New Haven, Conn

In a study of the swallowing mechanism described elsewhere,[1] the need for a pressure sensitive capsule arose Pressure changes within the esophagus produced by contraction and relaxation of the cricopharyngeus muscle were to be recorded These pressures are difficult to record, as the cricopharyngeus moves up and down during the act of swallowing, changing the relationship of the muscle to any stationary device in the esophageal lumen[1] A balloon connected by air-filled tubing to an electronic recording system had not produced successful results Brody and Quigley have called attention to the unsatisfactory physical characteristics of balloons Constriction of the balloon produces intraballoon pressures which do not accurately reflect pressures within the space being studied,[2] and in the study of the swallowing mechanism[1] the pressure changes recorded by the intra-esophageal balloon could not be consistently reproduced To overcome this difficulty it was decided to use a pressure sensitive capsule of cylindrical shape and of such dimensions that it would fit within the esophagus at the level of the cricopharyngeus muscle, be in contact with the muscle at all times, yet permit the muscle to slide over it when swallowing occurred It was important that the entire surface of the capsule be capable of responding to alteration in pressure, and that the effect of this response be transmitted to a system which would make a permanent visual record of the pressure variation As a qualitative record of pressure change fulfilled the needs of the experiment, exact quantitative estimate of pressure was not attempted except as required for calibration of the system

The pressure sensitive capsule described below (see Fig 1), a modification of the principle described by Lilly and Buchtal and Warburg[4] met the desired requirements A miniature differential transformer of the type described by Gauer and Gienapp[5] was considered, but discarded because it records only end pressures Here the sensitive structure is essentially a variable condenser, the capacitance of which varies when

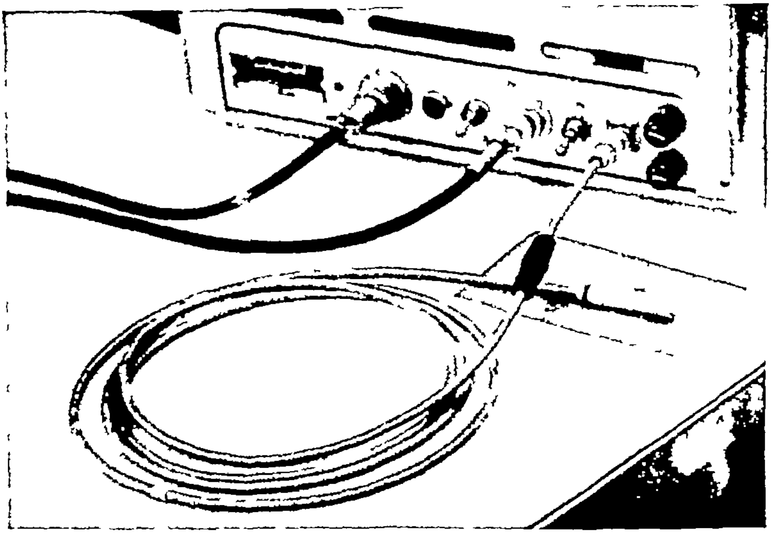

Fig 1 Pressure sensitive capsule cable and coil attached to the oscillator-amplifier

the two metallic surfaces separated by air come closer to each other, or move farther apart, as one is subjected to greater or less pressure than the other Aluminum foil was used for the metallic surfaces, but instead of air a thin sheet of rubber which forms a solid, flexible dielectric was employed to keep them apart The layers of foil and rubber were arranged concentrically to form a cylinder 1 cm in diameter and 5 cm long In order to record directly in a body cavity, rather than remotely as part of a gas or fluid filled system, a flexible water-tight cover protected the condenser from conducting solutions such as fluids in the esophagus, which could make a short circuit between the metallic surfaces

The capsule was mounted at one end of a coaxial cable,* 0.5 cm in diameter and 266 cm long, to permit insertion in the body cavity as well as attachment to an oscillator-amplifier. The coaxial cable is an important part of the arrangement, as it consists of a central wire separated from a braided shield in such a way that the spatial relationship of these two remains constant, and the capacitance of the cable varies as little as possible. Since cable and pressure capsule are part of the same electrical circuit, any variation in cable capacitance would simulate a change in capacitance of the pressure capsule and give a false indication of pressure change. The outer braided wire of the cable is attached to the grounded side of the electrical circuit, and, therefore, shields the inner wire from unwanted induced currents in the environment. Advantage is taken of this shielding effect when connecting the pressure capsule to the cable, as the outer of the two metallic surfaces of the condenser is attached to the outer braided wire of the cable.

In order to function properly the pressure sensitive capsule must be in series with a coil of just the right number of turns of No. 34 wire, so that together coil and variable condenser constitute a resonant circuit tuned to the oscillator or carrier frequency of the oscillator-amplifier system to which the cable is attached. A unique feature of the resonant circuit, as used in this case, is the separation of coil and pressure capsule. The coil is inserted in the cable at the end opposite to the pressure capsule, 9 cm from the connection to the oscillator-amplifier. This avoids placing the coil in a body cavity where it would be exposed to temperature and pressure changes that alter its inductance. Such changes in inductance would change the resonance of the circuit independently of the variable condenser, and produce unwanted deflections on the record not necessarily related to events occurring at the capsule end.

The oscillator-amplifier used† is similar in design to that described by Tomkins.[5] When the resonant circuit consisting of pressure capsule, coaxial cable and coil are attached to the input of this amplifier, they form one arm of an alternating current bridge which is balanced resistively but slightly unbalanced reactively. When the capacitance of the condenser varies, the reactive unbalance varies and the transmission of the bridge increases. The output voltage of the bridge is proportional to the reactive unbalance, and is changed in the amplifier circuit from an amplified radio-frequency signal to direct current. The pulsating direct current, an image of pressure change at the capsule is then used to drive the recorder, which in this case was a Sanborn Viso-Cardiette direct writer.

*Belden No. 8447

†Manufactured by Technitrol Engineering Co., Philadelphia, Pa.

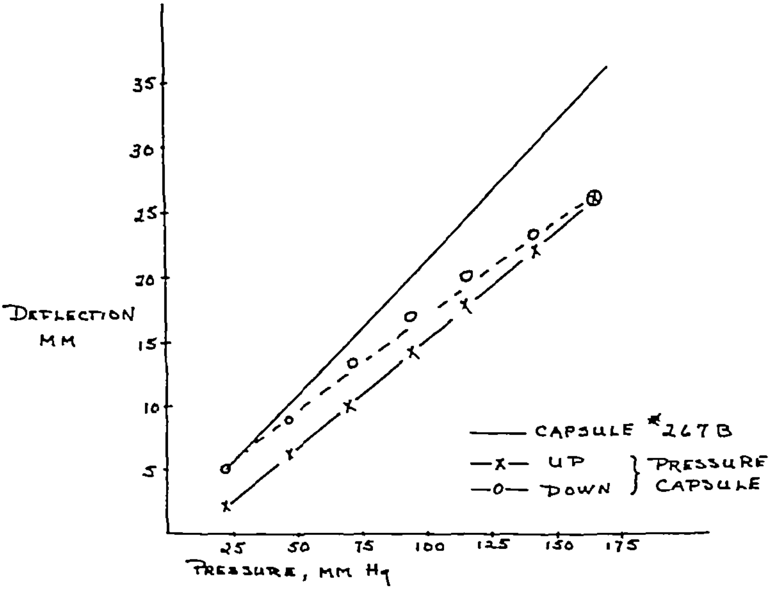

Fig. 2. Response to pressure change of the capsule described, compared to Sanborn capsule No. 267B

To determine whether it would follow pressure changes faithfully enough for the purposes of the experiment, a comparison of the performance of the capsule described was made with the Sanborn capsule No. 267B. This was accomplished by placing both capsules in the same air-filled system. The output of the oscillator-amplifier was fed into a DC coupling amplifier, which was one channel of a four channel recorder. The

Sanborn capsule was attached through its preamplifier to another channel of the same recorder The response of the Sanborn capsule was known to be linear, and the pressure of the system was varied in increments of 25 mm Hg as measured by the calibration of the Sanborn capsule The deflection in mm of the two capsules has been plotted against pressure, as shown in Fig 2, which indicated a fair linear response A good response to quick changes in pressure was observed when the pressure in the system was alternated two-and-a-half times a second

It is probable that the capsule could be made smaller, because of the inherent sensitivity of a radio-frequency device It may also be possible by further refinement in construction to increase the linearity of its response In addition to the application for which it was designed, there are other situations where it is desired to measure changes in intralumen pressure, and a transducer might have advantages Brody and Quigley compare various methods for recording these, and discusses their experience with them[2] One application which could be of considerable value, would be a direct recording of the response of bronchial musculature to various drugs

INTERMITTENT PAROTID SWELLING DUE TO ILL-FITTING DENTURES—AN ENTITY, ITS DIAGNOSIS AND TREATMENT*†

A C FURSTENBERG, M D ,
and
IRVING M BLATT, M D ,‡
Ann Arbor, Mich

Renewed interest in sialography, with significant improvement in its technique during the past few years, has provoked many studies of salivary gland disease and a number of original observations Notable among these has been a better understanding of the etiology, diagnosis, and treatment of inflammatory conditions of the major salivary glands Sialography, the process of demonstrating roentgenographically the salivary duct system after the injection of radiopaque material, has given us valuable aid in the diagnosis and classification of obstructive and non-obstructive inflammatory lesions[1,2] Secretory sialography[3] clearly indicates that both conditions are responsible for characteristic changes in the anatomical configuration and physiological function of the major salivary glands

We have become particularly interested in one such obstructive phenomenon and its mode of management, namely, obstructive sialodochitis We believe it to be an entity due to an inflammatory stricture at the papilla of the duct developing as the result of trauma from improperly fitting partial or complete dentures This condition appears to have a natural history, recognizable clinical manifestations, diag-

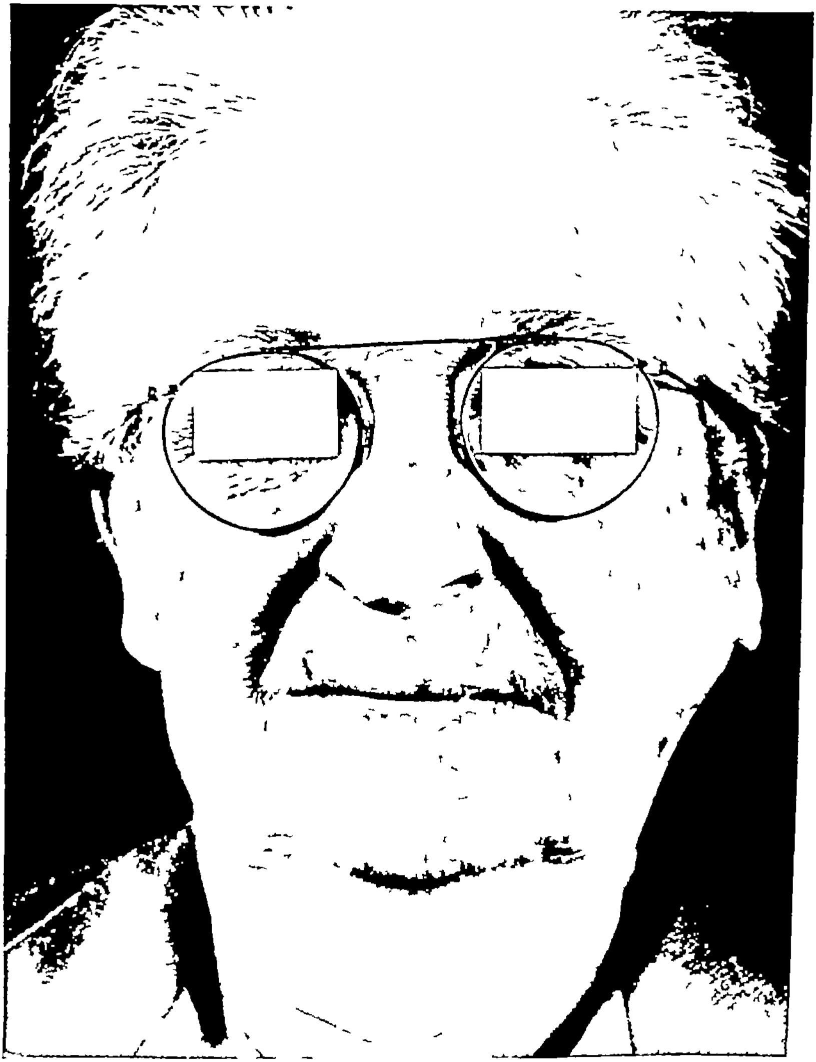

Fig 1 Case 1 Unilateral inflammatory cyst of the parotid gland

nostic radiographic features, and definite histopathologic changes

Until recently the management of this condition has consisted of frequent duct dilatations and the administration of antibiotics and chemotherapeutic agents for the relief of swelling and pain incident to the inflammatory reaction within the gland We should like, therefore, to describe the diagnostic features and pathogenesis of this condition, and to offer a simple operative procedure for its alleviation

PRESENTATION OF CASES

Case 1 G A. No 781775, a 72 year-old widow was admitted to University Hospital on April 22, 1954, for evaluation and treatment of a left parotid swelling of eight months duration the enlargement was noticed for the first time after eating There was pain characterized by 'a festering ache and a ropy feeling' in the left cheek. Over a four week interval the swelling did not recede completely but fluctuated at meal times between the size of a 'kernel and large lima bean" The size of the parotid mass remained stationary for three months prior to admission

The patient had been wearing complete dentures for more than 30 years Six years prior to admission she noticed that the upper dentures became increasingly mobile and often embarrassed her by falling upon the lower lip when opening the mouth this was also troublesome during mastication Various cements' were used in an effort to hold the upper plate in position

Physical examination revealed a 3x4 cm mass in the posteromedial portion of the left parotid gland which transmitted light (see Fig 1) The remainder of the parotid gland was diffusely palpable but not nodular When the mouth was opened the upper denture fell on the lower lip There was considerable front to rear and side to side movement of the upper denture. The parotid papilla on each side was hypertrophic and rigid Stensen's duct orifice was patent, and the duct, which was cord like was palpable throughout its buccal course Pressure over the gland gave rise to a profuse flow of clear saliva without an immediate return of parotid swelling Lemon stimulation produced a similar condition A size No 1 olive-tipped probe inserted into the duct revealed a fusiform stenosis 0 5 cm from the orifice At this point the wall of the duct imparted a gritty sensation There were no additional strictures in the bucco-masseteric course of Stensen's duct. On the contrary, the duct felt diffusely dilated Further dilation of the duct orifice preparatory to sialography promoted an active flow of saliva with lemon stimulation

A smear of the saliva collected by polyethylene catheterization failed to reveal any cells organisms or crystalline material The culture yielded organisms of the non pathogenic actinomyces species which were considered contaminants The total volume of parotid saliva secreted by continuous lemon stimulation after overnight fasting and collected by polyethylene catheterization was 16 4 c c in 60 minutes (see Table I)

Films of the left parotid sialogram taken after injection of 1 0 c c of Pantopaque showed elongation tortuosity and dilation of Stensen s duct without evidence of stricture in its bucco-masseteric course (see Fig 2) This was accompanied by displacement of the secondary and tertiary ducts about a space-occupying lesion within the left parotid gland There was minimal retention of contrast material on the post-evacuation films This sialographic picture was compatible with an inflammatory cyst and chronic main duct obstruction Aspiration of 17 c c of fluid was followed by injection of an equivalent amount of 30 per cent Urokon to outline the cyst cavity (see Fig 2)

A subtotal parotidectomy was performed with excision of the cyst

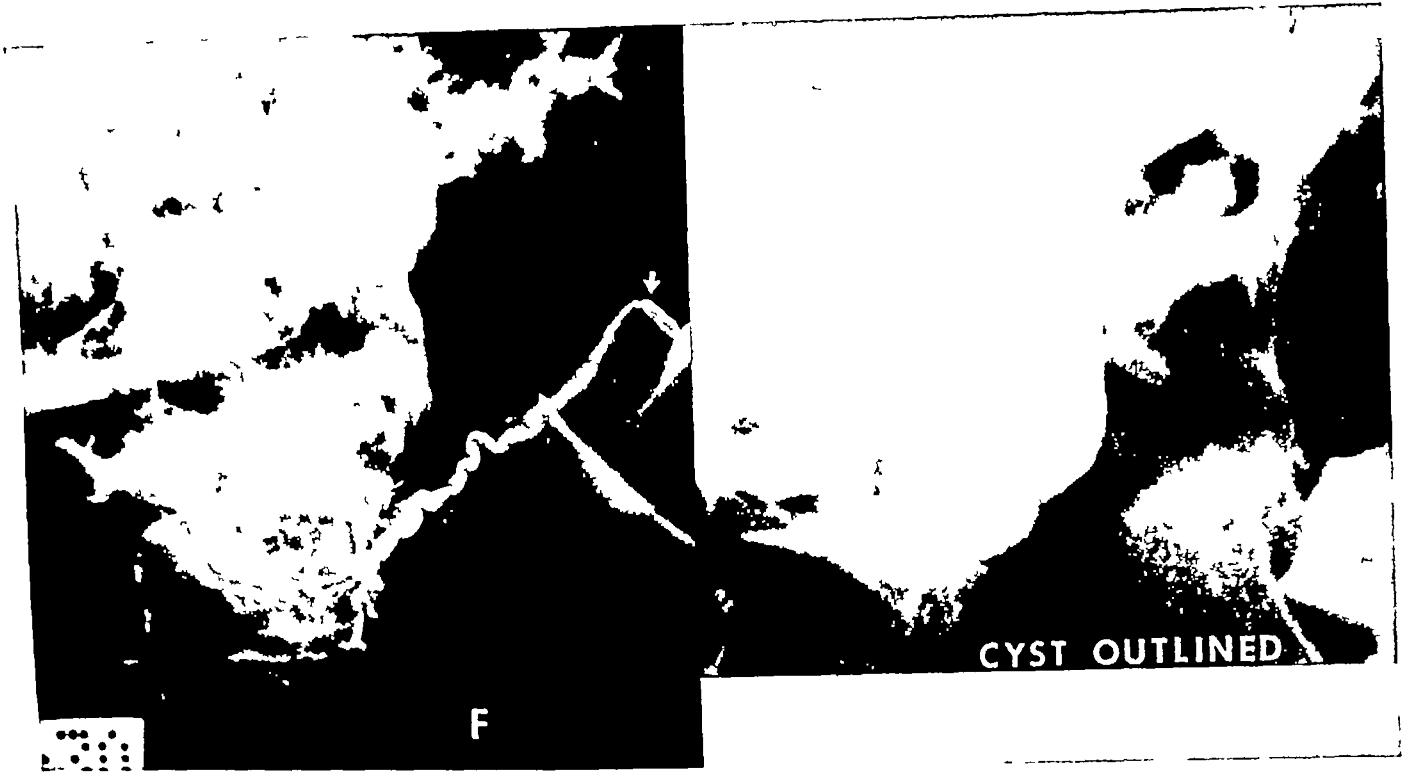

Fig 2 Sialogram of an inflammatory cyst associated with main duct obstruction
The Filling Phase shows elongation tortuosity and dilation of Stensen's duct with evidence of stricture at the orifice only The stricture has been widely dilated at the arrow Aspiration of 17 c c of fluid followed by injection of an equivalent amount of 30 per cent Urokon to outline the cavity of the cyst

There was considerable scar tissue in the wall of the cyst with evidence of chronic inflammation in the salivary gland (see Fig 3)

Case 2 K. S No 875192 a 58 year-old housewife was admitted to University Hospital on July 9 1957 with painful bilateral swelling of the parotid gland The patient was well until April, 1942, when suddenly she noted painful right parotid swelling while eating A diagnosis of mumps was made by the family physician Subsequent episodes occurred approximately every three months, all associated with eating In October, 1946 the left parotid gland was similarly involved

In 1938 upper and lower complete dentures had been made for the patient but they did not seem to fit satisfactorily During the ensuing years other dentures were provided but they never were entirely satisfactory for mastication

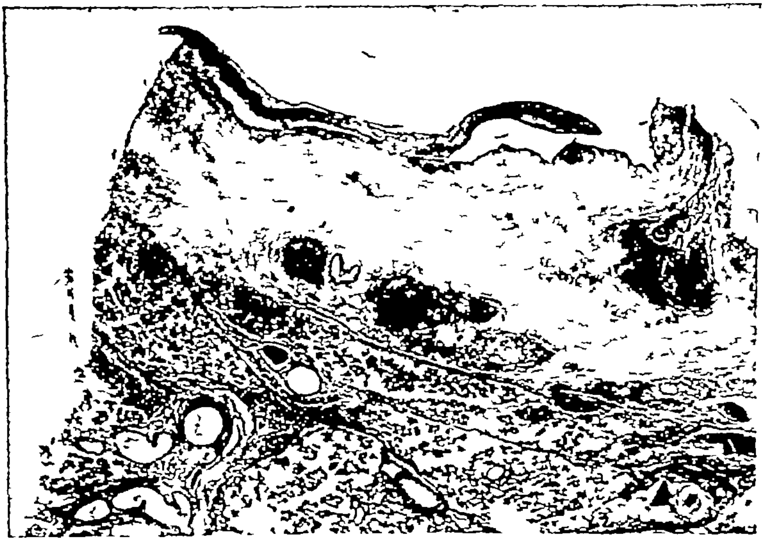

Fig 3 Case 1 The microscopic section shows considerable scar tissue in the wall of the cyst with chronic inflammation.

Physical examination revealed bilateral diffuse parotid enlargement (see Fig 4) The upper denture fell upon the lower lip when the mouth was opened The lower denture had considerable anteroposterior mobility and was observed to override each caruncula salivaris at the site where the submaxillary duct (Wharton's duct) opens into the floor of the mouth Both parotid papillae were hypertrophic and scarred The salivary flow from each parotid gland was sluggish Upon stimulation of salivary secretions by sucking a lemon slice the face swelled gradually, and the flow of saliva into the mouth came in spurts Probing of each Stensen s duct revealed a stricture at the duct orifices as well as additional strictures along the bucco-masseteric course of Stensen s duct. The wall of each Stensen s duct imparted a gritty sensation upon probing There were no strictures in either submaxillary (Wharton s) duct

A smear of parotid saliva collected by polyethylene catheterization revealed desquamated cuboidal epithelial cells No organisms were observed by smear or culture from either side The submaxillary saliva showed no cells or organisms Total volume of parotid saliva secreted by continuous lemon stimulation after overnight fasting was 17 7 c c in 60 minutes for the right parotid gland and 18 1 c c in 60 minutes for the left (see Table I) A quadriglandular sialogram was performed An injection of 0 9 c c of Pantopaque in each Stensen's duct revealed a markedly dilated and irregularly segmented main duct The submaxillary ducts (0 35 c c Pantopaque injected in each duct) were similarly involved although the degree of dilation was not so pronounced as in the case of Stensen s ducts (see Fig 5)

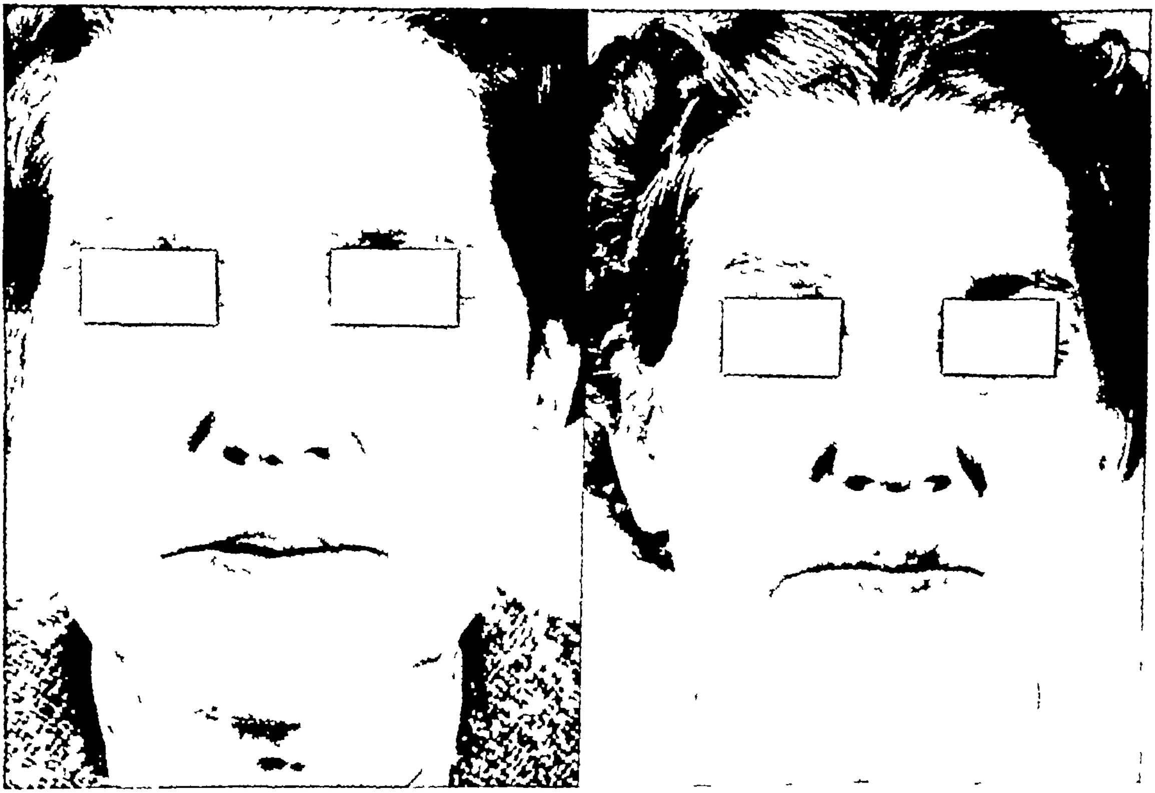

Fig 4 Case 2 Photographs taken before and one week after bilateral parotid dochoplasty

On July 16 1957 a bilateral dochoplasty of Stensen s duct was performed

Case 3 M B No 839162 A 46 year old wife of a physician came to University Hospital in April 1956 because of repeated painful swellings of the left parotid gland This patient had been asymptomatic until May 1955 when she noted a sudden post prandial left parotid swelling This was associated with a low grade fever Subsequently she complained of a feeling of tightness and dull pain in the bucco masseteric region while eating The diagnosis of mumps was made at the time of the original attack. During the next ten months there were similar episodes of pain and swelling in the left parotid area approximately once a month and invariably associated with her meals The swelling receded spontaneously on each occasion

Upper and lower partial dentures had been made for this patient in 1944 for the purpose of correcting her bite She stated that the upper dentures became loose frequently and had to be 'tightened" She preferred to chew her food on the right side

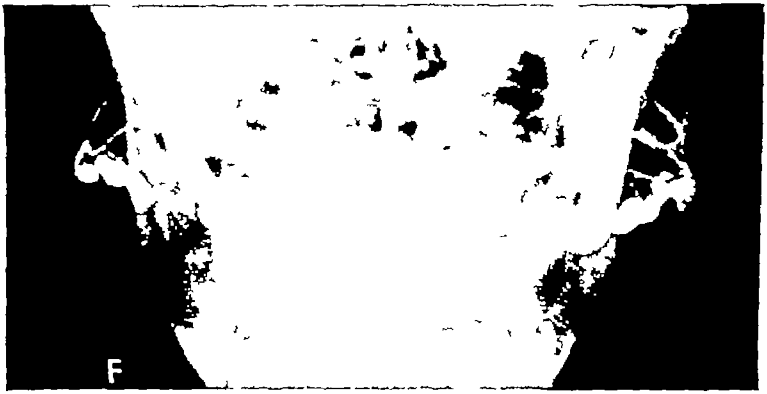

Fig 5 Sialogram of advanced main duct obstruction with secondary infection The Filling Phase reveals that each Stensen's duct is markedly dilated and irregularly segmented.

Physical examination revealed a moderately swollen diffusely palpable left parotid gland The left parotid papilla was hypertrophic A scanty amount of clear gelatinous saliva could be milked from the duct orifice Upon stimulation by sucking a lemon slice the left parotid gland swelled and a firm ropy Stensen's duct could be palpated along its bucco-masseteric course Upon further milking of the duct system by massage saliva entered the mouth with a squirt. Probing revealed a stricture 0 5 cm proximal to the duct orifice and only a size No 1 olive-tipped probe could be passed beyond the stricture Additional strictures were also encountered along the bucco masseteric course of Stensen's duct The wall of the duct imparted a gritty sensation upon probing The saliva contained desquamated cuboidal cells but no organisms were found in the smear or culture The total volume of parotid saliva secreted by continuous lemon stimulation (after overnight fasting) was 20 5 c c in 1 hr on the left side and 20 0 c c. in 1 hr on the right (see Table I) This secretion was obtained after the stricture near the orifice had been widely dilated

The sialogram revealed multiple strictures of Stensen's duct on the left side after injection of 0 8 c.c Pantopaque There was virtually complete retention of the contrast material on the five-minute post-evacuation film (see Fig 6) The filling and excretory films of the right parotid gland and submaxillary glands were normal

On June 15 1956 a dochoplasty was performed

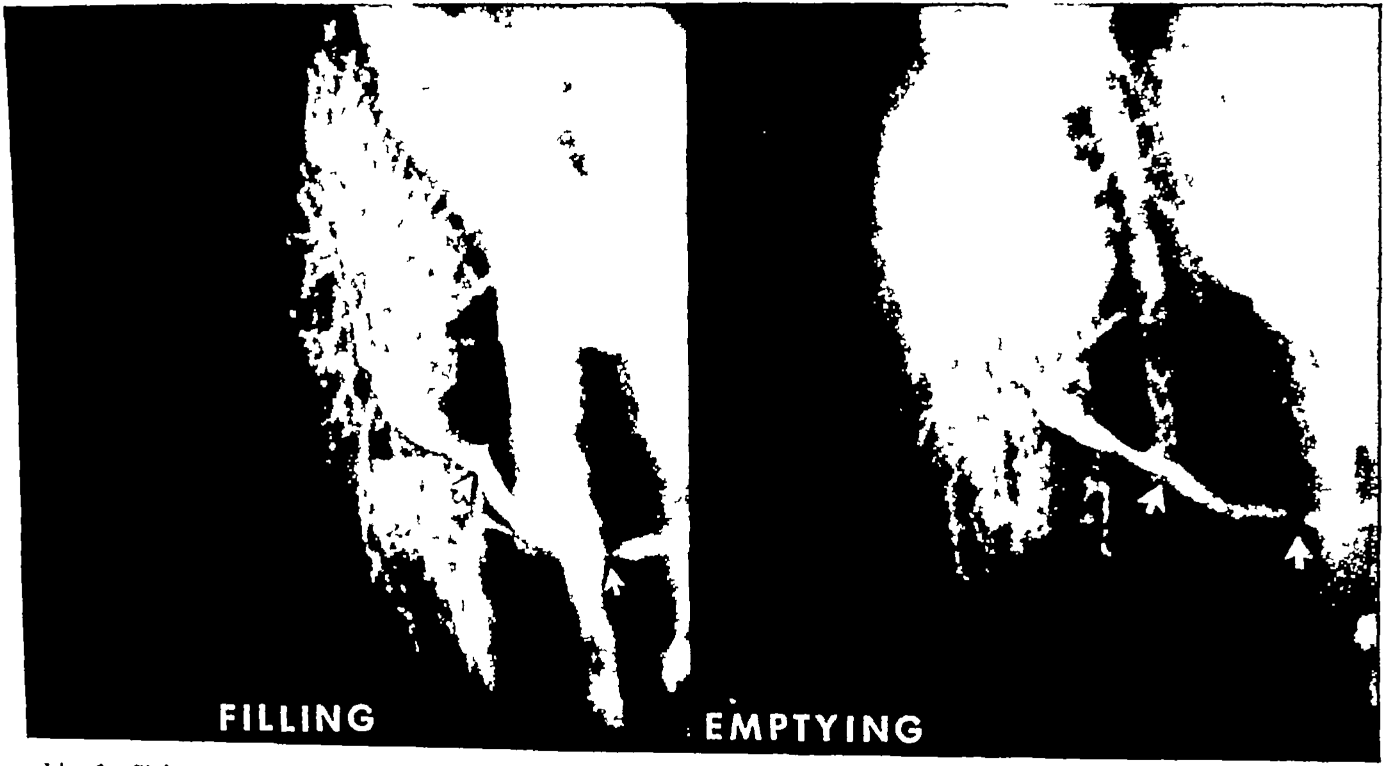

Fig. 6 Sialogram of uniform dilation of Stensen's duct with beading (2X enlarged) This appears to be an early anatomic alteration characterized by stricture formation (arrows) at the duct orifice and along the bucco-masseteric course of Stensen's duct In the 5-Minute Post-Evacuation Film the obstruction to salivary flow is verified by the unaltered appearance of the sialogram

THE CLINICAL PICTURE

As noted by other investigators,[4,5] the condition is associated with partial or complete dentures which are ill-fitting Diffuse parotid swelling with pain and a feeling of pressure in the cheek frequently occurs while eating When salivary flow is stimulated by a potent sialogogue (lemon) the gland may swell Upon massage of the parotid region, only a sluggish flow of clear saliva from a hypertrophic parotid papilla is noted The cord-like dilated Stensen's duct can usually be palpated along its bucco-masseteric course Upon probing the duct, dilated segments alternate with strictures A gritty sensation imparted to the probe by the hypertrophic and metaplastic duct epithelium (see Fig 9) may be mistaken for calcareous material

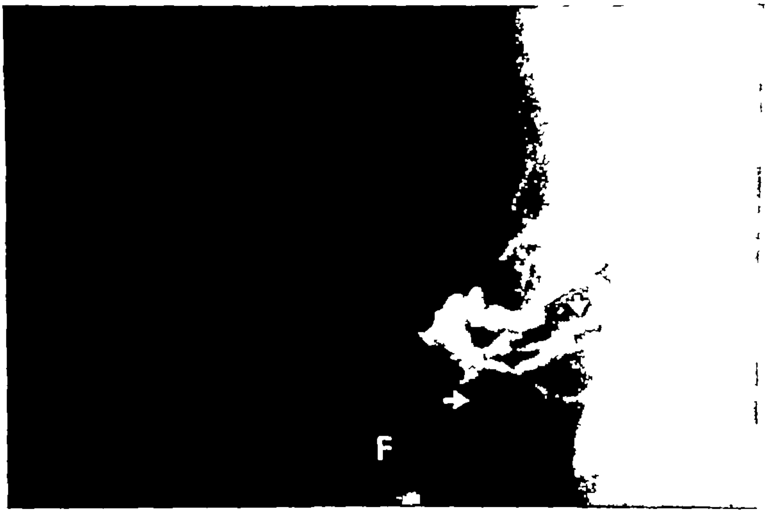

Fig 7 Case 2 A sialogram of the Filling Phase (2X enlarged) demonstrates that the secondary ducts (arrows) may also be involved in obstructive sialodochitis however there is no alteration of the most peripheral radicals This is the differential point between obstructive sialodochitis and non-obstructive sialectasis

THE PATHOGENESIS

This condition appears definitely to be associated with the

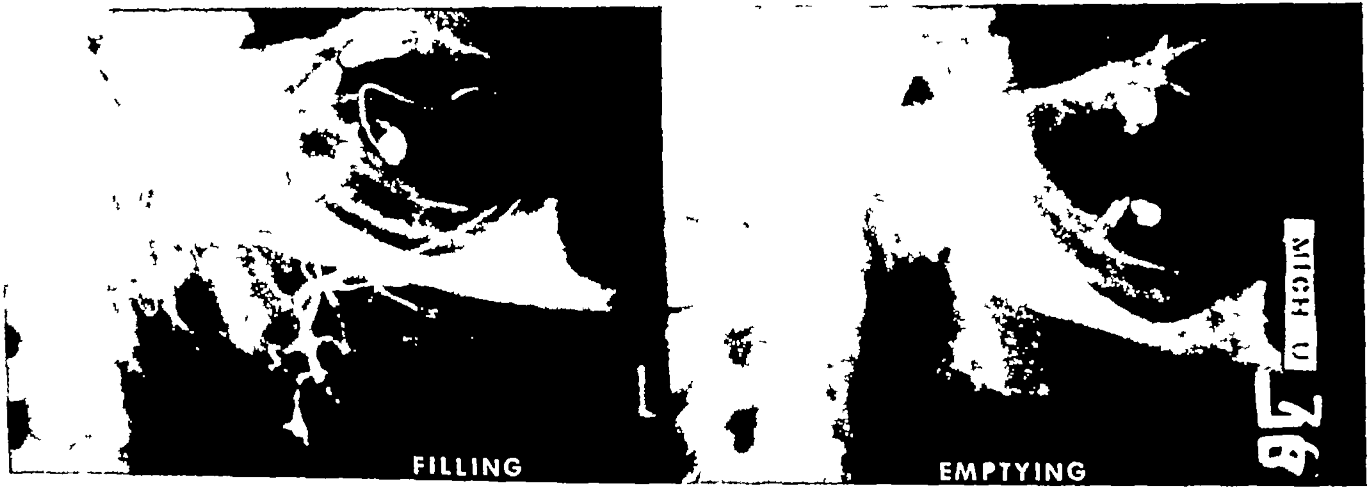

Fig 8 Case 2 The Filling Phase of this quadriglandular sialogram demonstrates the markedly dilated and irregularly segmented main ducts (Stensen s ducts) The submaxillary ducts (Wharton s ducts) can be similarly involved though the degree of dilation is not so pronounced There is no alteration of the peripheral duct architecture The Post-Evacuation Film indicates that the obstruction at the outlet (orifice) is the principal deterrent to evacuation

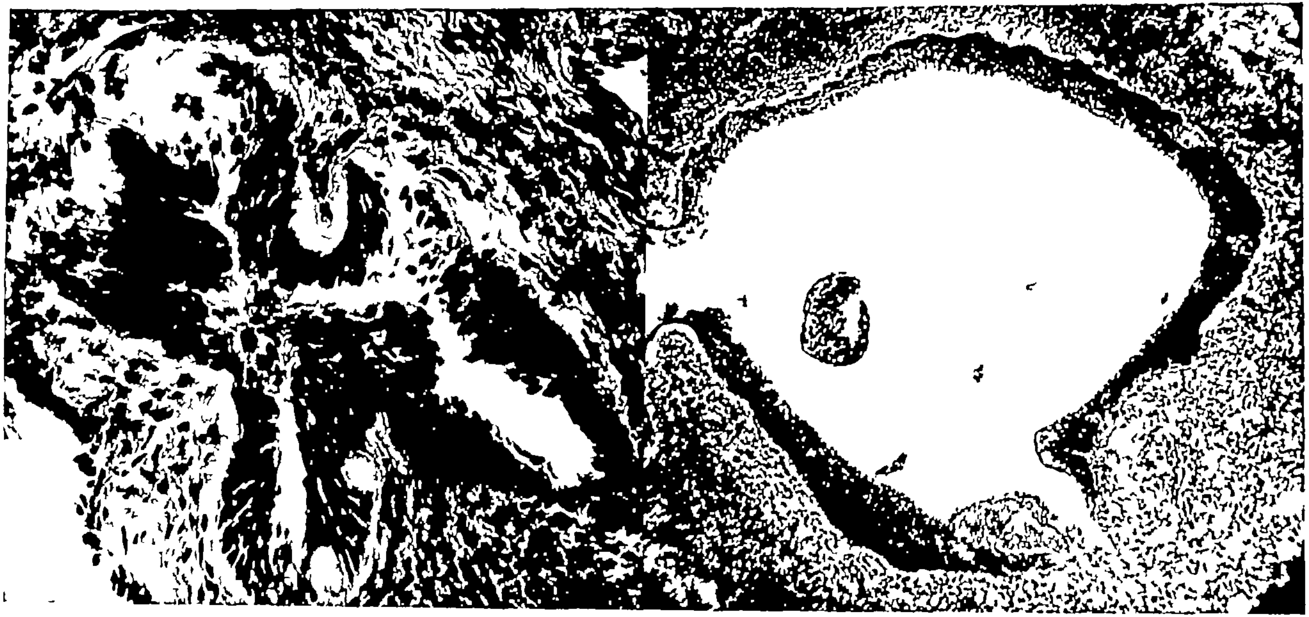

Fig 9 Case 2 Microscopic sections taken from (A) the constricted orifice of Stensen s duct (B) the greatly dilated portion of the main duct just proximal to the stricture There is metaplasia scar tissue formation and stenosis at the site of the stricture This is consequent upon traumatization of Stensen s duct orifice in the parotid papilla

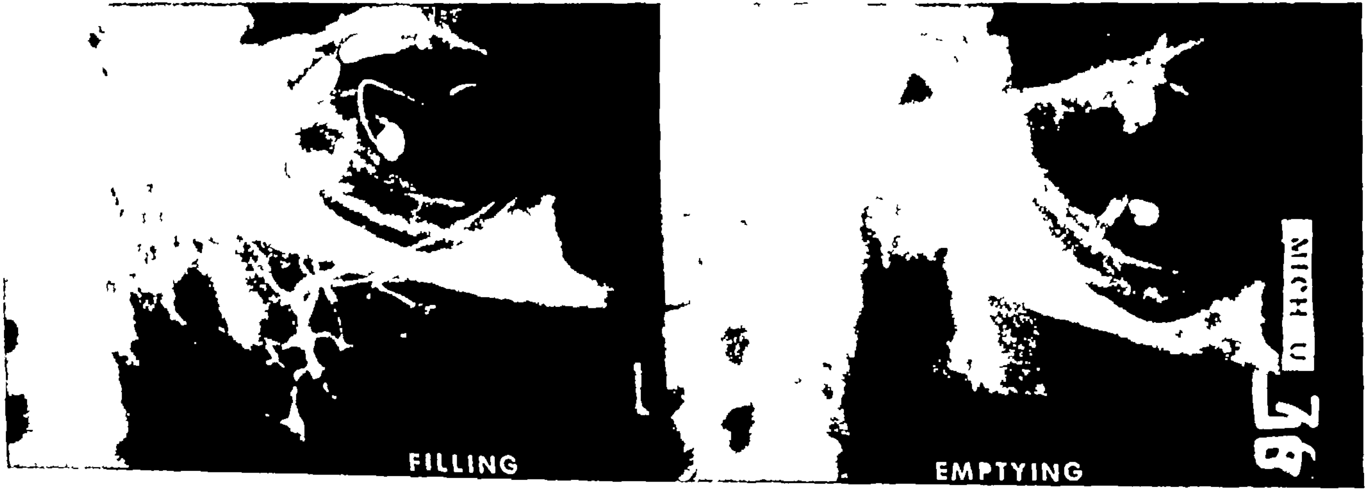

Fig 8 Case 2 The Filling Phase of this quadriglandular sialogram demonstrates the markedly dilated and irregularly segmented main ducts (Stensen s ducts) The submaxillary ducts (Wharton s ducts) can be similarly involved though the degree of dilation is not so pronounced There is no alteration of the peripheral duct architecture The Post-Evacuation Film indicates that the obstruction at the outlet (orifice) is the principal deterrent to evacuation

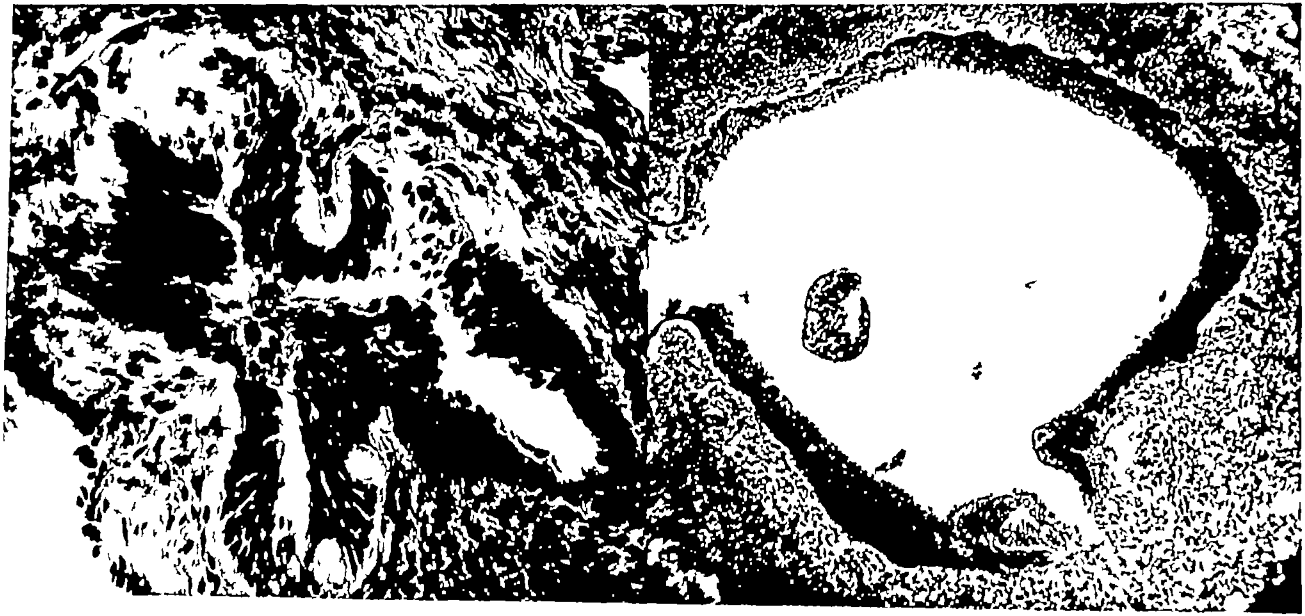

Fig 9 Case 2 Microscopic sections taken from (A) the constricted orifice of Stensen's duct (B) the greatly dilated portion of the main duct just proximal to the stricture There is *metaplasia* scar tissue formation and stenosis at the site of the stricture This is consequent upon traumatization of Stensen's duct orifice in the parotid papilla

presence of dentures The patient is required to alter the mechanism of mastication in a manner which does not sustain the normal chewing habit As food is being chewed on one side of the mouth, the parotid papilla on the opposite side tends to be sucked mesially and bitten Mastication is further rearranged and altered when alveolar absorption occurs, allowing the dentures to shift about while chewing

When the parotid papilla is subjected to repeated trauma and inflammation, fibrous tissue proliferation and scar tissue cicatrization occur This interferes with normal salivary flow, and the ensuing pressure behind the stricture results in dilatation of the gland duct It is not long before secondary bacterial infection supervenes with a diffuse inflammatory reaction along the bucco-masseteric course of Stensen's duct and with production of multiple inflammatory strictures If a stricture in the secondary or tertiary ducts seals off a section of secreting acinar tissue an inflammatory cyst may be formed (see Fig 2)

THE SIALOGRAM WITH CLINICAL AND HISTOLOGICAL CORRELATION

The diagnostic features of this condition are dilatation and stricture formation in the main salivary duct *without the terminal peripheral duct involvement* seen in sialectasis The degree of anatomic alteration depends on the frequency, severity and duration of *1* Obstruction caused by injury to the parotid papilla, *2* Secondary bacterial infection associated with interference of salivary flow

Among the patients above described, three roentgenographic patterns can be distinguished

1 ELONGATION, TORTUOSITY AND DILATATION OF THE MAIN DUCT

These changes are noted when a stricture is present near the duct orifice (see Fig 2) Filling phase films and probing demonstrated the stricture Some of the secondary and tertiary radicals share in the dilatation If a stricture in the minor ducts resulting from a parotid infection seals off a section of secreting acini an inflammatory cyst may be formed A monolocular cyst with considerable scar tissue in its wall and with surrounding parenchymal pressure atrophy is seen in Fig 3 The stricture was probably the result of a parotitis eight months prior to admission to the hospital, the only such episode experienced by the patient

2 UNIFORM DILATATION OF STENSEN'S DUCT WITH BEADING

This appears to be an early anatomic alteration of the duct characterized by stricture formation at its orifice and along its bucco-masseteric course We note these changes in Stensen's duct of patient (Case 3) The emptying film shows virtually complete retention of the contrast material (see Fig 6) The mechanism of retention is no doubt related to the checking action of the salivary flow by multiple strictures along the course of the duct and the non-distensible stricture at the duct orifice

3 MARKED DILATATION AND IRREGULAR SEGMENTATION OF THE MAIN DUCT

These changes are seen in patient (Case 2), in whom ill-fitting dentures were worn for 19 years, with recurrent episodes of parotid swelling As noted in the filling phase, the secondary ducts are also involved, but the most peripheral radicals do not participate in the inflammatory process (see Fig 7) This represents an advanced composite picture of main duct obstruction and secondary bacterial infection The submaxillary ducts can be similarly involved if the lower denture is faulty, although the degree of dilatation is not pronounced The post-evacuation film demonstrates that the obstruction at the outlet is the principal deterrent to evacuation (see Fig 8) When the stenotic duct orifices are removed surgically and a duct-plasty is performed, the continuous flow of saliva is re-established and the parotid swelling recedes Histologic sections of the constricted duct orifice show metaplasia, scar formation and stenosis that are the result of trauma of Stensen's duct in the parotid papilla (see Fig 9)

DISCUSSION

Obstructive sialodochitis due to ill-fitting dentures is not a common disorder when compared with salivary gland inflammation caused by calculi or by the non-obstructive sialodochiectasis (sialectasis) group of diseases such as recurrent pyogenic parotitis, Sjogren's syndrome and Mikulicz disease Only three such cases (2 7 per cent) have been observed in a total of 138 patients referred to the clinic for various inflammatory lesions of the salivary glands since July, 1953 These cases also represent only 0 75 per cent of 352 sialograms made since the above date Because of the morphologic pattern of main duct "estasia" produced by alternating dilatations and strictures, the condition belongs to the obstructive sialodochiectasis group as classified by various investigators[1,4,7], however, obstructive sialodochitis should not be confused with non-obstructive sialectasis In the former, there is no alteration in the terminal ducts nor diminuation in the volume of saliva secreted[8] In the latter, however, we note dilatation of many of the terminal ducts, and a definite diminution in the quantity of saliva secreted by the diseased gland

TABLE I—SECRETION VOLUME STUDIES OF PURE PAROTID SALIVA IN C C/HR

Method of Collection	Stimulation Feeding	Via Polyethylene Catheter Continuous Lemon Slices			
Normal Female Age 44	21 c c	Case 3	Age 46	20 5 c c 20 0 c c	Left Parotid, Right Parotid
Normal Female, Age 60	17 5 c c	Case 2	Age 58	17 7 c c 18 1 c c	Right Parotid, Left Parotid
Normal Female, Age 70	17 0 c c	Case 1	Age 72	16 4 c c	Left Parotid

In obstructive sialodochitis, associated with ill-fitting dentures, the volume of pure parotid saliva secreted in c c per hr does not appear to vary from the normal (see Table I), and this probably explains the normal architectural pattern of the terminal ducts seen roentgenographically Possibly, too, it accounts for the fact that no pyogens or inflammatory cells are present Thus, the mechanism which resists retrograde infection of salivary parenchyma by mouth organisms[6] can operate successfully in the face of increased pressure gradients of dilatation and strictures, as long as the normal complement of acinar tissue is available and sufficiently productive to wash the organisms out of the duct

Anatomically, two types of duct obstruction are apparently produced—that which is noted at the duct orifice and obstruction along the bucco-masseteric course of the duct The duct orifice obstruction is caused by trauma to the parotid papilla The bucco-masseteric obstruction appears to be a more advanced stage of the condition resulting from secondary basterial infection and inflammatory reaction along the bucco-masseteric course of Stensen's duct

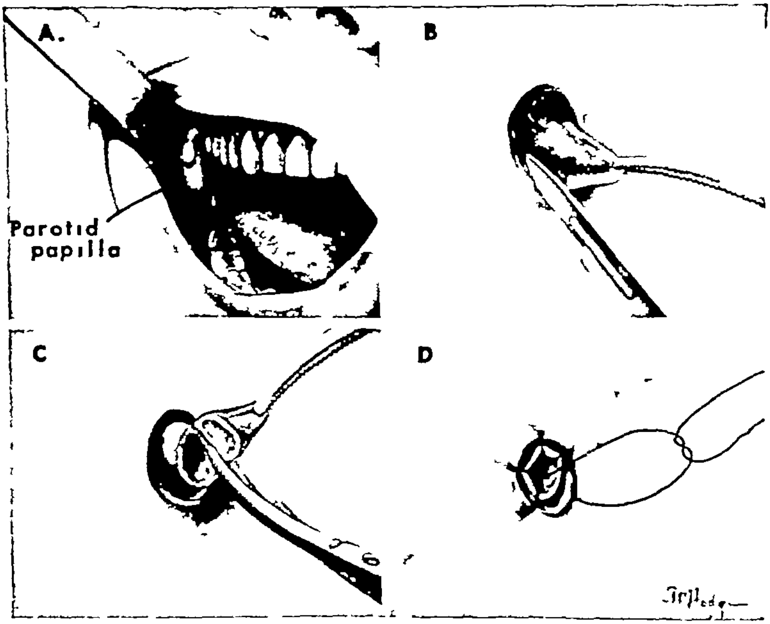

Fig 10 Technique of Dochoplasty A—Parotid papilla opposite second molar tooth. B—The parotid papilla is grasped and the stenotic portion of Stenson's duct is dissected free from the surrounding buccal tissue C—The papilla is amputated D—The open end of the duct is sutured with fine silk to the surrounding mucous membrane

TREATMENT

The treatment is surgical The technique of dochoplasty is

DISCUSSION

Obstructive sialodochitis due to ill-fitting dentures is not a common disorder when compared with salivary gland inflammation caused by calculi or by the non-obstructive sialodochiectasis (sialectasis) group of diseases such as recurrent pyogenic parotitis, Sjogren's syndrome and Mikulicz disease. Only three such cases (2.7 per cent) have been observed in a total of 138 patients referred to the clinic for various inflammatory lesions of the salivary glands since July, 1953. These cases also represent only 0.75 per cent of 352 sialograms made since the above date. Because of the morphologic pattern of main duct "estasia" produced by alternating dilatations and strictures, the condition belongs to the obstructive sialodochiectasis group as classified by various investigators[1,4,7], however, obstructive sialodochitis should not be confused with non-obstructive sialectasis. In the former, there is no alteration in the terminal ducts nor diminuation in the volume of saliva secreted.[8] In the latter, however, we note dilatation of many of the terminal ducts, and a definite diminution in the quantity of saliva secreted by the diseased gland.

TABLE I—SECRETION VOLUME STUDIES OF PURE PAROTID SALIVA IN C.C./HR.

	Method of Collection	Via Polyethylene Catheter			
	Stimulation Feeding	Continuous Lemon Slices			
Normal Female, Age 44	21 c.c.	Case 3	Age 46	20.5 c.c. 20.0 c.c.	Left Parotid, Right Parotid
Normal Female, Age 60	17.5 c.c.	Case 2	Age 58	17.7 c.c. 18.1 c.c.	Right Parotid, Left Parotid
Normal Female, Age 70	17.0 c.c.	Case 1	Age 72	16.4 c.c.	Left Parotid

In obstructive sialodochitis, associated with ill-fitting dentures, the volume of pure parotid saliva secreted in c.c. per hr. does not appear to vary from the normal (see Table I), and this probably explains the normal architectural pattern of the terminal ducts seen roentgenographically. Possibly, too, it accounts for the fact that no pyogens or inflammatory cells are present. Thus, the mechanism which resists retrograde infection of salivary parenchyma by mouth organisms[6] can operate successfully in the face of increased pressure gradients

GRANT TO JEWISH HOSPITAL, ST LOUIS

The receipt of a $5,000 grant from the Louis D Beaumont Foundation for the furtherance of research in the field of surgical rehabilitation of hearing at the Jewish Hospital of Saint Louis was announced recently by Dr Ben H Senturia, Director of the Department of Otolaryngology The check was presented to the Hospital by Mr Morton J May, Trustee of the Foundation

The surgical rehabilitation program is a recently expanded one, functioning on both clinical and research levels It includes comprehensive pre- and post-operative hearing testing, an evaluation of the function of the Eustachian tube, and surgical correction of the pathologic changes which involve the ear drum, ossicular chain and middle ear simple enough Under local anesthesia (procaine 1 per cent) injected about the orifice of Stensen's duct, the papilla is grasped and amputated (see Fig 10) This simple procedure exposes the stenotic duct, which is then dissected free from the surrounding tissue for a distance usually of something less than a centimeter until its dilated portion is identified At this point the duct stands out conspicuously because of its marked dilation The open end of the duct is then sutured, with fine silk, to the surrounding mucous membrane in a manner which exposes the duct to free communication with the oral cavity

Antibiotics and chemotherapeutic agents may be used for several days postoperatively Healing is kindly and prompt Rapid regression of parotid swelling occurred in the three patients herein reported, and they have remained asymptomatic to date

SUMMARY

1 Ill-fitting dentures can cause the syndrome of obstructive sialodochitis with intermittent parotid swelling We believe it can be regarded a definite entity

2 The pathogenesis and clinical picture are presented with radiographic and histologic correlation

3 Secretory sialography is useful in making the diagnosis and in differentiating it from non-obstructive sialectasis

The histologic picture is that of stenosis, scar tissue formation, and metaplasia of the duct epithelium, all compatible with traumatization of the parotid papilla

a congenital disease in which the basic difficulty is an inborn error of metabolism transmitted as a sex-linked recessive trait demonstrable clinically only in males, *second*, an acquired form of agammaglobulinemia which occurs in either sex and has its onset at any age, *third* an extension of the neonatal agammaglobulinemia beyond the time at which normal production ordinarily begins In these cases, he finds a generalized absence of lymphoid tissue including tonsils and adenoids, with the lives of the patients a constant succession of bacterial infection, most frequently encountered as chronic lung disease, sinusitis, otitis media, pharyngitis and occasionally either a sprue-like syndrome or recurrent bacterial meningitis

It occurred to us that in studying clinical patients, instead of studying the agammaglobulinemic, much could be learned from the patient with hypogammaglobulinemia Electrophoretic patterns were performed on 126 patients with chronic recurrent infections, which would respond temporarily to antibiotics but would recur when they were stopped In an effort to keep the results practical, the tests were made at easily available commercial laboratories rather than by our own highly specialized technicians, for while this might diminish the accuracy slightly, it would provide a tool available to most physicians The results fell into three main categories the first, consisted of 58 patients who had normal Gammaglobulin levels, the second group of 24 patients, chiefly Navajo Indians, in which there was a marked increase in Gammaglobulin, and the third group of 44 people in which there was a deficiency This is a study of these cases which had at least a 40 to 50 per cent deficiency

Twenty-one patients of ours fall into the deficiency classification Five have been reported previously[3] Of the 16 subsequently found, 13 suffered with chronic pharyngitis, having large, raised plaques of lymphoid tissue in the pharynx and nasopharynx, and slight to moderate glandular adenopathy of the cervical chain Of the remaining, two patients had chronic draining ears, and the last, a sinus infection

One of the ear problems had been subjected to a mastoidec-

EFFECT OF HORMONES ON HYPOGAMMAGLOBULINEMIA *†‡

DAVID A DOLOWITZ, M D ,
THOMAS F DOUGHERTY, Ph D , (By Invitation),
and
ROBERT D HIGGINBOTHAM, Ph D , (By Invitation),
Salt Lake City, Utah

A deficiency of gammaglobulin is found in certain cases of chronic upper respiratory infection Often, this type of problem case will improve while being given the appropriate antibiotic, only to regress into the chronic ailment when such medication is stopped It has been known that Gammaglobulin, given parenterally, will give protection for periods of three to four weeks This is a report of studies to see whether thyroid and steroid hormones can bring the Gammaglobulin back to more normal levels with relief of the infection

Recently, Good[1] studied "Experiments of Nature" to see whether an understanding of the mechanisms of antibody and Gammaglobulin production can be found by studying the characteristics and adjustment of tissues in patients suffering from extreme disturbances of the immunological mechanism

His work centered chiefly on agammaglobulinemia which he feels has four cardinal features *1* Increased susceptibility to infection, *2* Absence of Gammaglobulin from the blood and tissues, *3* Absence of circulating antibody from the blood and tissues, *4* Failure of antibody production in response to antigenic stimulation

He recognizes three forms of this disease *First*, Bruton's,[2]

the pituitary, might also increase Gammaglobulin production It was realized that profound changes in resistance are not necessarily associated with either hypo- or hyper-thyroidism, but dysfunction of the thyroid has been related to resistance through the above mentioned mechanisms Since the thyroxine has been reported to increase opsonin production,[6 7] it was felt that an iodine-containing portion of thyroid secretion would be the most desirable to use

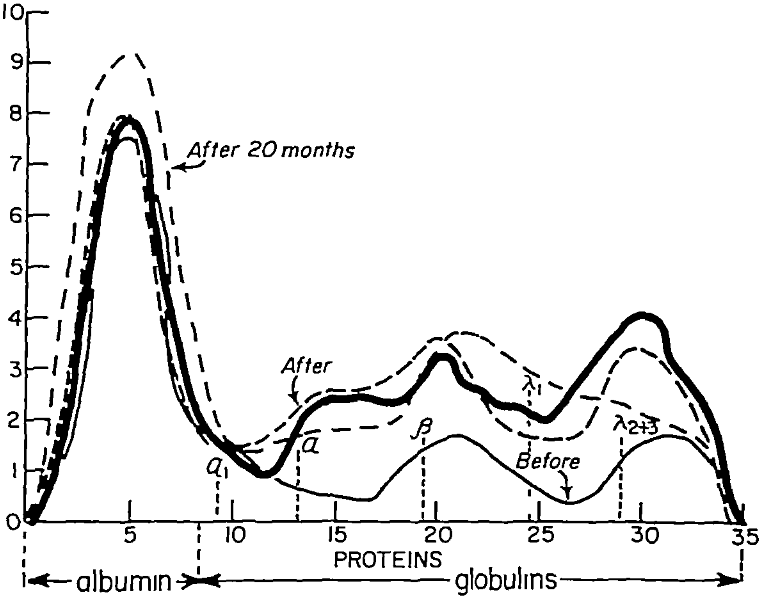

Fig 1

Sodium liothyronine (Cytomel*) was thought to be the most desirable iodine containing thyroid extract for the study Its action[8] is believed to be directly on the peripheral tissues, and immediate results could be expected without awaiting intermediate metabolic conversions It is effective in some cases where other thyroid hormones fail In addition, because of its rapidity of onset of action, symptoms of overdose would be recognizable promptly enough for safe withtomy twice, once in the Service 14 years ago, and a second radical operation three years ago Despite the surgery, the ear continued to drain and granulations kept forming very rapidly, resisting all attempts to remove them One antibiotic after another was used without benefit until the organism (Pseudomonas Aeruginosa) developed resistance An electrophoretic pattern of serum proteins demonstrated the suspected deficiency He was given 10 cc of Gammaglobulin intramuscularly every four weeks, the appropriate dosage for his weight This treatment has continued for a period of nine months The ear has dried during this time, and the granulations are slowly disappearing He is being treated with the appropriate antibiotic in addition to this therapy, but while there were no results on the antibiotic alone, the Gammaglobulin plus the antibiotic has so far been quite successful It is interesting to note that electrophoretic studies still show the same deficiency present as existed when the therapy was started, despite the clinical improvement

---

*The Cytomel was generously supplied by Mr John Simon of Smith Kline & French Laboratories Philadelphia Pa

As reported a year ago,[3] it was found that when the antibodies were not being adequately secreted, steroids might allow the cells, lymphocytes and/or plasma cells to "secrete" retained Gammaglobulin

Of the five cases reported, one has not returned Three are well clinically after receiving Meticortelone, 25 mgms intramuscularly every three weeks for several months They now return only periodically for check-up The fifth is still under treatment, and still reports for 25 mgms of prednisolone intramuscularly every month As long as he has this he is free of sore throat, but on the three occasions when he has omitted the treatment, the pharyngitis returned, though less severely The electrophoretic pattern still shows a definite Gammaglobulin loss, but it is slowly returning to normal, and the lymphoid hyperplasia is clearing (see Fig 1)

It occurred to us that since thyroid produced an increased lymphocytosis[4] followed by a later parallel mononuclear production, and increased protein metabolism, it might increase the circulating Gammaglobulin It also was possible that small doses of thyroid, which would enhance steroid production via

Since that time he has been given one dose of ten micrograms of Cytomel for four days, every three weeks As long as this is taken, his ear remains dry With colds, he is given an appropriate prophylactic antibiotic Although it is realized that this will not affect the Proteus, it is believed this will keep down the coccal forms which may allow the Proteus to start spreading With this combination his infection has been kept under control for the past eight months

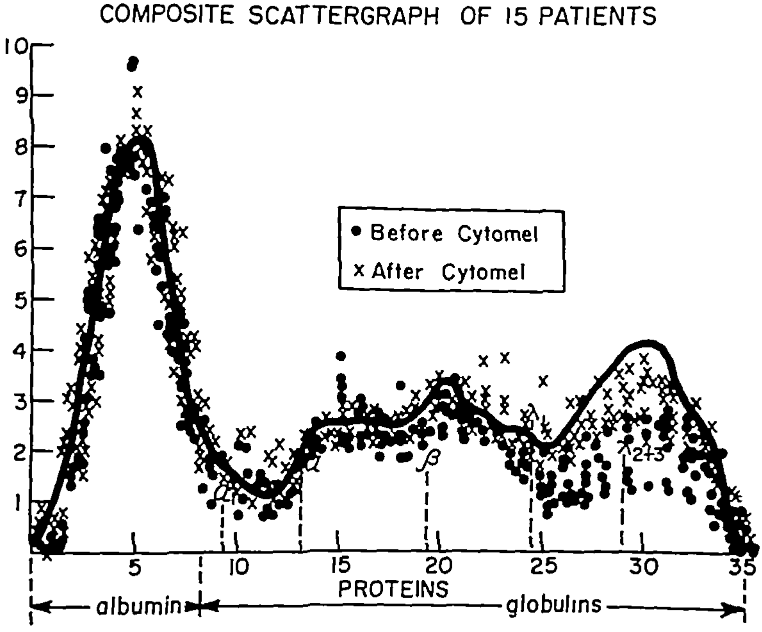

Fig 3

Fifteen patients with chronic pharyngitis and hypogammaglobulinemia followed the same pattern Thirteen of these were adults and two children, one a child of one of the adults The adults were maintained on ten micrograms of Cytomel for four days This raised their levels of Gammaglobulin almost to normal (see Fig 3) This increased level persisted for about three weeks and was coincident with the disappearance of their clinical symptoms During this period, the drawal It is absorbed readily from the gastro-intestinal tract, and rapidly cleared from the blood stream, being more loosely bound to the plasma proteins than thyroxin, hence, the oral administration would be the most satisfactory as well as the most effective

The first patient in whom the use of this drug was attempted was a five-year-old child with chronic Proteus middle ear infection Here, one antibiotic after another had been used until they had lost their capacity to destroy the infection After each subsequent cold, there was a return of the running ear, until no further medication was available Electrophoresis at this time confirmed a low serum Gammaglobulin level (see Fig 2) He was given five micrograms of Cytomel a day for four days without any effect, however, when the dosage was raised to ten micrograms of the sodium liothyronine a day for four days, the Gammaglobulin was raised to almost normal levels, and the ear improved tremendously This clinical effect lasted for about three weeks

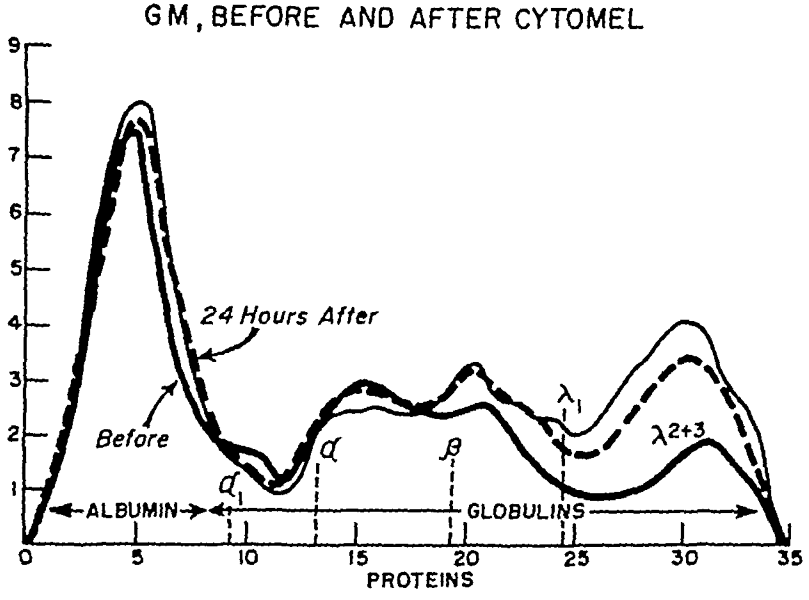

Fig 2

resistance with dysthyroidism but no effect with hypo- or hyperthyroidism

Protein bound iodine studies showed most of the levels within normal limits, usually close to the higher level of normal Very little rise was found with the small doses of Cytomel given

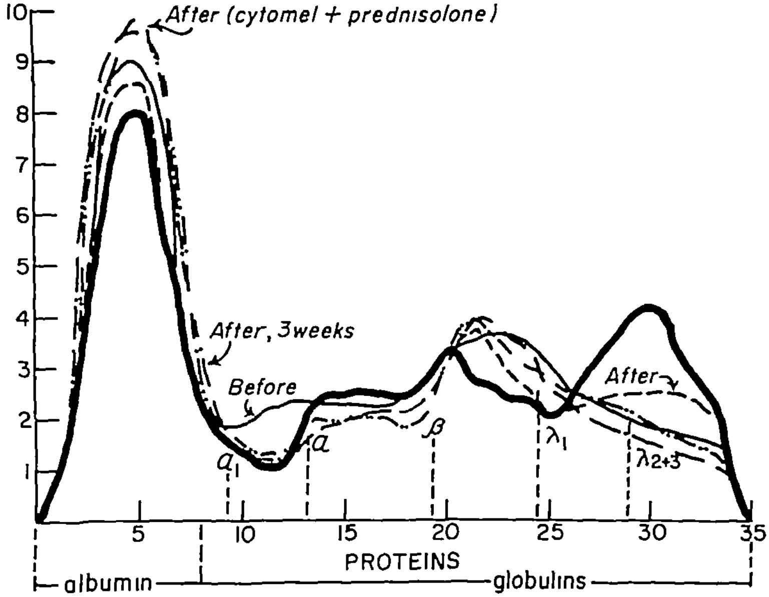

Fig 5

Since it is felt that the effect of liothyronine was mediated via the adrenal cortical hormones, an attempt was made to see whether this action could be enhanced by giving the patient 10 to 25 micrograms of Cytomel and five milligrams of prednisolone a day for four days To our dismay, the combination produced a lesser increase in the Gammaglobulin than did either drug alone, confirming the findings of Summers[9] and Hollender[10] that corticosteroids do not supplement thyroid therapy symptomatically It is felt that Cytomel may act through pituitary stimulation of the adrenals When adrenal hormone is also supplied, the stimulus is weakened and hence general lassitude, fatigue and throat soreness disappeared After several courses of the liothyronine the lymphoid nodules began to diminish in size as well as redness The electrophoretic patterns taken at the end of a three-week period usually demonstrated that the levels had diminished to the low present at the onset of treatment The children responded similarly to doses of five micrograms of Cytomel a day for four days It is interesting to note that of these two patients, a mother and son, had demonstrated very similar types of curve (see Fig 4)

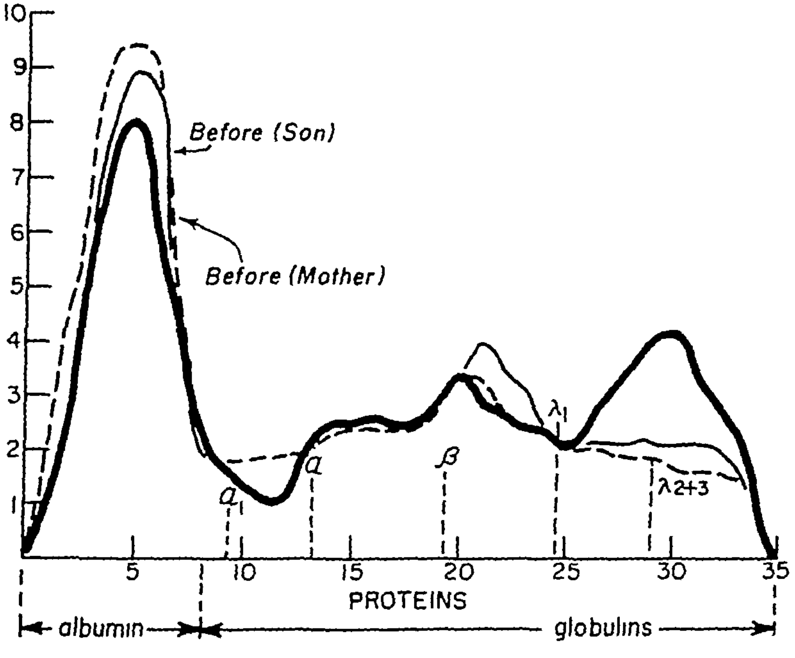

Fig 4

In three cases where 25 micrograms of Cytomel were given, the rise of the Gammaglobulin was less than with ten micrograms (see Fig 5) It is interesting to speculate why the response is limited to a narrow band, since the Gammaglobulin rise is lessened on either high or low doses This seems to agree with the clinical finding of a correlation of lessened

CAROTID BODY TUMORS

Report of One Case *†

FERNAND MONTREUIL, M D ,

Montreal, Canada

Carotid tumors are not frequent, and few surgeons have had the opportunity of operating on any large number of cases Small series of cases have been reported by several authors, many with an excellent review of the literature Morfit and co-authors, in a recent paper, emphasized two points which are brought out in the present case report First, these tumors are not as benign as previously claimed, and are found to invade locally and even disseminate, providing the cases are followed long enough Second, it is often possible to remove carotid body tumors without having to sacrifice the large vessels

This "potato tumor," as it is sometimes called, arises from the carotid body, a small ovoid mass found resting in the loose connective areolar tissue situated on the medial aspect of the carotid bifurcation Luschka was the first to describe this small organ, composed of an agglomeration of rounded lobules separated one from the other by fibrous septa containing blood vessels Each of these lobules is nourished by a small arteriole branching from a principal artery derived directly from the common carotid The cells are closely related to the vessels and are grouped into small nests or strands The shape of the cell is variable, a spherical nucleus has a fine chromatic network and the cytoplasm is granular, acidophilic and non-chromaffin Histologically similar non-chromaffin bodies or tissues are present along the aorta, the jugular bulb, the ganglion nodosum, the ciliary body (in the monkey), and finally in the coccygeal body The carotid is probably the best known of these bodies, forming what is now referred to

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication March 19 1958

the response is poorer Another possibility is that Cytomel's action is a direct one on the protein fraction transporting the oxidation enzymes

In summation, further studies confirm our impression of a year ago that there are two types of hypogammaglobulinemia the *most* common type is the one reported by Good, in which there is little lymphoid tissue, the second is a numerically much smaller type in which hypertrophied lymphoid tissue is present, but where antibodies are not adequately secreted In this latter group, administration of liothyronine or cortical steroid hormones stimulates secretion of the lymphoid tissue The antibody liberated contains sufficient quantity of Gammaglobulin to show an effect on the electrophoretic pattern This has usually been accompanied by clinical improvement in our small number of cases This series is not large enough to do more than indicate the necessity of further study to help explain the inter-relationship *of hormones and resistance* to infection, however, for the clinician, it offers a valuable therapeutic tool in the aid of a small group of patients

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication March 19 1958

as the "chemoreceptor system" The physiology of this organ is not as yet well understood Its pathology appears to be limited to tumor formation only

The presence of a mass or lump in the neck may, for a long time be the one and only symptom of a carotid body tumor The mass has usually been present and slowly growing for a period of five to six years before the patient consults In a series of cases reported by Hendrick, the average duration of symptoms was eight years before patients sought relief The tumor is a slowly growing one It is deeply situated in the lateral portion of the neck, under the sterno-mastoid muscle, at the level of the carotid bifurcation The tumor is round or ovoid, firm to palpation and is not fixed to the skin It is neither painful nor tender It has been reported as being depressible and as transmitting pulsations It is movable in a lateral but not in a vertical direction, and does not move on swallowing As it increases in size the tumor may grow medially and project into the pharynx, or grow up and extend to the base of the skull Bulging of the pharyngeal wall was found to be a presenting symptom in a good number of cases, and in one reported by Hendrick, was such as to interfere with swallowing The tumor is usually unilateral, although bilateral cases have been reported Symptoms due to compression of surrounding structures are next in frequency Pressure on the recurrent laryngeal nerve, the vagus, the cervical sympathetic, the hypoglossal, the phrenic and the cervical plexus, causing corresponding paresis or paralysis, have all been reported In the present case the VIIth, VIIIth, IXth, Xth, and XIth cranial nerves were all involved It is unique in this respect, as no other case was found in the available literature in which so many nerves were affected

Grossly, a carotid tumor is a firm, reddish-brown, lobulated mass of variable size surrounded by a capsule

Histologically, Masson states that the tumor very closely reproduces the architecture of a normal carotid body The glandular lobules separated by fibrous septa containing vessels are increased, not only in number but also in size This explains the very marked vascularity of these tumors and the profuse hemorrhage with which their removal is always accompanied It would appear as a hyperplasia, and for this reason it has once been suggested that these tumors be called "goiters of the carotid body" (Dietrich and Siegmund) (see Figs 1, 2, 3)

The tumor is encapsulated, with the secondary nodules in turn, also encapsulated Long strands of cells are separated from one another by conjunctival septa, often presenting hyaline degeneration The cellular nests, or strands, are themselves divided into narrow trabeculae by a very fine conjunctivo-vascular system The cells are polygonal, with a fine granular cytoplasm and a comparatively small nucleus, which is hyper-chromatic One or two acidophilic nucleoli are often seen Two histological patterns are described, the alveolar and the peritheliomatous, in which the cellular units are smaller and more irregular than in the alveolar pattern

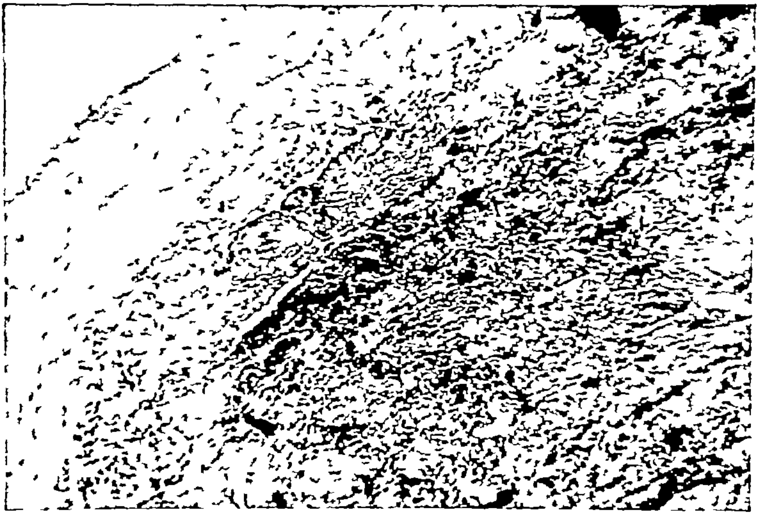

Fig 1 Microphotograph of carotid paraganglioma showing a well defined capsule X48

Masson considers most of these tumors benign but at the same time describes a malignant form, which he considers of low grade malignancy but capable of local and regional invasion Harrington and co-authors, in their review of 20 cases, reported evidence of malignancy in ten, as shown by active mitotic figures, cellular variations, giant cells and by invasion of the capsule Their criterion of malignancy is based on histological findings only, and not substantiated by follow-up or post-mortem examination On the other hand, Pettet and co-authors, after reviewing 314 cases found in the literature and 47 cases treated at Mayo, came to the conclusion that these tumors were very rarely malignant Goormaghtigh and Pattyn report two cases, one of which was malignant with metastases in the cervical, mediastinal and retro-peritoneal nodes, the lungs and lumbar vertebrae, proven at autopsy It can be concluded that there is no uniformity of opinion in regard to the malignancy of these tumors It is hoped that with time and a proper follow-up of operated and non-operated cases, a better understanding of carotid body tumors will result

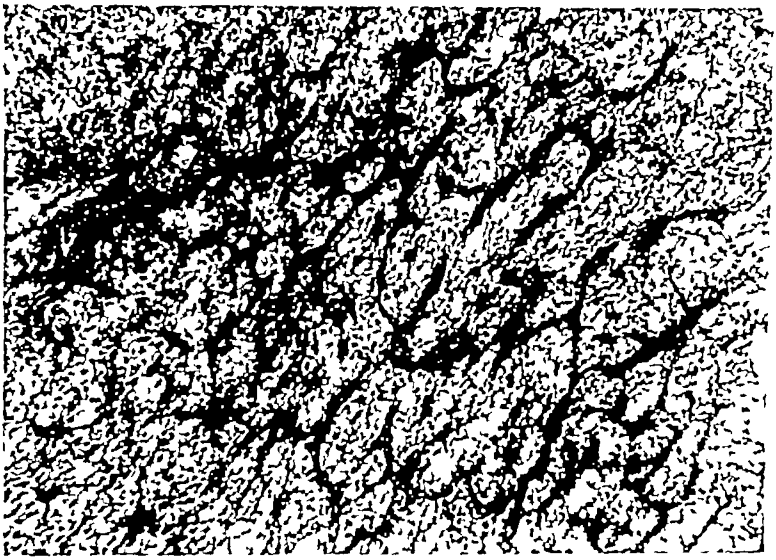

Fig 2 Cellular strand or nests are seen to be separated from one another by fibrous septa X60

The diagnosis of a carotid body tumor is not an easy one to make and few pre-operative diagnoses have been made The history of a slowly growing, non-tender mass in the lateral portion of the neck, at the level of the carotid bifurcation, movable in a lateral and not in a vertical direction, should make one suspect this type of tumor Aspiration biopsy has been recommended, but is not without danger, and is very often inconclusive

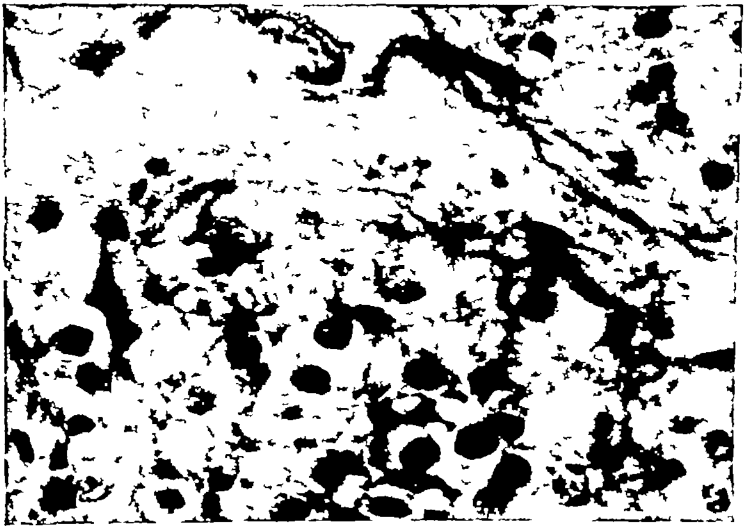

Fig 3 Higher magnification showing cellular details the Cytoplasm is granular acidophilic and non-chromaffin The nucleus is spherical and presents a fine chromatic network ×418

Carotid body tumors do not respond to radiation therapy and the treatment remains a surgical one Until recent years the indication and advisability of surgical removal was often questioned because of the high mortality and morbidity associated with the ablation of these tumors, particularly when excision of the carotid arteries became necessary It has now been shown that a great number of these tumors can be removed without injury to the vessels, if a careful dissection is done along the serosal plane of the arteries concerned, furthermore, when it becomes necessary to include the carotids along with the specimen, anastomosis or arterial grafts have been found quite successful in reducing this high mortality rate. This question is well discussed by Conley and others.

A 53-year-old male was referred by the Rehabilitation Center in April, 1954, for a laryngeal examination prior to vocal training, which had been recommended because of a hoarseness of some years standing. The history of this patient's complaints is long and complicated, but most interesting, and I shall briefly summarize it chronologically as follows:

In 1950 the patient first complained of hoarseness and saw a physician, who told him that he had an enlarged right tonsil, for which he recommended some ten treatments of deep radiotherapy. No change in either the hoarseness or the size of the right tonsil resulted.

In 1951 the tonsils were removed, and it was then realized that the right tonsil was not enlarged but was being pushed forward and medially by some extrinsic mass. Histological examination of the tonsil at this time did not reveal any pathology.

Shortly following tonsillectomy the patient noted a small swelling behind the angle of the jaw. According to the patient, this mass has varied from day to day until the present time.

Four or five months later the patient's voice became lower in pitch and less powerful. He also began having difficulty swallowing and reported that he would have frequent choking spells.

In 1952 weakness of the right shoulder and right arm were noted, and wasting of the sterno-mastoid and shoulder muscles quickly set in. At the time of consultation the patient stated that hearing in the right ear had been decreasing for the last six months or so.

X-rays of the chest in 1951 were reported as negative.

Examination (April 21, 1954)

The patient is a well developed and well nourished white male of about stated age He talks in a somewhat monotonous and muffled voice which definitely lacks volume Wasting of the sterno-mastoid and shoulder muscles on the right is quite apparent

Ears—Canals are normal Healed perforation in both drums

Nose—The septum is straight Mucous membrane is normal in appearance and no secretions are to be seen

Nasopharynx—There is a smooth bulging of the right lateral nasopharyngeal wall with loss of all landmarks The mucous membrane covering this mass is normal in appearance

Oropharynx—Dentures The tongue is normal in appearance and mobility The tonsils have been removed and the right tonsillar fossa is seen to bulge forward and medially This bulging or mass is continuous with that noted in the nasopharynx The soft palate on the right side and the uvula are deviated to the left There is no gag reflex

Larynx—The right cord is paralyzed in abduction, otherwise the larynx is normal There is considerable pooling of secretions in the right pyriform sinus

Neck—A marked atrophy of the sterno-mastoid and trapezius muscles on the right side is noted A firm mass can be palpated behind and below the angle of the jaw This mass, best palpated by bidigital palpation, is continuous with the mass noted in the oro and nasopharynx It is firm, non-tender and gives the impression of very slight mobilization in a lateral direction

A tentative diagnosis of tumor of the neck, probably mixed tumor, with paralysis by pressure of VIIIth, IXth, Xth, and XIth cranial nerves is made The patient is requested to come to hospital for further investigation and removal of this mass

The patient was admitted to N D H (4666) on May 2, 1954, and following examinations obtained

Audiometric—Total loss of hearing on the right.

grafts have been found quite successful in reducing this high mortality rate This question is well discussed by Conley and others

A 53-year-old male was referred by the Rehabilitation Center in April, 1954, for a laryngeal examination prior to vocal training, which had been recommended because of a hoarseness of some years standing The history of this patient's complaints is long and complicated, but most interesting, and I shall briefly summarize it chronologically as follows

In 1950 the patient first complained of hoarseness and saw a physician, who told him that he had an enlarged right tonsil, for which he recommended some ten treatments of deep radiotherapy No change in either the hoarseness or the size of the right tonsil resulted

In 1951 the tonsils were removed, and it was then realized that the right tonsil was not enlarged but was being pushed forward and medially by some extrinsic mass Histological examination of the tonsil at this time did not reveal any pathology

Shortly following tonsillectomy the patient noted a small swelling behind the angle of the jaw According to the patient, this mass has varied from day to day until the present time

Four or five months later the patient's voice became lower in pitch and less powerful He also began having difficulty swallowing and reported that he would have frequent choking spells

In 1952 weakness of the right shoulder and right arm were noted, and wasting of the sterno-mastoid and shoulder muscles quickly set in At the time of consultation the patient stated that hearing in the right ear had been decreasing for the last six months or so

X-rays of the chest in 1951 were reported as negative

Examination (April 21, 1954)

The patient is a well developed and well nourished white was obvious that we were dealing, not with a mixed tumor but probably with a glomus tumor, because of its locality and its very marked vascularization The lower limit of the mass was at the level of the carotid bifurcation, and superiorly it extended to the base of the skull, where a round smooth erosion measuring about 1½ cm in diameter could be felt with the examining finger The tumor appeared to have originated

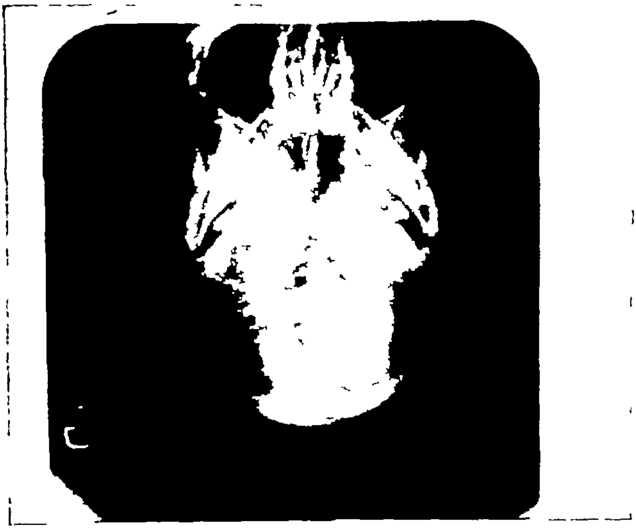

Fig 4 X-ray of the base of the skull shows a smooth erosion of the right petrous pyramid at the level of the jugular foramen. The internal auditory meatus has been completely destroyed

posteriorly to the internal carotid artery, around which it had extended and surrounded it laterally and partially covered its anterior walls It was very closely connected to the artery by numerous fibro-vascular bands, which took on pedicle-like proportions in its postero-inferior, inferior and antero-superior aspects

By a rather laborious blunt and sharp dissection, always attended by considerable oozing, the mass was finally liberated, except for its antero-superior attachments Prolonged efforts to free the mass at the base of the skull by finger dissection being unsuccessful, a tonsil snare was carefully

Vestibular—Complete loss of function of the right

Blood—RBC, 4,775,000, WBC, 8,250, Hmg, 97 Differential within normal limits

Urea and blood glucose normal

Bleeding and clotting times normal

Urinalysis normal

Neurological Consultation (Dr L Rinfret) Paralysis due to pressure by cervical tumor of VIIIth, IXth, Xth and XIth cranial nerves Some fibrillations of the right side of the face are noted, right facial weakness is suggested

Radiological Examination, May 12 Lungs are normal (C37339) Cranium and cervical region "Presence of a soft tissue mass bulging into the right side of the nasopharynx, which extends upwards through the base of the skull, into which it has produced a large defect posterior to the petrous pyramid at the level of the jugular foramen, furthermore, there is erosion of the posterior border of the pyramid with complete destruction of the internal auditory meatus This destruction does not involve the cochlea but has markedly thinned out the petrous bone This erosion extends posteriorly to the occipital foramen We are dealing with a large erosion with well defined contours It has the appearance of a destruction by pressure, most probably by a benign tumor The jugular bulb is most probably involved by the tumor We can definitely say that the VIIIth cranial nerve is involved, as are the nerves above or posterior to the VIIIth This is a nasopharyngeal lesion which has invaded the posterior fossa by destruction of the occipital bone and the petrous pyramid There are no signs of increased intra-cranial pressure or of pathological calcifications," Dr Léger (see Fig 4)

Surgery was performed under general penthothal anesthesia on May 11, 1954 Through a large horizontal incision the mass was exposed after mobilization of the flaps and the sterno-mastoid muscle, which was reflected backward Overlying the tumor a small lymph node was removed and found to be normal on frozen section After exposing the mass it tip and probably also involving the floor of the middle fossa, there was no evidence of pharyngeal or naso-pharyngeal mass Dr Rinfret, the neuro-surgeon, who had seen this patient prior to operation three years before, was called in on consultation Arteriography of the right carotid artery was unsuccessful, but the left carotid artery was injected with

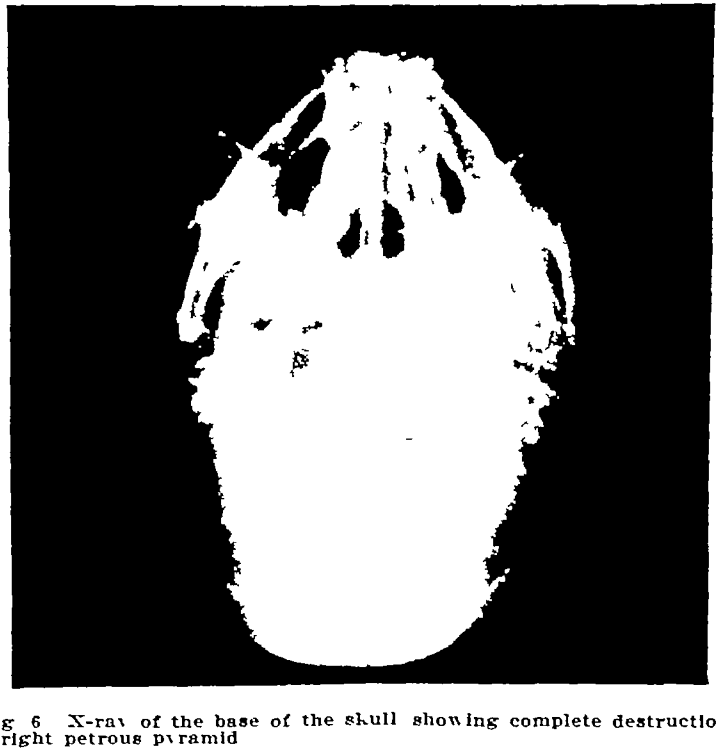

Fig 6 X-ray of the base of the skull showing complete destruction of the right petrous pyramid

Hypaque and showed nothing abnormal There was reflux of the dye into the right carotid and it was concluded that this one was probably occluded at the level of the petrous bone (see Figs 6, 7)

On October 18th, a ventriculography was unrevealing, and it was thought that the destructive process involving the petrous bone did not extend intra-cranially A right sub-inserted as high as possible and the tumor was snared off Examination of the specimen revealed an intact capsule During the operation, which the patient withstood without ill effects, 1000 cc of glucose and 1000 cc of blood were given The post-operative course was essentially uneventful and the patient was discharged from the hospital one week after surgery Pathology reported a softish, flattened 2 5x5x4 cm well encapsulated mass, which histological section revealed to be a carotid body tumor (see Fig 5)

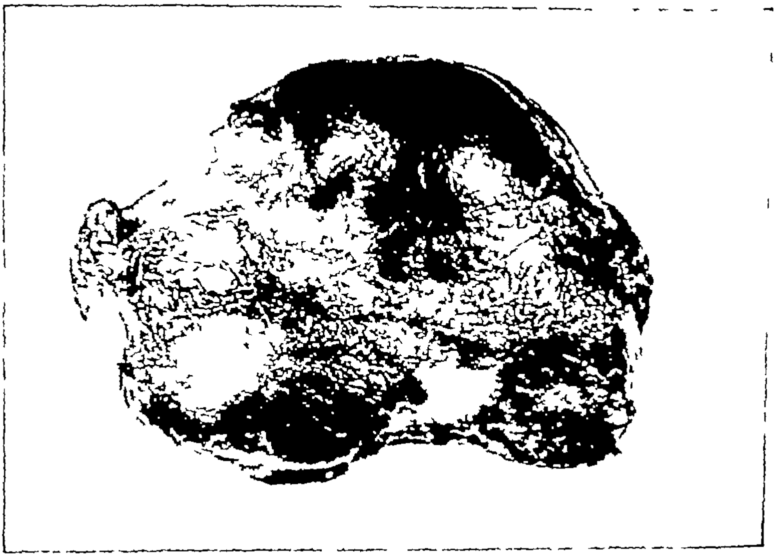

Fig 5 The surgical specimen measured 2 5x5x4 cm and was surrounded by an intact capsule

Three months after operation the patient reported some improvement in the movements of his arm, but all other paralyses remained the same There was nothing to note on periodic check-ups until October, 1957, at which time he reported that a right facial paralysis had gradually set in during a period of one month

The patient was admitted to the hospital for further investigation Externally, there was no evidence of recurrent tumor mass X-rays of the base of the skull showed complete destruction of the right petrous pyramid, extending to its

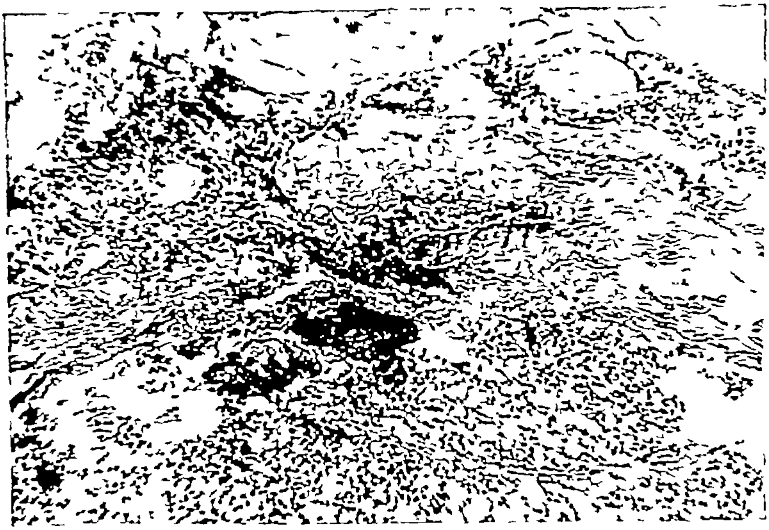

Fig 8 Microphotograph of the intra-cranial tumor shows paraganglionic cells invading the capsule X48

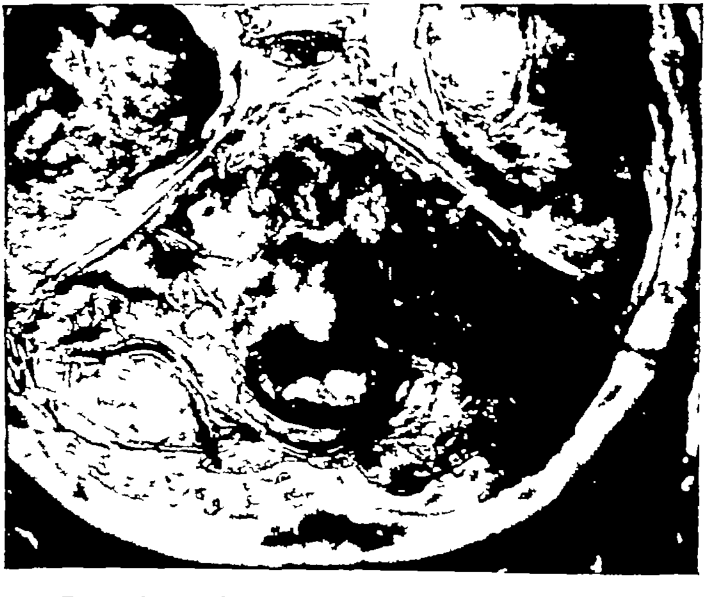

Fig 9 Base of the skull viewed intra-cranially The right petrous pyramid has been completely replaced by tumor

occipital craniotomy was then performed by Dr Rinfret After easy retraction of the right cerebellum a very hemorrhagic mass was exposed and as much of it as possible was removed This tumor proved to be carotid body tumor and showed the same histological pattern as the cervical tumor excised three years before except that in the present specimen

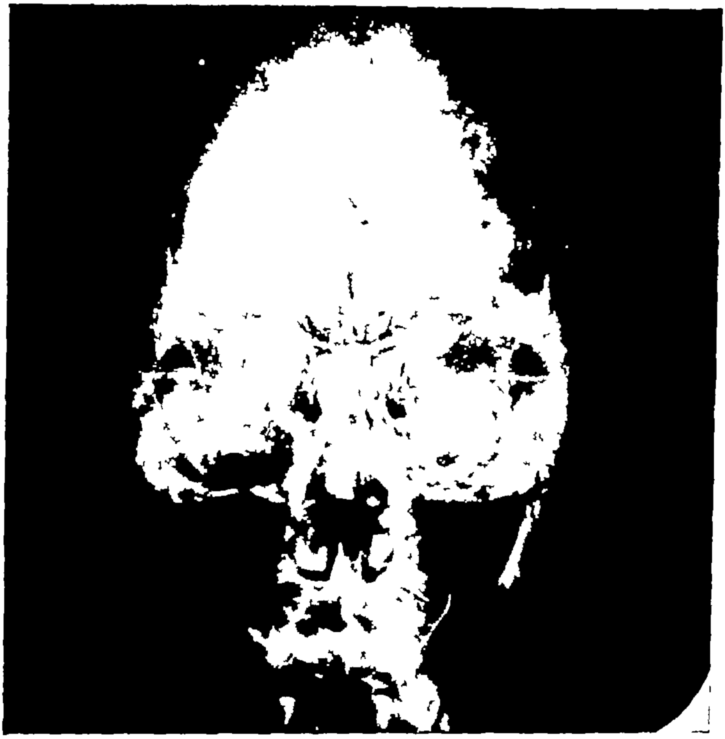

Fig 7 P A view showing destruction of the petrous bone

there was definite capsular invasion (see Fig 8) The patient never fully regained consciousness following surgery and died seven days later Post-mortem examination was most revealing The immediate cause of death was due to an infarct of the left posterior myocardium Examination of the base of the skull and the brain showed extensive invasion of the petrous bone and the right cerebellum The diameter of the petrous bone was enlarged throughout, and

The loss of function of the cranial nerves was slow and gradual, as shown by the complete loss of inner ear function without the patient having complained of subjective vestibular symptoms at any time The cranial nerves were at first probably involved through compression and not infiltration

Although somewhat tedious, the cervical mass was removed with an intact capsule without injury to the carotid arteries

Three years later extensive tumor formation was found to have destroyed all the petrous bone and invaded the right cerebellum with a minimum of symptoms

Both arteriography and ventriculography proved to be most misleading in this case

The tumor was locally malignant and invasive but did not metastasize Its growth was slow and destructive and probably extended over a period of more than seven years

It is difficult to believe that the intra-petrosal and intracranial tumors were an extension of the cervical tumor, as this one had been removed with a complete and intact capsule Multiple paragangliomas have been reported, and it is not unlikely that in the present case two independent tumors, one arising from the carotid body and one intra-cranial tumor taking origin from intra-petrosal non-chromaffin bodies developed

Photographs were taken by the Cancer Institute, Notre-Dame Hospital, Dr L C Simard, Director

grossly appeared to have been completely replaced by tumor The petrous bone is being processed for serial sections It was impossible to free the right cerebellum because of its invasion by tumor measuring 5x2 5 cm The right cerebellar tonsil was deformed and the left one herniated The bulbar region was normal Dissection of the right carotid artery, which has been thought to be thrombosed, revealed it to be patent throughout (see Figs 9, 10)

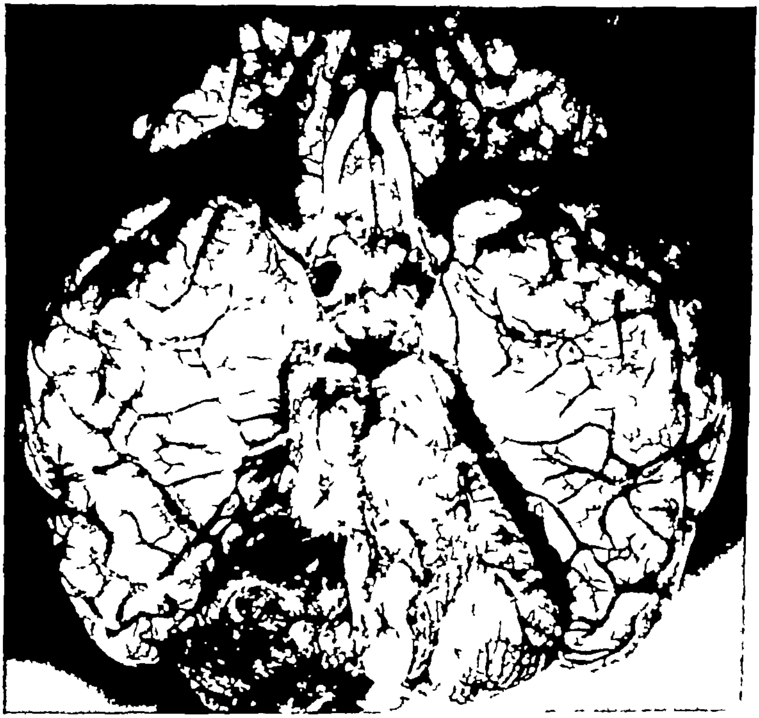

Fig 10 The brain viewed from below A large tumor mass has invaded the right cerebellum

Many points are of interest in this unusual case Four years had elapsed from the time the patient first complained of hoarseness to the time the cervical mass was removed

During this period four cranial nerves became involved as the tumor grew up and caused pressure and erosion at the base of the skull

OFFICE CLOSURE OF TYMPANIC PERFORATIONS A NEW APPROACH *

ARTHUR L JUERS, M D ,

Louisville, Ky

There has been considerable increase in interest concerning closure of central tympanic perforations in the past several years The advantages of closing a perforation are as follows

1 Improvement in hearing is usually obtained The degree of improvement to be anticipated can be estimated by comparing the initial audiometric test level with that obtained by placing a paper patch over the perforation In some instances the hearing level obtained by closure exceeds that obtained by patch application

2 The patient can tolerate getting water in the ear—permitting swimming, showers, etc

3 Recurrent otorrhea is unlikely to occur during respiratory infections

Closure treatment should be attempted in all dry central perforations in which a complete marginal rim exists The ear should be dry for several weeks before closure is attempted There should be no evidence of chronic middle ear or attic disease such as granulations, cholesteatoma debris or squamous epithelium invasion on the promontory The Eustachian tube should be inflatable

Older methods of perforation closure consisted of repeated marginal chemical cautery and the application of some type of patch In 1949 Dunlap and Schuknecht[1] reported their results in treating central perforations by means of repeated cautery and the daily instillation of a few drops of saturated solution of urea Of 20 perforations so treated, 11 had been closed with an average of 18 treatments each Six were still

was decided to rely largely upon marginal mechanical trauma to maintain an active border The inflammatory reaction is created by having the patient instill four drops of a urea boric acid solution in the ear canal twice daily Urea solution was first used for this purpose by Dunlap and Schuknecht[1] Linn[3] used Euthymol as an irritant solution

The addition of the use of loupe magnification in carrying out marginal treatment enabled me for the first time to appreciate what was taking place at the edge of the perforation Loupe magnification is absolutely essential Before any treatment is initiated, the margin of the perforation usually presents a beaded or rounded edge Whether the stratified squamous epithelium extends beyond the inner edge of the margin cannot be determined on external inspection Visible decrease in the size of the perforation does not occur until there is hyperemia of the tympanic membrane and a pink granular perforation margin The outer edge of the perforation then loses the "beaded" appearance somewhat

I first attempted to produce a traumatized perforation margin by serrating the edge with a myringotomy knife point Occasional activity was produced, but the results were not superior to the use of cautery After considerable trial and error a marginal eversion technique was evolved Special curettes and hooks are used for this purpose At the initial marginal treatment the curette edge is placed just within the perforation edge and brought out with fairly vigorous pressure against the margin The basic objective is to evert the marginal epithelium and leave the substantia propria exposed to start granulations Perforations which heal with rather vascular granulation formation seem to be less inclined to present an atrophic thin drum when healed than do those which have only minimal granulation formation In the healing process, the squamous epithelium sometimes seems to grow faster than the granulation tissue and again grows inward over the edge, thereby impeding further closure progress Granulations then accumulate behind the perforation margin on the tympanic side Everting the epithelium and "rolling" the granulation tissue outward into the plane of the perforation realigns the tissues so that closure again under treatment and three failed to show any evidence of healing In 1953 Derlacki[2] reported a modified version of a method of treatment originally described by Linn[3] He reported approximately 70 to 75 per cent closures The average number of treatments for those in which closure was accomplished was 14 6 Myringoplasty[4] techniques have been evolved in the past few years, because office closure treatment was rather prolonged and, even if continued a year or two, still left a sizeable number of failures

Dunlap and Schuknecht[1] describe the histopathology at the perforation margin as follows

> "The process of drum repair stops when the more hardy, rapidly growing stratified squamous epithelium of the external surface of the drum grows over the perforation edge and meets the pseudostratified columnar or cuboidal mucous membrane of the middle ear Destruction of the perforation margin with acid removes this epithelial barrier and, by tissue destruction incites an inflammatory healing response in the drum margin Fibroblastic proliferation in the middle layer of the granulating margin is responsible for the laying down of interlacing fibers of collagen The epithelium grows over the perforation in four days to a week, and must be repeatedly destroyed When collagen fibers are completely formed they shorten The shrinking of this circular band of interwoven collagen fibers may facilitate closure by purse string action"

Two clinical facts have been known for many years concerning the healing of tympanic perforations The first is that many fresh traumatic perforations will frequently heal rather promptly Second, healing is sometimes accelerated if there is some secondary tympanic infection It, therefore, seemed logical that closure treatment should incorporate these two basic principles, *i e*, maintaining a raw, traumatized perforation margin and, by means other than infection, producing the equivalent of an inflammatory reaction The objection to using repeated chemical cautery, once the healing process is initiated, is that the proliferative margin is partially destroyed each time cautery is applied For this reason it was decided to rely largely upon marginal mechanical trauma to maintain an active border The inflammatory reaction is created by having the patient instill four drops of a urea boric acid solution in the ear canal twice daily Urea solution was first used for this purpose by Dunlap and Schuknecht[1] Linn[3] used Euthymol as an irritant solution

The addition of the use of loupe magnification in carrying out marginal treatment enabled me for the first time to appreciate what was taking place at the edge of the perforation Loupe magnification is absolutely essential Before any treatment is initiated, the margin of the perforation usually presents a beaded or rounded edge Whether the stratified squamous epithelium extends beyond the inner edge of the margin cannot be determined on external inspection Visible decrease in the size of the perforation does not occur until there is hyperemia of the tympanic membrane and a pink granular perforation margin The outer edge of the perforation then loses the "beaded" appearance somewhat

I first attempted to produce a traumatized perforation margin by serrating the edge with a myringotomy knife point Occasional activity was produced, but the results were not superior to the use of cautery After considerable trial and error, a marginal eversion technique was evolved Special curettes and hooks are used for this purpose At the initial marginal treatment the curette edge is placed just within the perforation edge and brought out with fairly vigorous pressure against the margin The basic objective is to evert the marginal epithelium and leave the substantia propria exposed to start granulations Perforations which heal with rather vascular granulation formation seem to be less inclined to present an atrophic thin drum when healed than do those which have only minimal granulation formation In the healing process, the squamous epithelium sometimes seems to grow faster than the granulation tissue and again grows inward over the edge, thereby impeding further closure progress Granulations then accumulate behind the perforation margin on the tympanic side Everting the epithelium and "rolling" the granulation tissue outward into the plane of the perforation realigns the tissues so that closure again under treatment and three failed to show any evidence of healing. In 1953 Derlacki[2] reported a modified version of a method of treatment originally described by Linn.[3] He reported approximately 70 to 75 per cent closures. The average number of treatments for those in which closure was accomplished was 14.6. Myringoplasty[4] techniques have been evolved in the past few years, because office closure treatment was rather prolonged and, even if continued a year or two, still left a sizeable number of failures.

Dunlap and Schuknecht[1] describe the histopathology at the perforation margin as follows:

"The process of drum repair stops when the more hardy, rapidly growing stratified squamous epithelium of the external surface of the drum grows over the perforation edge and meets the pseudostratified columnar or cuboidal mucous membrane of the middle ear. Destruction of the perforation margin with acid removes this epithelial barrier and, by tissue destruction incites an inflammatory healing response in the drum margin. Fibroblastic proliferation in the middle layer of the granulating margin is responsible for the laying down of interlacing fibers of collagen. The epithelium grows over the perforation in four days to a week, and must be repeatedly destroyed. When collagen fibers are completely formed they shorten. The shrinking of this circular band of interwoven collagen fibers may facilitate closure by purse string action."

Two clinical facts have been known for many years concerning the healing of tympanic perforations. The first is that many fresh traumatic perforations will frequently heal rather promptly. Second, healing is sometimes accelerated if there is some secondary tympanic infection. It, therefore, seemed logical that closure treatment should incorporate these two basic principles, *i.e.*, maintaining a raw, traumatized perforation margin and, by means other than infection, producing the equivalent of an inflammatory reaction. The objection to using repeated chemical cautery, once the healing process is initiated, is that the proliferative margin is partially destroyed each time cautery is applied. For this reason it cover the perforation margin and the adjacent outer surface of the tympanic membrane In one instance some of the anesthetic reached the middle ear, and a short period of vertigo followed Complete anesthesia is difficult to obtain near the malleus and near the tympanic ring

2 *Treatment of Perforation Margin.*

On the initial marginal treatment, I have used chemical cautery on only a few In the majority, the marginal eversion technique was used In one instance (Ear No 2) a combination of cautery and marginal curettage was used The combination may be better as an initial treatment than either method by itself Further clinical experience will be necessary on this point

On all follow-up treatments the marginal eversion method was used exclusively as soon as the margin became "active" If the margin has a fine granular appearance and the somewhat gray epithelial layer is not growing inward, only gentle eversion and "freshening" of the granular tissue is carried out with the curette No attempt is made to cut out granulation tissue If the epithelium is growing inward over the edge, the margin again has a more firm, "rolled in" appearance, and the epithelial layer is then everted with the curette and hook Granulation tissue on the inner surface is everted Some bleeding ensues, but this is not removed, as a blood clot may serve as somewhat of a matrix for connective tissue growth across the perforation

When the perforation extends to the edge of the malleus, the edge of the pars tensa seems to wrap partially around the malleus handle and is separated from the malleus by means of the curette and hook This frees the edge of the tympanic membrane and facilitates the start of granulation tissue formation In ear No 8 a large granular mass formed around the end of the malleus after a few treatments, and the progress of healing was very rapid thereafter

3 *Placement of Cottonoid® Patch*

In the Linn treatment, a small piece of cotton was fashioned into a pad and placed against the tympanic membrane It progresses In general, the granulations should be everted rather than cut away There may be occasional exceptions on which comment will be made under the discussion of cases

MARGINAL EVERSION TECHNIQUE

1 *Anesthesia*

Adequate anesthesia of the perforation margin is essential, as the marginal manipulations are too painful to be tolerated without anesthesia Block injection anesthesia such as is used for stapes mobilization was not entirely effective and, furthermore, is not practical as a repeated office procedure After trying various preparations I found Bonain's solution the most effective, but was somewhat hesitant to use this preparation because of its slightly caustic nature, apparently it is well tolerated Perhaps a minimal degree of chemical irritation accelerates the desired inflammatory action Just enough is applied with a small cotton-tipped applicator to

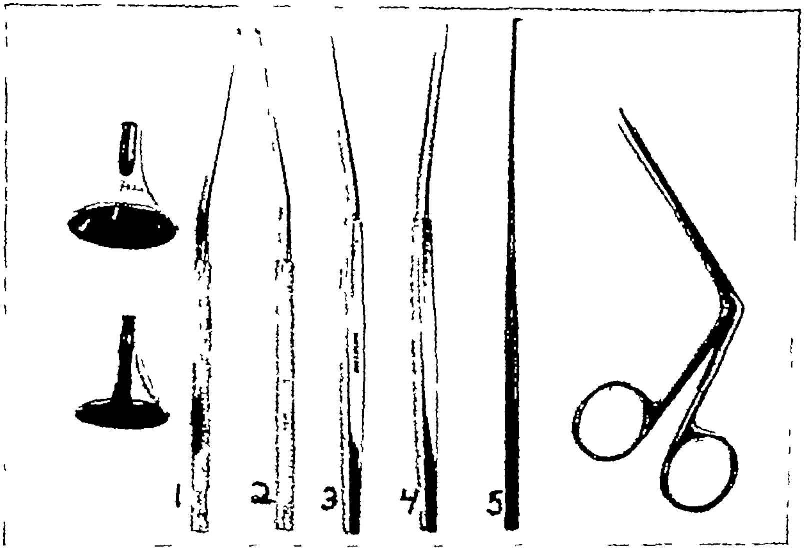

Fig 1 A wide aperture Boucheron ear speculum is preferred Instruments Nos 1 and 2 are special 00 curettes with special angles to permit an unobstructed view while working The ring is sharp on both sides (Storz) Nos 3 and 4 are sharp right angle hooks (V Mueller) No 5 is a Day ear hook A small standard alligator forceps is used to place the cottonoid patch in the ear canal

cover the perforation margin and the adjacent outer surface of the tympanic membrane In one instance some of the anesthetic reached the middle ear, and a short period of vertigo followed Complete anesthesia is difficult to obtain near the malleus and near the tympanic ring

2 Treatment of Perforation Margin.

On the initial marginal treatment, I have used chemical cautery on only a few In the majority, the marginal eversion technique was used In one instance (Ear No 2) a combination of cautery and marginal curettage was used The combination may be better as an initial treatment than either method by itself Further clinical experience will be necessary on this point

On all follow-up treatments the marginal eversion method was used exclusively as soon as the margin became "active" If the margin has a fine granular appearance and the somewhat gray epithelial layer is not growing inward, only gentle eversion and "freshening" of the granular tissue is carried out with the curette No attempt is made to cut out granulation tissue If the epithelium is growing inward over the edge, the margin again has a more firm, "rolled in" appearance, and the epithelial layer is then everted with the curette and hook Granulation tissue on the inner surface is everted Some bleeding ensues, but this is not removed, as a blood clot may serve as somewhat of a matrix for connective tissue growth across the perforation

When the perforation extends to the edge of the malleus, the edge of the pars tensa seems to wrap partially around the malleus handle and is separated from the malleus by means of the curette and hook This frees the edge of the tympanic membrane and facilitates the start of granulation tissue formation In ear No 8 a large granular mass formed around the end of the malleus after a few treatments, and the progress of healing was very rapid thereafter

3 Placement of Cottonoid® Patch

In the Linn treatment, a small piece of cotton was fashioned into a pad and placed against the tympanic membrane It seemed that the rounded contour of the pad would tend to invert the epithelial edge and impede progress of the granulation activity Consequently I have used a flat compressed cotton preparation known as Cottonoid® The commercial preparation is rather thick and is split in half A piece is cut out to approximate the size of the tympanic membrane It is moistened with the urea-boric acid drops in order to make the patch more flexible, and is then placed against the drum with an alligator forceps With a small blunt Day ear hook it is pressed against the entire membrane, care being taken not to push it through the perforation

4 Irritant Drops

This solution consists of 2 per cent boric acid and 5 per cent urea in physiological saline The patient is instructed to instill 4 or 5 drops twice daily Definite hyperemia is induced Occasionally the patient will complain of a slight feeling of irritation at first The urea is the irritant factor, and the boric acid was added to lessen any tendency toward annoying infection

Mucoid discharge from the middle ear developed in a few instances This was removed from the middle ear by inflation and aspiration Treatment of the perforation was continued in these cases, and the added middle ear reaction may have accelerated the rapidity of closure Should a definite suppurative process develop, then closure treatment should perhaps be temporarily interrupted and the otitis appropriately treated

5 Interval of Treatment

Marginal treatment has, in general, been carried out at two-week intervals Whether this is the optimal interval remains to be determined The number of cases treated has been too small to vary the technique appreciably It is possible that inactive margins should be treated more often The tissues must, of course, be given time to react

DISCUSSION OF CASES

The treatment of 15 consecutive central perforations is summarized in Table I Each circle represents the tympanic membrane, showing the size and location of the perforation at each treatment Several significant observations have been noted

In studying the change in shape of the larger perforations it is evident that the initial closure progress is generally in the central portion of the tympanic membrane A bean shaped perforation assumes an oval appearance The portion of the perforation margin closest to the malleus shows earlier hyperemia and marginal granulation than does the area adjacent to the tympanic ring This is undoubtedly due to the fact that the malleolar vessels become hyperemic more readily than do those in the lower portion of the membrane Healing does not progress until hyperemia is evident

NAME AGE		EAR NO	HEARING BEFORE CLOSURE	 AFTER CLOSURE	
T W 13	R.	1	8	2		L	2	25	5	J A 27		3	45	30	H.S. 33		4	38	15	N.K. 36		5	30	8	C.R. 47		6	33	8	T.J 56		7	33	15	M.S 43		8	20	3	L.R 29		9	10	3	J W 8	R.	10	22	3		L	11	30		J.W 24	R	12	7			L	13	7		E.H. 29		14	17		O.H 54		15	62		
TABLE I

Ears Nos 11, 14 and 15 showed early healing activity in the perforation margin nearest to the malleus, however, the inferior portion nearest the tympanic rim continued to show a firm, beaded non-granular margin At the sixth treatment in each, the inferior margin of the perforation was cauterized with trichloracetic acid and vigorously curetted Ears Nos 14 and 15 are beginning to show granulation activity in the entire marginal circumference following the cautery and curette treatment Ear No 11 is still rather inactive, due to the fact that the patient frequently omits the instillation of the drops On a few occasions the patch appeared quite dry when the patient came in for treatment

The tympanic membrane in ears Nos 12 and 13 (patient J W) showed a thick pale appearance rather than one of hyperemia Even though the perforations were small, healing progress has been virtually nil The epithelium has persistently inverted during the interval between treatments Though abundant granulation tissue has formed, it has been pale in appearance rather than the usual pink The tissues present almost an allergy-like reaction rather than an inflammatory one At the tenth treatment all granulation tissue was removed with a curette and the margin cauterized At the time of this writing, it is too soon to state whether healing progress will ensue It may be necessary to change the nature of the drops in this case Ultimate healing should be possible since the perforations are small

In summarizing the results obtained by this method of treatment, it is noted that 10 of 15 perforations so treated have to date closed with an average of 4 2 treatments each Three of the remaining five cases have shown some initial progress (ears 11, 14 and 15) and then reached a standstill I believe that the reason for this lack of continued progress is due to insufficient mechanical trauma to initiate healing in the inferior margin of the perforation In the future management of such cases it is planned to use marginal cautery and curettage to the inactive portion of the perforation margin on the second or third treatment if granulation formation is not apparent at this time An additional reason for slow progress in ear 11 is that this patient did not use the drops regularly The need for regular use of the drops must be explained and stressed at the beginning of treatment The exact reason for progress failure in ears Nos 13 and 14 remains to be determined Since these perforations are relatively small, it is possible that some variation from the above routine may meet with eventual success

A few patients with central perforations were not able to come in for regular treatment and were treated with only marginal eversion and the application of a dry paper patch without the use of drops One healed promptly, and the other is showing satisfactory progress My impression is that healing in these were more rapid than was noted in the past when cautery and a dry patch were used These cases are not included in the tabulation

SUMMARY

1 A new approach to office closure of central tympanic perforations is presented It embodies the following changes from previously reported methods

a The use of loupe magnification to reveal details of marginal changes during the progress of healing and to permit more precise mechanical technique of marginal traumatizing measures

b The use of marginal trauma, rather than cautery, after healing progress has been initiated

c Everting the marginal granulation tissue and epithelium

d Using a flat "Cottonoid®" patch in order to lessen the liklihood of inverting the marginal epithelium

e The use of Bonain's anesthesia before treatment

2 Ten central perforations have been healed with an average of 4 2 treatments each The other five cases are still under treatment, and three of these are showing progress

PRIMARY CLOSURE OF THE RADICAL MASTOIDECTOMY WOUND, A TECHNIQUE TO ELIMINATE POSTOPERATIVE CARE *

J H THOMAS RAMBO, M D ,†

New York, N Y

It has been said that the history of medicine furnishes no chapter which excels in interest the one devoted to perfecting surgical procedures for the alleviation of suppurations within the temporal bone To the pioneers in the surgery of chronic otorrhea we owe the fact that the radical mastoidectomy, as practiced today, has reduced the mortality in chronic temporal bone surgery to a minimum, however, the problem of getting a dry, healed ear following this surgery has not been solved by the progress in surgical techniques for the removal of pathological processes That the problem continues to exist needs no elaboration, for it is common to all who do mastoid surgery

In a previous paper, entitled "Factors Affecting Healing Following Temporal Bone Surgery,"[1] I pointed out that the temporal bone surgeon, unlike the general surgeon dealing with soft tissue wounds, does not have the crucial advantage of being able to close his surgical wounds primarily Our two greatest handicaps are *1* That our wounds must heal by secondary repair, *2* that the healing processes are supported by a poor blood supply derived from a bony cavity These difficulties result not only in a poor quality of healing, but also in a slow process of healing which often allows complicating factors to develop that further delay or completely arrest the progress of repair I also pointed out that in this course of events the advantage of good temporal bone surgery is often lost because the ear continues to drain

†From the Department of Otolaryngology New York Eye and Ear Infirmary

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication May 26 1958

Although I had long considered the problem, when the article referred to above was written I did not see the possibility of developing a surgical technique for primary closure of a radical mastoid wound which would eliminate the need for postoperative care The problem consists of closing an endaural opening with tissue that overlies an air cavity Free skin grafts placed in the breech would slough due to the lack of blood supply, and the extent of skin available from the external auditory canal, in any combination of pedicle flaps, is inadequate to close an enlarged endaural opening

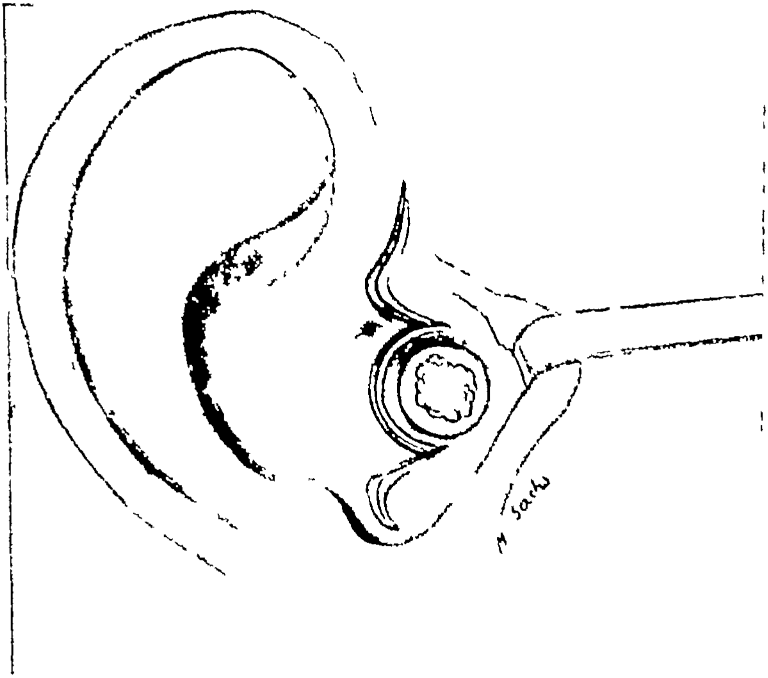

Fig 1 The endaural incisions consist of superior and inferior incisions from the drum outward joined posteriorly by a circumferential incision just superficial to the drum

During the past year-and-a-half my experience with the temporal muscle plastic, in the performance of musculoplasty, has suggested a method for primary closure of the radical mastoidectomy wound As used in musculoplasty,[2,3] the temporal muscle plastic has solved the vital problem inherent in all reconstructive surgery of the middle ear, that of bridging an air-containing middle ear space It has accomplished this by reason of the fact that a pedicle flap not only makes available any necessary amount of tissue to cover a large air space, but also carries with it a self-sustaining blood supply, it does not need to obtain blood supply from adjacent structures The same principle can be used to close an endaural opening

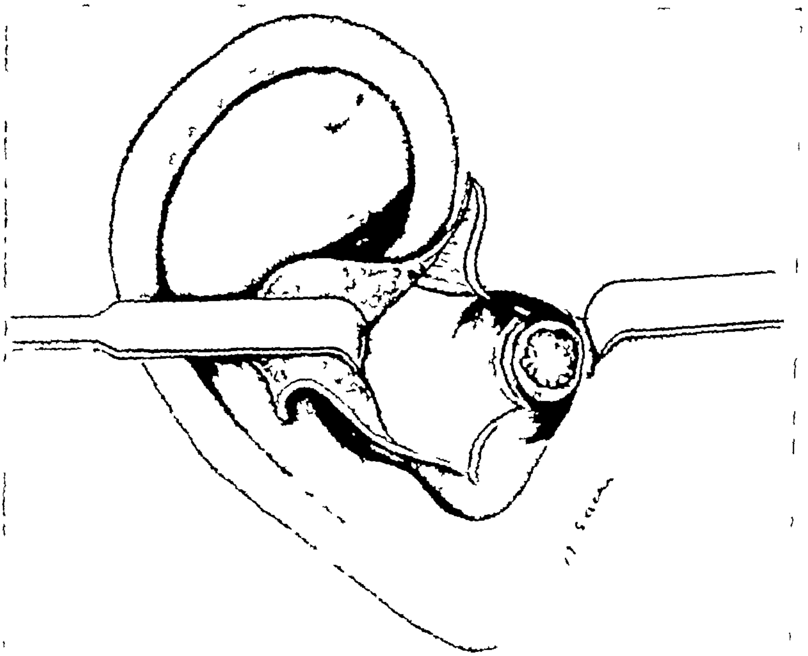

Fig 2 The skin of the posterior half of the external auditory canal is reflected as a pedicle flap An elliptical piece of conchal cartilage is removed and the mastoid cortex exposed

The technique is described in the legends accompanying Figs 1 through 9, which follow

COMMENT

Now what is actually being done with this technique? It is simply a way to cooperate with nature's efforts to close off a wound in the temporal bone in the most direct and efficient way possible. It is a natural physiological condition to have a permanently closed air space within the temporal bone open to the pharynx through the Eustachian tube It is present in the normal ear, consisting of the middle ear cavity and the antrum (see Fig 10-A)

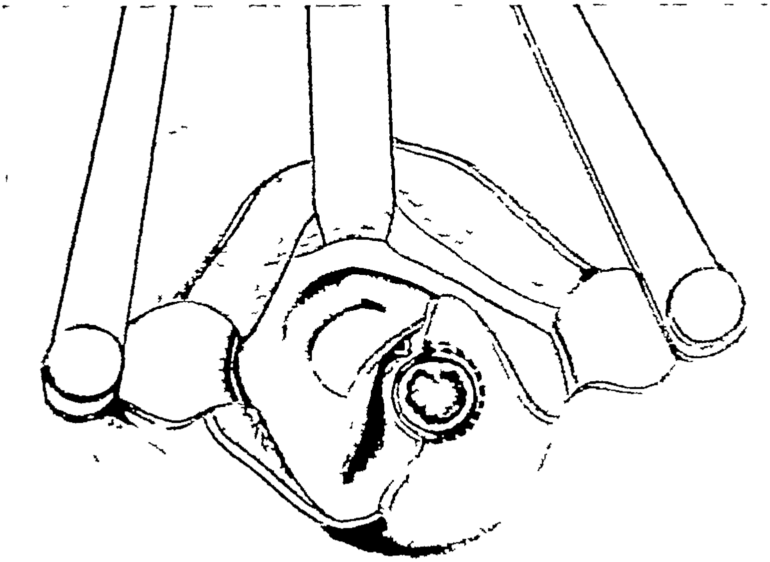

Fig 3 The mastoid is excavated to remove all diseased tissue The bony posterior canal wall is taken down a circumferential incision is then made anteriorly to separate the canal skin from the drum

After a simple mastoidectomy, with removal of the bone in the mastoid region, a larger space results, consisting of the middle ear, the antrum, and the mastoid cavity (see Fig 10-B) For many years we have been closing off this enlarged air cavity by primary wound closure with after care that is practically negligible This has made the simple mastoidectomy the most gratifying operation available today in temporal bone surgery, for both the patient and the surgeon

With primary closure of the radical mastoidectomy wound we are following the same principle We simply enlarge the cavity to include not only the mastoid area but also the space previously occupied by the external auditory canal (see Fig 10-C) It does not matter whether the space is large or small so long as it is connected to the pharynx through the Eustachian tube In each of these instances of enlarging the normal air cavity in the temporal bone, the space is maintained by air pressures through the Eustachian tube, while mucosa extends itself into the enlarged cavity Only one thing is essential, a thorough radical mastoidectomy must be performed In addition to the removal of all foci of infection, particular attention must be directed to the elimination of any type of

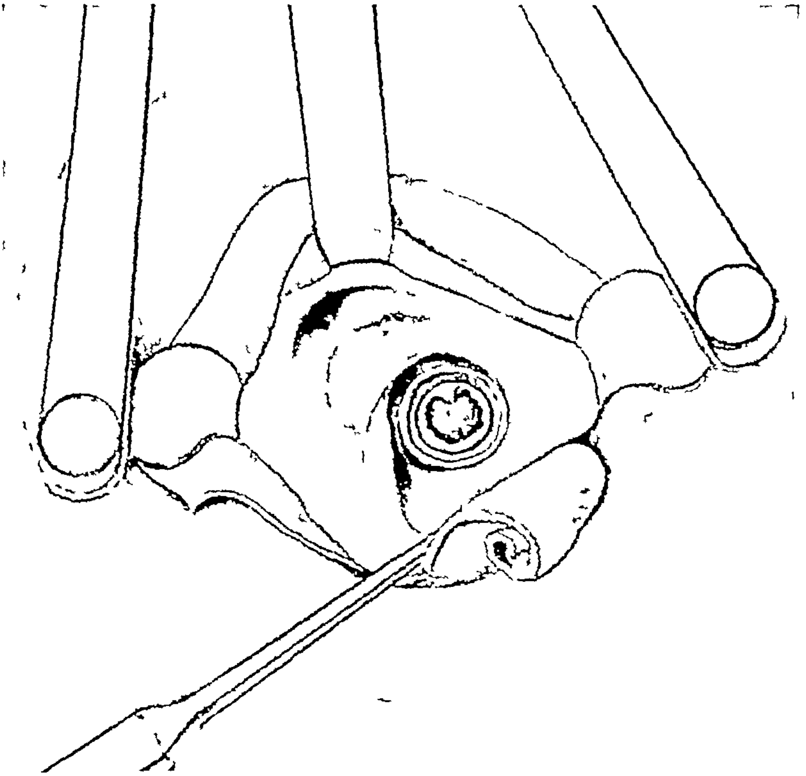

Fig 4 The anterior canal skin is then reflected as a pedicle flap

squamous epithelium It is perfectly clear that remnants of cholesteatomatous material cannot be left in a cavity that is to be permanently closed

This method furnishes a durable healing which will not break down, as it often does in secondary repair when poorly nourished epithelium has grown over bone With primary closure of the radical mastoidectomy wound, patients may take showers and swim Another important advantage is that there is no postoperative cavity which requires periodic care

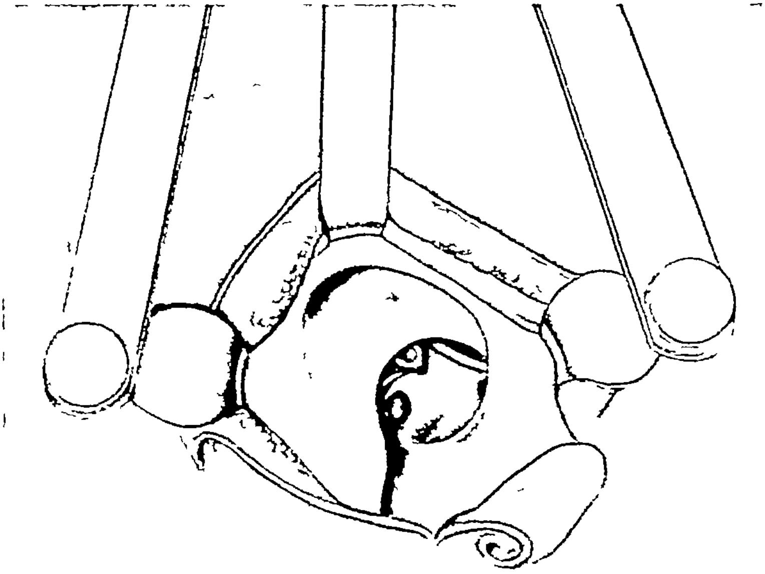

Fig 5 With the skin of the external auditory canal reflected out of the way as two pedicle flaps the radical mastoidectomy can then be completed with meticulous removal of all epithelial and diseased processes

Today, restoration of hearing in deafness, caused by long-standing chronic otitis, is being accomplished In such cases

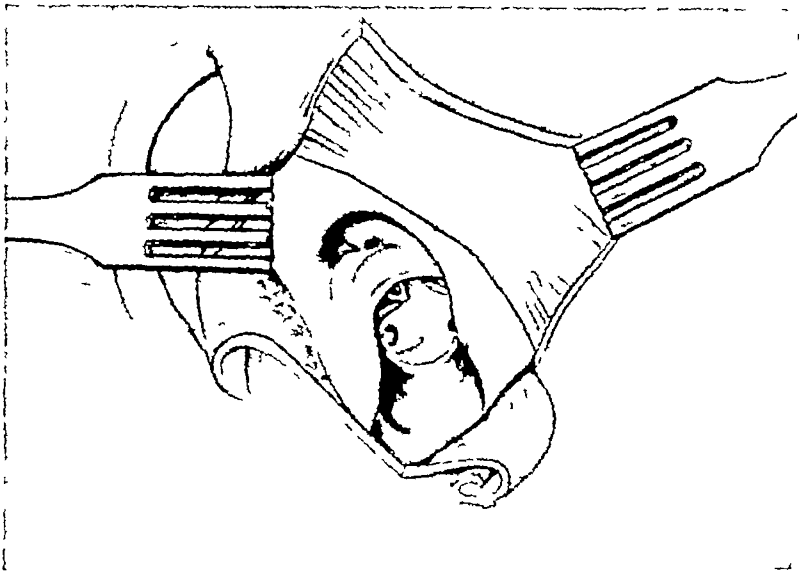

Fig 6 The temporal muscle is then exposed by extending the superior endaural incision upward and by separating the loosely attached scalp from the temporal fascia

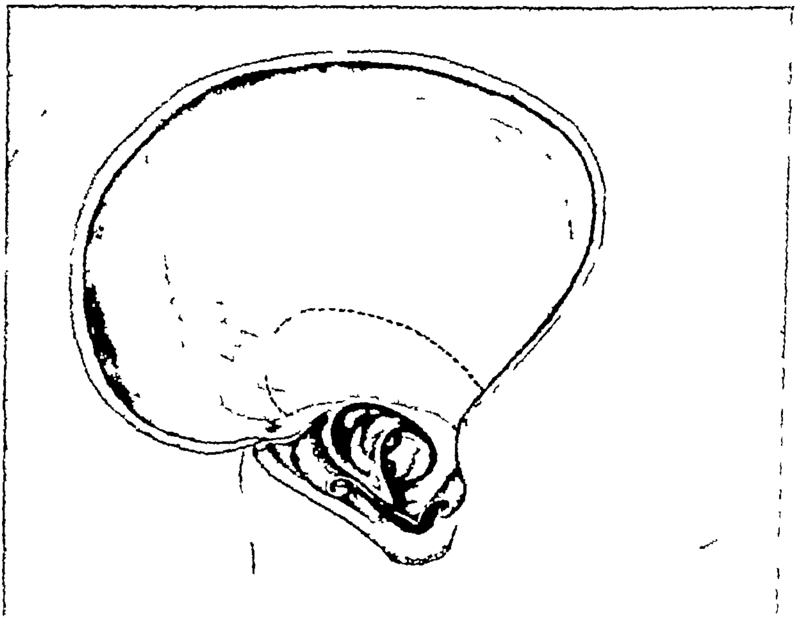

Fig 7 A temporal muscle pedicle flap is cut as indicated The flap receives an abundant blood supply mainly from the posterior deep temporal artery which courses upward and backward in the area of the muscle included in the flap

an open cavity is essential for the transmission of sound vibrations to the inner ear Primary closure is not suggested, of course, in these ears, where an open cavity serves a useful purpose, but it is a logical procedure for those patients with poor bone conduction, where an open cavity does not serve any useful purpose Aside from those in whom bone conduction is a consideration, there is also a large group of patients with chronic ears who either do not wish to have an extensive plastic reconstructive operation, or for whom such an operation would not be indicated in the best judgment of the surgeon Among these are the very young, the very old, and those with serious systemic disease Patients with one normal ear who have no real hearing handicap but who would like to get rid of the basic disease and symptoms, and

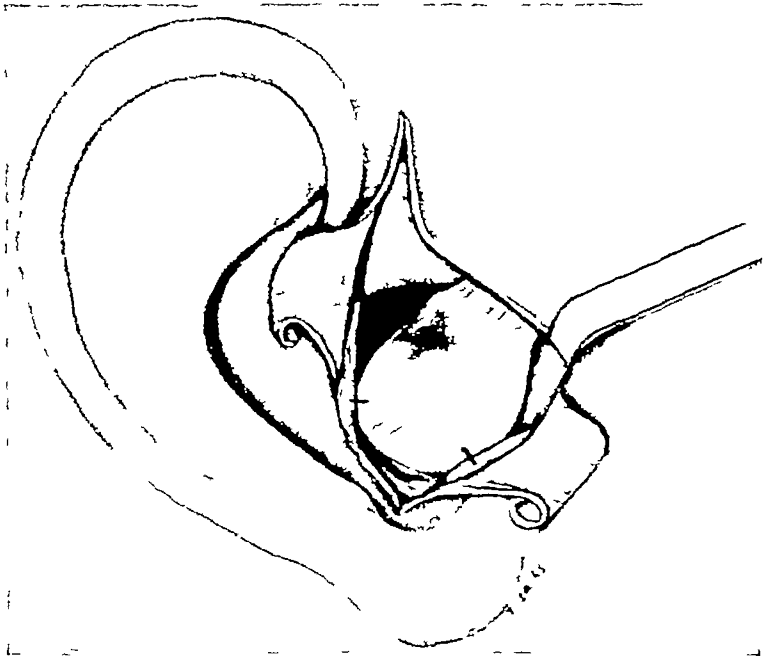

Fig 8 The temporal muscle pedicle flap is then rotated over the area of the endaural opening The free end is sutured anteriorly and posteriorly to the soft tissue underlying the skin

get a dry ear in the simplest and easiest way possible, might well be considered logical choices for the procedure

Even where an open cavity is maintained, the use of the temporal muscle plastic in a postoperative radical cavity—to create a closed middle ear space and to line the cavity with soft tissue which contributes an abundant blood supply—has proved an excellent way of getting prompt healing The problem of secondary healing is mainly one of blood supply For instance, we need only to recall how well scalp wounds heal, where there is a rich blood supply In those radical mastoidectomies, where this technique has so far been used to promote healing, and in one-stage musculoplasties as well as in the first stage of two-stage musculoplasties, the abun-

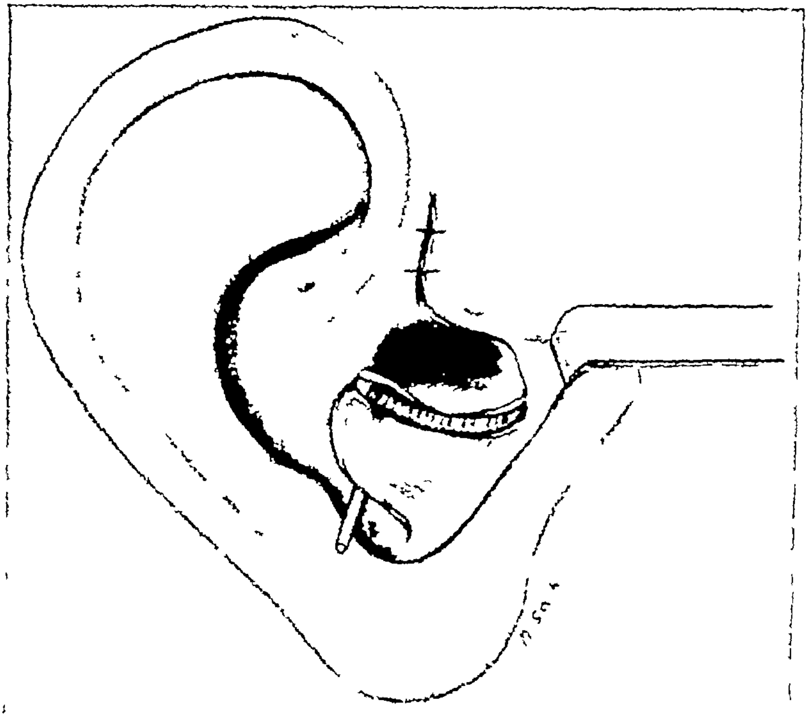

Fig 9 The two pedicle skin flaps previously prepared are then laid in place over the muscle The superior endaural incision is sutured a polyethylene tube is left in place for several days as a temporary drain from the cavity

dant blood supply furnished by the temporal muscle pedicle flap has given a rapidity of healing that has been almost a revelation It must be pointed out, however, that although this method has provided rapid and uncomplicated healing following the classical radical mastoidectomy, it does not provide all the advantages of primary closure These are quick healing by primary intention, the elimination of a cavity which requires periodic postoperative care, and the elimination of restrictions on the part of the patient concerning swimming and taking showers

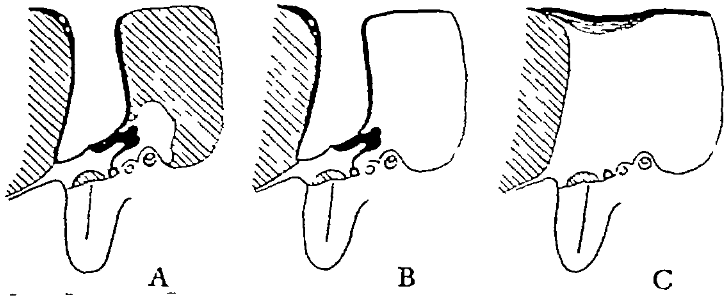

Fig 10-A. Air space in the normal ear B—Air space following simple mastoidectomy C—Air space following radical mastoidectomy with primary closure

Whether techniques are directed toward restoration of hearing, or simply to a cure of the basic disease and attempts to obtain a dry ear, my experience thus far leads me to the conviction that the use of the temporal muscle plastic in surgery of the chronic ear will prove to be the solution to the problem of the persistently draining postoperative cavity

BRIEF REVIEW OF TYPICAL CASES

Case 1 A 60-year-old woman with fair bone conduction In the ear operated she had a large perforation of the drum destruction of the ossicular chain suppuration and a large polyp protruding into the external auditory canal She complained of headaches and some instability of balance No practical hearing had been present in the ear for ten years and she had become well adjusted to getting along with the adequate hearing in the other ear The patient worked in a department store and she volunteered the information that postoperative visits would be difficult for her to arrange She was interested only in getting rid of her symptoms and the chronic otorrhea with the least possible get a dry ear in the simplest and easiest way possible, might well be considered logical choices for the procedure

Even where an open cavity is maintained, the use of the temporal muscle plastic in a postoperative radical cavity—to create a closed middle ear space and to line the cavity with soft tissue which contributes an abundant blood supply—has

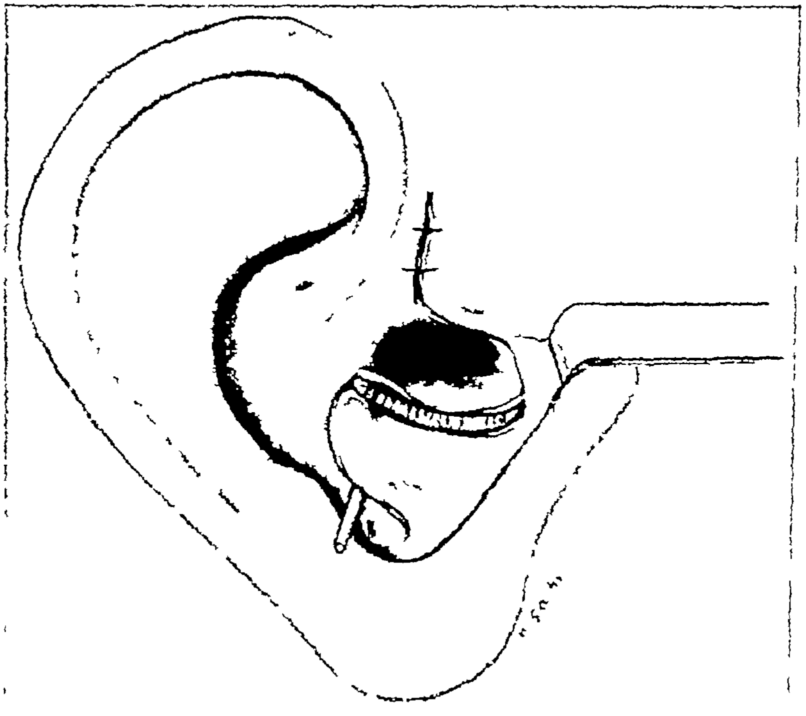

Fig 9 The two pedicle skin flaps previously prepared are then laid in place over the muscle The superior endaural incision is sutured a polyethylene tube is left in place for several days as a temporary drain from the cavity

proved an excellent way of getting prompt healing The problem of secondary healing is mainly one of blood supply For instance, we need only to recall how well scalp wounds heal, where there is a rich blood supply In those radical mastoidectomies, where this technique has so far been used to promote healing, and in one-stage musculoplasties as well as in the first stage of two-stage musculoplasties, the abunwas revised and a technique for obtaining rapid healing which differs from the three preceding cases was utilized This consisted of bringing a long pedicle flap, cut from the temporal muscle down into an open cavity to contribute an abundant blood supply to the healing processes and to bridge and seal the middle ear space Three weeks after operation the patient was forced to leave the city He returned seven weeks postoperatively with a healed, dry ear he required no further care

AMERICAN BOARD OF OTOLARYNGOLOGY

The American Board of Otolaryngology will conduct only one examination in 1958, and this will be October 6-9, 1958, in Chicago, Illinois, at the Palmer House.

For further information address Dr Dean M Lierle, Secy-Treas, University Hospital, Iowa City, Iowa

trouble A radical mastoidectomy was performed with primary closure of the wound Healing was complete, and the patient was discharged after one month

Case 2 A 46 year-old woman with poor bone conduction in the affected ear Cholesteatoma was present with destruction of the drum and ossicular chain Since an open cavity would serve no logical purpose in this case a radical mastoidectomy was performed with primary closure At the end of five weeks this patient had a dry healed ear (see Fig 11)

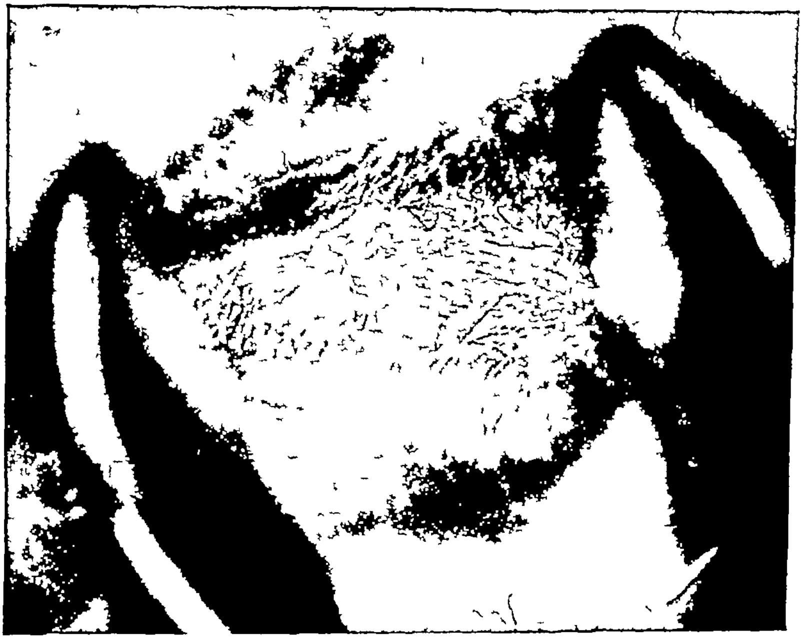

Fig 11 Primary healing in a typical case one month postoperative is shown

Case 3 An 8 year old boy Cholesteatoma was present in the affected ear after a long history of ear trouble with repeated antibiotic treatments Removal of the soft infected cells in the mastoid area, which are typically found in these ears left a huge cavity after the radical mastoidectomy In my experience this type of large cavity in children, has proven to be extremely difficult to heal With the primary closure technique the healing was complete in four weeks As is natural for a boy of his age he is very much interested in swimming His parents have been told that he may swim without concern for his ear

Case 4 A 33 year old business man who came to New York from South America for revision of a radical mastoidectomy which had been performed in Hungary at the age of six There had been suppuration from the ear since his childhood The Eustachian tube was open to the cavity, which contained infected polypi and granulation tissue Bone conduction was poor, and he had had no hearing in the affected ear since early youth The patient had normal hearing on the opposite side The cavity

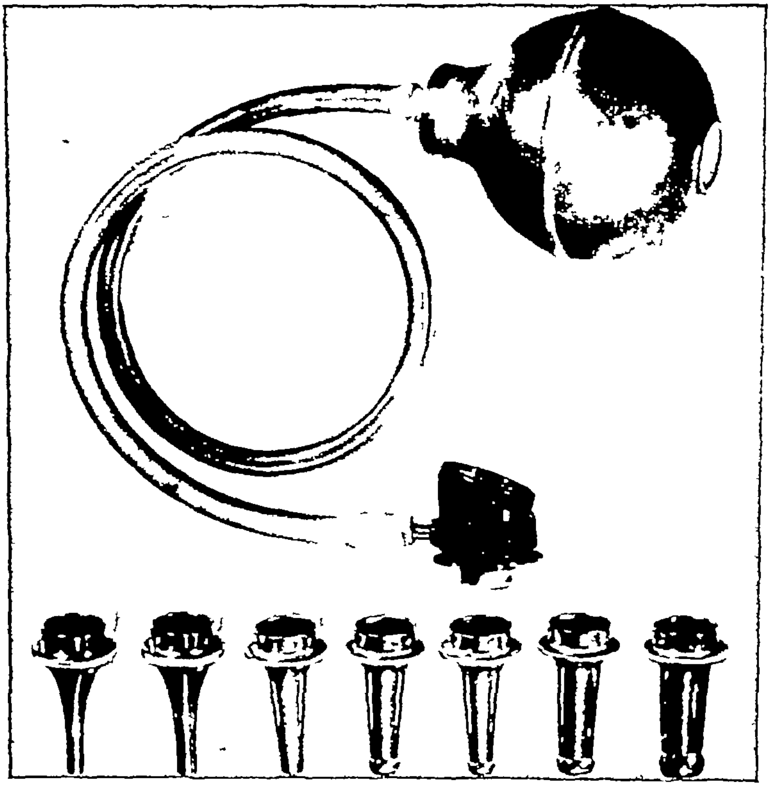

Fig 1 Pneumatic otoscope with specula of seven sizes which permit its use in a patient of any age This is essential for the diagnosis of middle ear effusion

ache has not done his duty unless, after pain and fever subside, he determines whether or not the hearing has returned to normal

DIAGNOSIS

Given a patient with a conductive hearing loss, the physician should suspect the presence of fluid in the middle ear Inspection of the drum reveals moderate retraction Often the drum has an amber color Occasionally a fluid level will be seen, and sometimes one will see bubbles of air in the fluid if it is of the serous type The most important single diagnostic method, which in my experience is almost infallible,

MIDDLE EAR EFFUSION—SYSTEMIC FACTORS[*]

F W Davison, M D,[†]

Danville, Pa

This clinical entity has many synonyms, including secretory otitis media, non-suppurative otitis media, serous otitis media, catarrhal otitis media and hydrotympanum It is a common condition, our department treats more than 300 cases each year There is much disagreement in the literature regarding etiology and treatment In an effort to clarify my own ideas, I have analyzed the case histories of 100 patients who had non-suppurative fluid in the middle ear demonstrated by myringotomy and aspiration

SYMPTOMS

The most common symptom is a conductive-type hearing loss, shown by pure tone audiometry and tuning fork tests It is important to have bone conduction tests, because there is nothing characteristic about the shape of the audiometric curve by air, but a high tone loss is not uncommon If the disease is unilateral, the Weber test is referred to the ear with poor hearing Most of the patients had a blocked or full feeling in the affected ear, the typical history states that the symptoms developed following an acute nasopharyngitis

Most acute middle ear infections respond promptly to administration of antibiotics, but in many cases hearing loss due to fluid in the middle ear persisted until the fluid was removed from one to six months later I think the increased number of patients with hearing loss owing to middle ear effusion is due to the fact that too many physicians do not utilize myringotomy, as well as antibiotics, for treatment of acute otitis media The physician treating a child with ear-

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication May 26 1958

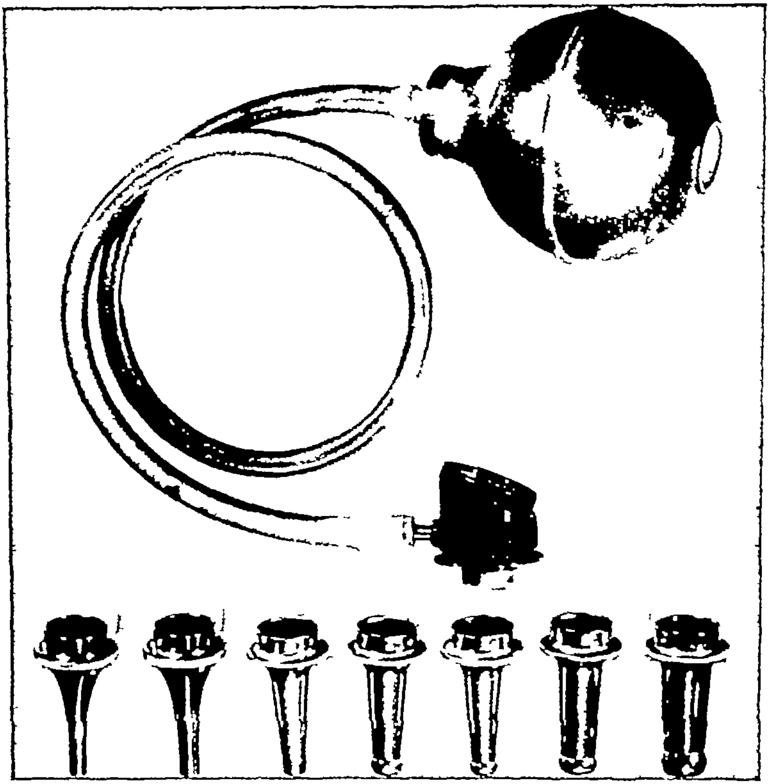

Fig 1 Pneumatic otoscope with specula of seven sizes which permit its use in a patient of any age This is essential for the diagnosis of middle ear effusion

ache has not done his duty unless, after pain and fever subside, he determines whether or not the hearing has returned to normal

DIAGNOSIS

Given a patient with a conductive hearing loss, the physician should suspect the presence of fluid in the middle ear Inspection of the drum reveals moderate retraction Often the drum has an amber color Occasionally a fluid level will be seen, and sometimes one will see bubbles of air in the fluid if it is of the serous type The most important single diagnostic method, which in my experience is almost infallible, is use of the pneumatic otoscope, shown in Fig 1 If there is fluid in the middle ear *the drum moves poorly,* and the degree of impairment of mobility is in proportion to the amount of fluid in the middle ear If the middle ear contains the thick, gummy type of secretion, the drum is practically fixed In case of doubt, one should do a diagnostic myringotomy and aspiration, using a small spot suction tip against, not through, the myringotomy incision I use a 15 gauge 3½-inch needle with the point ground off and a 30-degree bend close to the hub This is illustrated in Fig 2 Aspiration with a 20 or 22-gauge needle inserted through the drum cannot possibly remove the thick, gluey mucus so frequently present in these cases

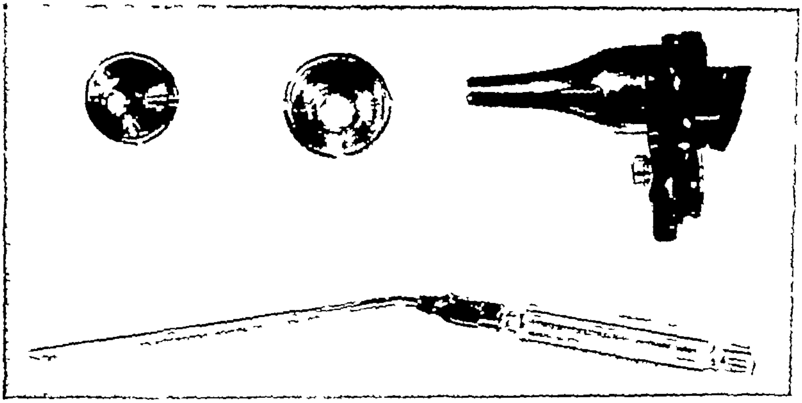

Fig 2 Aural magnifier very helpful when doing a myringotomy and 15 gauge aspirating tip

In order to use the Siegle type pneumatic otoscope effectively, one must have a speculum that fits the canal snugly I use specula of seven sizes

It is not necessary to use a Eustachian catheter for either diagnosis or treatment If one suspects fluid in the middle ear, diagnostic myringotomy and aspiration should be utilized If correctly done it is almost painless, and can be done without anesthesia, either general or local, if the doctor has the patient's confidence One patient had learned how to obtain relief by puncturing his own drum with the point of a sharpened toothpick

ETIOLOGY

I acknowledge with pleasure the fact that my interest in this subject was stimulated by Gordon Hoople's[2] article entitled, "Otitis Media with Effusion, a Challenge to Otolaryngology," published in the May-June, 1950, issue of the Transactions of the American Academy of Ophthalmology and Otolaryngology Most of the important facts regarding middle ear effusion can be found in Dr Hoople's article

I call your attention to one of Dr Hoople's paragraphs, which reads as follows "It should not be forgotten that the diagnostic endeavors should be directed not only to the ear, but to the discovery of *general conditions,* which are abnormal"

It seems self-evident that treatment to be effective must be directed at the etiology It has been said that anything which causes Eustachian tube obstruction, either partial or complete, can cause middle ear effusion, but there are many causes of middle ear effusion and *two or more factors* may be operative in any one patient.

Etiologic factors may be divided into two classes *1* Local, and *2* Systemic All too frequently we have been concerned chiefly with the local factors, especially hyperplastic lymphoid tissue

My experience agrees with that of Baron[1] who says that, "A clean, careful surgical removal of nasopharyngeal lymphoid tissue is better than radiation," however, in only 50 per cent of these 100 cases was careful adenoidectomy a complete answer to the problem Eleven of these patients, after coming to us for treatment, required a second adenoidectomy, and one required a third

The patient who has only one or two recurrences of middle ear effusion per year when he has an acute upper respiratory infection, has no serious problem The patients whose charts

I analyzed had two or more recurrences per year The apparent etiologic factors are listed in Table I

TABLE I—APPARENT ETIOLOGIC FACTORS

		Cases
1	Hypertrophied adenoid or recurrent lymphoid tissue in the nasopharynx	53
2	Recurrent acute nasopharyngitis (Seven of these had hypogammaglobulinemia)	36
3	Allergy	18
4	Hypothyroidism	11
5	Obesity	9
6	Carcinoma of the nasopharynx	1

LARGE ADENOID AND RECURRENT LYMPHOID TISSUE IN THE NASOPHARYNX

Our experience agrees with that of Perlman,[3] who stated that there is no correlation between the size of the adenoid mass and the presence of middle ear effusion His illustrations (Figs 3-6) show the large amounts of glandular, fatty and lymphoid tissue in close relation with the Eustachian tube, and suggest that an excess amount of any of these tissue elements may produce tubal obstruction Thoughtful reading of Perlman's article will, I think, discourage anyone from using a Eustachian bougie, or from advising the use of a radium applicator

Fifty patients who had their adenoids removed stopped having recurrences of middle ear effusion Ten patients who had recurrent lymphoid tissue in the nasopharynx and recurrent middle ear effusion were treated with X-ray therapy In nine out of ten cases X-ray therapy failed to prevent recurrent middle ear effusion It seems obvious that we should consider the *causes* of lymphoid hyperplasia and not confine our efforts to surgical removal or X-ray therapy Hypertrophied lymphoid tissue, considered as a local factor, may be due to repeated attacks of adenoiditis or nasopharyngitis, but the abnormal susceptibility to infection is often due to a systemic factor, such as adrenocortical insufficiency or hypogammaglobulinemia, so it is very difficult to be sure

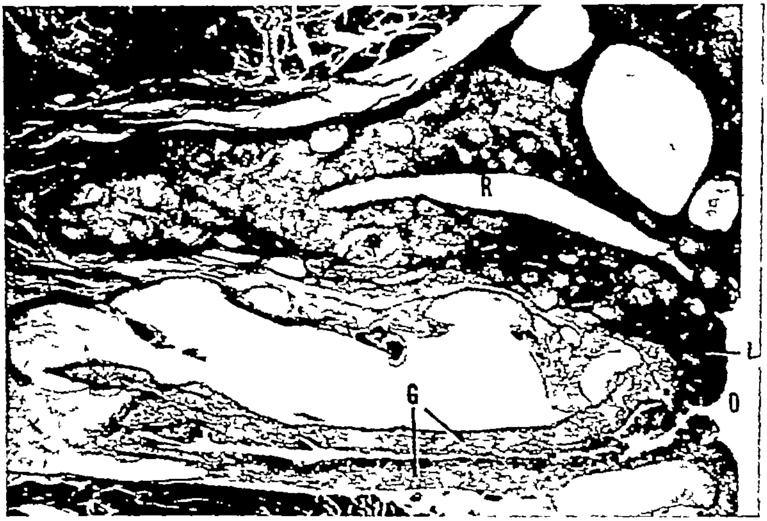

Fig 3 Section through the mouth of the tube (0) and Rosenmuller s Fossa (R) Note the large number of glands (G) along the tube and the lymphoid tissue in the Rosenmuller s Fossa on the torus (L) and at the opening of the tube (Courtesy of Dr H B Perlman)

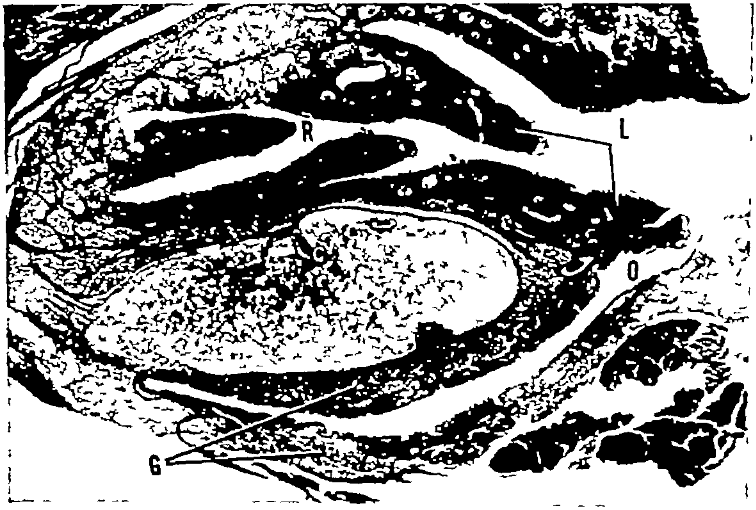

Fig 4 Shows the tube lined by glands (G) Rosenmuller s Fossa (R) containing large amount of lymphoid tissue (L) continuing over the torus at the opening of the tube (O) (Courtesy of Dr H B Perlman)

I analyzed had two or more recurrences per year The apparent etiologic factors are listed in Table I

TABLE I—APPARENT ETIOLOGIC FACTORS

		Cases
1	Hypertrophied adenoid or recurrent lymphoid tissue in the nasopharynx	53
2	Recurrent acute nasopharyngitis (Seven of these had hypogammaglobulinemia)	36
3	Allergy	18
4	Hypothyroidism	11
5	Obesity	9
6	Carcinoma of the nasopharynx	1

LARGE ADENOID AND RECURRENT LYMPHOID TISSUE IN THE NASOPHARYNX

Our experience agrees with that of Perlman,[3] who stated that there is no correlation between the size of the adenoid mass and the presence of middle ear effusion His illustrations (Figs 3-6) show the large amounts of glandular, fatty and lymphoid tissue in close relation with the Eustachian tube, and suggest that an excess amount of any of these tissue elements may produce tubal obstruction Thoughtful reading of Perlman's article will, I think, discourage anyone from using a Eustachian bougie, or from advising the use of a radium applicator

Fifty patients who had their adenoids removed stopped having recurrences of middle ear effusion Ten patients who had recurrent lymphoid tissue in the nasopharynx and recurrent middle ear effusion were treated with X-ray therapy In nine out of ten cases X-ray therapy failed to prevent recurrent middle ear effusion It seems obvious that we should consider the *causes* of lymphoid hyperplasia and not confine our efforts to surgical removal or X-ray therapy Hypertrophied lymphoid tissue, considered as a local factor, may be due to repeated attacks of adenoiditis or nasopharyngitis, but the abnormal susceptibility to infection is often due to a systemic factor, such as adrenocortical insufficiency or hypogammaglobulinemia, *so it is very difficult* to be sure that local factors are strictly local except in those cases in which adenoidectomy stops the recurrences The age distribution is shown in Table II

TABLE II —ONE HUNDRED CASES OF MIDDLE EAR EFFUSION

	Cases
1—10 years	65
11—20 years	16
21—30 years	6
31—40 years	4
41—50 years	3
51—60 years	2
61—70 years	2
71—80 years	2
Sixty males forty females	Total 100

This table, showing that 65 per cent of these patients are in the first decade, suggests two etiologic factors

1 Poor immunity mechanisms, known to be more common in childhood

2 Hyperplastic lymphoid tissue, known to be more common in childhood

The influence of hormones on lymphoid tissue is shown by normal involution at the time of puberty This suggests that the great enlargement of lymphatic structures, frequently seen in early childhood, may be due to insufficiency of steroids, either gonadal or adrenocortical White[6] points out that there is a marked decrease in the size of lymphoid tissues in response to administration of adrenocortical hormones, and that patients having Addison's Disease have marked enlargement of all lymphoid tissues

Diet is another factor to be considered In our experience, a high carbohydrate diet in childhood causes an overgrowth of lymphoid tissue

Yoffey and Courtice[7] state that the total amount of lymphoid tissue in the body is about 1 per cent of the body weight, so in removing tonsils and adenoids we are removing only a small fraction of the total lymphoid tissue

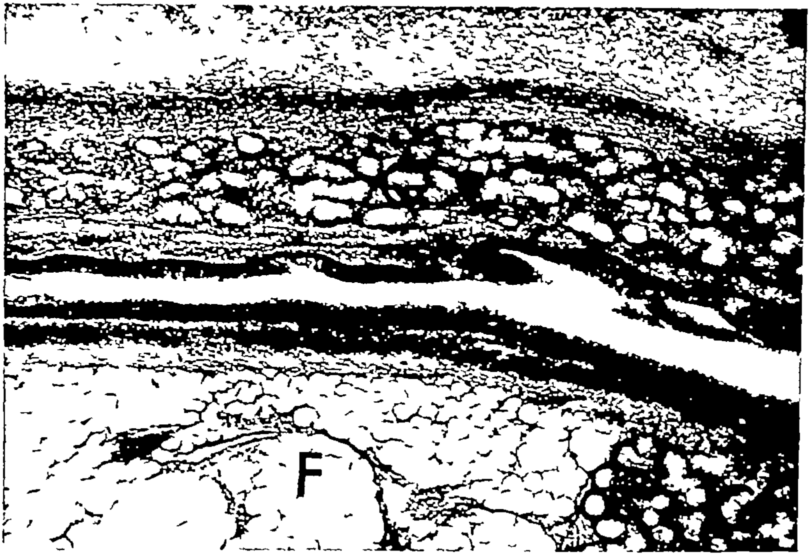

Fig 5 Photomicrograph through the cartilaginous portion of the tube showing the large amount of fat and glandular elements along the walls of the tube These tissue elements are probably important in tubal function and are particularly resistant to radiation (Courtesy of Dr H B Perlman)

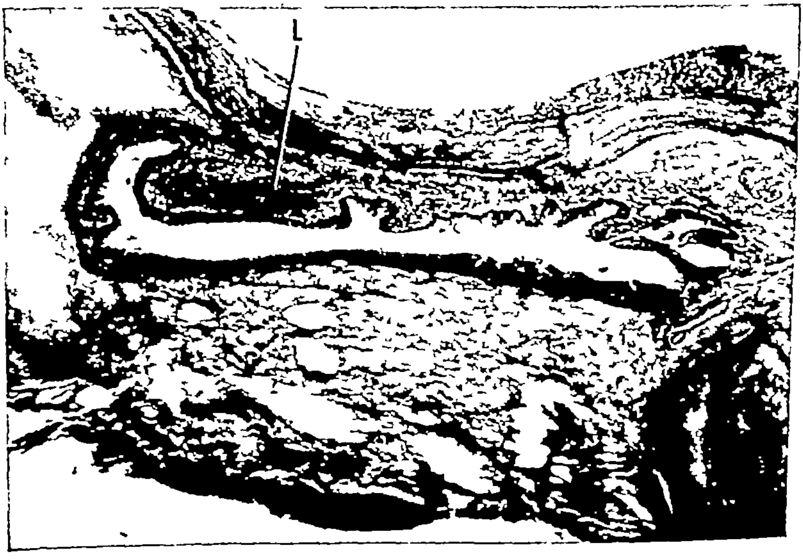

Fig 6 Section through the Eustachian tube above the torus showing mucous membrane folds and the subepithelial lymphoid tissue (L) which may influence tubal function (Courtesy of Dr H B Perlman)

that four of their twelve patients having Gamma globulin deficiency were also allergic, and two of these required specific allergic therapy in addition to Gamma globulin in order to control the main presenting symptoms This is a clearly written concise article, which helped to focus my attention upon the importance of recognizing Gamma globulin deficiency in patients who are infection-prone

There are, of course, other factors which cause an individual to be infection-prone, namely overnutrition, undernutrition, poor adrenocortical function, poor thyroid function and deficiencies in the properdin system,[4] about which we are just beginning to learn

NASAL ALLERGY

The 18 individuals in this group had either food or inhalant sensitivity or both, demonstrated by history, skin tests and response to treatment All of the patients in this group had had previous adenoidectomy but continued to have recurrence of middle ear effusion until the allergic factor was recognized and treated by either avoidance of hyposensitization

HYPOTHYROIDISM

The group of 11 patients with clear-cut hypothyroidism all responded well to administration of either dessicated thyroid or to triiodothyronine. The diagnosis was suggested by the usual signs and symptoms, and was confirmed by laboratory tests showing low protein bound iodine and high serum cholesterol levels One patient, a woman aged 67, who had a very large adenoid which Dr Cole, my associate, removed, had a PBI of 3 03 mcg and a cholesterol level of 302 mg per cent She responded well to adenoidectomy and administration of dessicated thyroid She had previously been told to get rid of her dog and parakeet because the edematous state of her nasal mucosa suggested an "allergic" etiology

The X-ray bone age is useful for diagnosing hypothyroidism in children One youngster, aged nine, had been wearing a hearing aid for three years Her X-ray bone age was reported as six years Bilateral myringotomy and aspiration

RECURRENT ACUTE NASOPHARYNGITIS

This group of 36 patients is composed of those who had previously had an adenoidectomy, but who continued to have attacks of middle ear effusion each time they suffered an acute upper respiratory infection This group might well be called the "infection-prone" group of patients, because they had from three to twelve upper respiratory infections per year, often with high fever and sometimes with complications It seems obvious that there is some systemic deficiency which makes individuals in this group abnormally susceptible to infection After we began looking for it, we found seven individuals in this group who had hypogammaglobulinemia, according to our standards This diagnosis will bear some discussion, because there are those academic purists who do not use this term unless the Gamma globulin levels are extremely low According to our laboratory, the normal range of Gamma globulin is 0 7 to 2 1 gm per 100 cc , as determined by filter paper electrophoresis The Gamma globulin determinations for these seven patients, all of whom were children under ten years of age, were 0 66 gm or 10 per cent, 0 55 gm or 8 per cent, 0 75 gm or 11 per cent, 0 8 gm or 12 per cent, 0 54 gm or 8 per cent, 0 54 gm or 7 per cent and 0 61 gm or 10 per cent A figure frequently quoted in the literature as normal Gamma globulin is 15 per cent of the total serum protein

According to our standards all of these youngsters were deficient in Gamma globulin All of them continued to have frequent recurrences of respiratory infection followed by middle ear effusion despite adenoidectomy, vaccine therapy, allergic management, X-ray therapy and multiple courses of antibiotics, *until* Gamma globulin was administered by intramuscular injection once a month in quantities ranging from 3 to 5 cc , depending upon the age of the patient Our experience suggests that a Gamma globulin level below 1 gm per cent predisposes to frequent infections, and that these patients benefit by administration of Gamma globulin

Four of the seven children who had hypogammaglobulinemia also had allergic symptoms Turner and Dobson[5] reported that four of their twelve patients having Gamma globulin deficiency were also allergic, and two of these required specific allergic therapy in addition to Gamma globulin in order to control the main presenting symptoms This is a clearly written concise article, which helped to focus my attention upon the importance of recognizing Gamma globulin deficiency in patients who are infection-prone

There are, of course, other factors which cause an individual to be infection-prone, namely overnutrition, undernutrition, poor adrenocortical function, poor thyroid function and deficiencies in the propeidin system,[4] about which we are just beginning to learn

NASAL ALLERGY

The 18 individuals in this group had either food or inhalant sensitivity or both, demonstrated by history, skin tests and response to treatment All of the patients in this group had had previous adenoidectomy but continued to have recurrence of middle ear effusion until the allergic factor was recognized and treated by either avoidance of hyposensitization

HYPOTHYROIDISM

The group of 11 patients with clear-cut hypothyroidism all responded well to administration of either dessicated thyroid or to triiodothyronine The diagnosis was suggested by the usual signs and symptoms, and was confirmed by laboratory tests showing low protein bound iodine and high serum cholesterol levels One patient, a woman aged 67, who had a very large adenoid which Dr Cole, my associate, removed, had a PBI of 3 03 mcg and a cholesterol level of 302 mg per cent She responded well to adenoidectomy and administration of dessicated thyroid She had previously been told to get rid of her dog and parakeet because the edematous state of her nasal mucosa suggested an "allergic" etiology

The X-ray bone age is useful for diagnosing hypothyroidism in children One youngster, aged nine, had been wearing a hearing aid for three years Her X-ray bone age was reported as six years Bilateral myringotomy and aspiration

RECURRENT ACUTE NASOPHARYNGITIS

This group of 36 patients is composed of those who had previously had an adenoidectomy, but who continued to have attacks of middle ear effusion each time they suffered an acute upper respiratory infection. This group might well be called the "infection-prone" group of patients, because they had from three to twelve upper respiratory infections per year, often with high fever and sometimes with complications. It seems obvious that there is some systemic deficiency which makes individuals in this group abnormally susceptible to infection. After we began looking for it, we found seven individuals in this group who had hypogammaglobulinemia, according to our standards. This diagnosis will bear some discussion, because there are those academic purists who do not use this term unless the Gamma globulin levels are extremely low. According to our laboratory, the normal range of Gamma globulin is 0.7 to 2.1 gm. per 100 cc., as determined by filter paper electrophoresis. The Gamma globulin determinations for these seven patients, all of whom were children under ten years of age, were 0.66 gm. or 10 per cent, 0.55 gm. or 8 per cent, 0.75 gm. or 11 per cent, 0.8 gm. or 12 per cent, 0.54 gm. or 8 per cent, 0.54 gm. or 7 per cent and 0.61 gm. or 10 per cent. A figure frequently quoted in the literature as normal Gamma globulin is 15 per cent of the total serum protein.

According to our standards all of these youngsters were deficient in Gamma globulin. All of them continued to have frequent recurrences of respiratory infection followed by middle ear effusion despite adenoidectomy, vaccine therapy, allergic management, X-ray therapy and multiple courses of antibiotics, *until* Gamma globulin was administered by intramuscular injection once a month in quantities ranging from 3 to 5 cc., depending upon the age of the patient. Our experience suggests that a Gamma globulin level below 1 gm. per cent predisposes to frequent infections, and that these patients benefit by administration of Gamma globulin.

Four of the seven children who had hypogammaglobulinemia also had allergic symptoms. Turner and Dobson reported

5 Recurrences will be frequent until the systemic causes of lymphoid hyperplasia are found and corrected

6 A careful, visually guided surgical adenoidectomy stops recurrences in only 50 per cent of these cases

7 X-ray therapy to the nasopharynx stopped recurrences in only one of ten cases treated

8 Multiple etiologic factors are present in at least 50 per cent of these cases

promptly restored her hearing Her thyroid deficiency was at first corrected by triiodothyronine and then dessicated thyroid was used as maintenance therapy Her hearing gain has been maintained

OBESITY

Patients in this group of nine continued to have middle ear effusion until they could be induced to reduce their weight by means of low carbohydrate diet The obese person has excess fatty tissue compressing the lumen of the tube The overweight factor can be readily overlooked unless the doctor is willing to take the height and weight of the patient and compare it with the height weight table This simple measure should not be beneath the dignity of any otolaryngologist who considers himself a physician None of these nine patients was demonstrably hypothyroid, but four of the 11 hypothyroid patients were obese, and carbohydrate restriction was urged in addition to administration of thyroid

TUMOR OF THE NASOPHARYNX

There happened to be only one patient in the total number of 100 who had a carcinoma of the nasopharynx This case reminds us that we should be alert to suspect tumor of the nasopharynx in any adult who has middle ear effusion

SUMMARY AND CONCLUSIONS

1 Middle ear effusion is a common condition

2 A Siegle type pneumatic otoscope is the most important diagnostic instrument

3 Recurrent nasopharyngitis and hyperplastic lymphoid tissue in the nasopharynx are the apparent local etiologic factors in most cases

4 Recurrences will be frequent until the systemic deficiencies responsible for the infection-prone status are corrected One of these frequently overlooked is Gamma globulin deficiency mid-line approach through the thyroid cartilage is used, and in providing for greater accuracy in dividing the contralateral cord and ventricular band, furthermore, removal of the anterior segment of thyroid cartilage in continuity provides an additional margin of safety in lesions approaching or beginning to cross the anterior commissure

The term "extended fronto-lateral" seems appropriate in describing an adaptation of this technique to lesions of somewhat greater extent, such as those showing, *a* posterior extension to or beyond the tip of the vocal process, but not into the posterior commissure, *b* beginning impairment of motility without actual fixation of the cord, *c* limited and superficial extension to ventricle or margin of ventricular band, or *d* subglottic extension amounting to no more than a few millimeters Such lesions are removed *en bloc,* along with a large portion of thyroid cartilage with or without the entire arytenoid, on occasion a horizontal or vertical segment of the cricoid may be included

Post-operative webbing and stenosis are minimized by careful forward suturing of the mucosal edge on the contralateral side, the use of a mold (foam-rubber covered with latex, or acrylic), or immediate skin grafting with insertion of a latex-covered foam-rubber mold The principles in the latter are those described by Erich[2] in the treatment of chronic laryngeal stenosis and subsequently by Figi[3] in the treatment of carcinoma

Obviously careful evaluation of the gross extent of the lesion is required before a decision can be made as to the most suitable type of operation Motility is best studied by indirect laryngoscopy On direct laryngoscopy, the use of a forward telescope is helpful in determining the antero-posterior extent (magnified image), the for-oblique and right-angle telescopes, along with planigraphy, are useful in detecting sub-glottic extension

TECHNIQUE OF EXTENDED FRONTO-LATERAL PARTIAL LARYNGECTOMY *†

CHARLES M NORRIS, M D ,

Philadelphia, Pa

Until recent years, the procedure of laryngofissure (thyrotomy) was the only type of partial laryngectomy widely used, however, it is now quite well established that certain lesions, formerly thought unsuitable for any procedure less than total laryngectomy, because of location or extent, may be treated by other forms of partial laryngectomy without appreciable increase in recurrence rate

In the type of laryngofissure commonly used, excision of one cord, ventricle and portion of ventricular band is accomplished following sub-perichondrial separation of these structures from the inner surface of one thyroid ala Portions of the corresponding thyroid ala have at times been removed simultaneously, since this has appeared to favor return of voice (Jackson[4]) The "anterior commissure" technique of Jackson has been useful in cases where resection of the anterior portions of the contra-lateral cord and ventricular band in continuity has seemed advisable, however, in these circumstances, present trends in technique favor removal of an anterior vertical segment of thyroid cartilage, left attached to the soft tissues being removed

This variation in technique is exemplified by the operation of Cerf,[1] the "bi-lateral thyrotomy" of Kemler,[5] and the "fronto-lateral" operation as described by Leroux-Robert[6] The latter term seems to be an accurately descriptive and desirable one All of these techniques are advantageous in avoiding the hazard of inadvertent division through the anterior commissure and/or the lesion, which may occur when a

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication Feb 27 1958

teriorly through the upper portion of the ventricular band to the arytenoid

9 Posteriorly, the excision is completed by extending the superior line of excision downward behind the arytenoid (if the arytenoid is to be removed) or through the base of the vocal process Strong forward traction (the crico-arytenoid joint capsule and inferior cornu having been previously incised) will facilitate inclusion of an adequate margin of normal tissue posteriorly when the arytenoid is to be removed in continuity

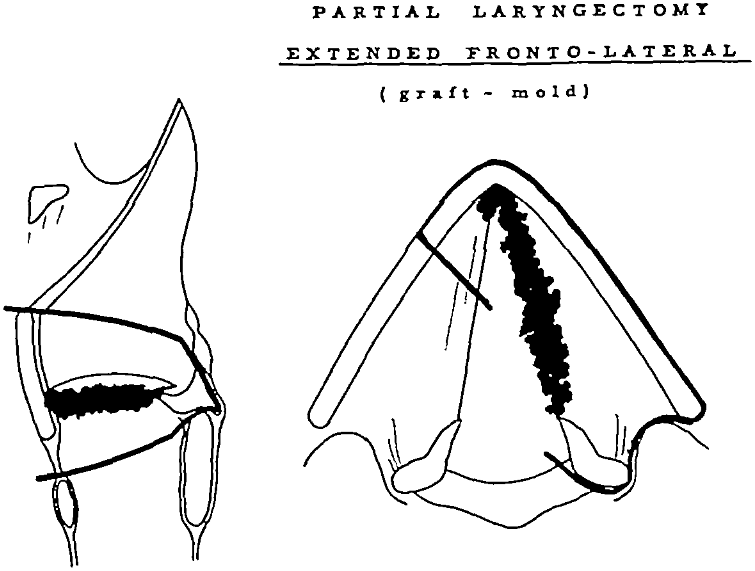

Fig 1 Extended frontol-lateral type of partial laryngectomy Usual lines of excision are shown in saggital and horizontal planes

10 The type of repair is naturally determined by the extent of excision required *a*. If less than one-third of the contralateral cord and ventricular band have been included in the excision, the mucosal edge on this side is anchored forward by horizontal mattress sutures of No 00000 chromic catgut brought through the external perichondrium of the remaining portion of thyroid ala A cylindrical foam-rubber mold subcutaneous tissues in midline from hyoid to supra-sternal notch

2 Vertical incision in the mid-line from hyoid to suprasternal notch Exposure of trachea (by division of thyroid isthmus if necessary), tracheostomy and insertion of endotracheal catheter with inflatable cuff well below the cricoid level General anesthesia is then induced (pentothal and nitrous-ether-oxygen)

3 Vertical division of thyroid ala on contra-lateral (uninvolved or least involved) side, 6 to 12 mm from the midline This is accomplished with the circular saw, attempting to divide only cartilage or cartilage and inner perichondrium

4 Vertical division through crico-thyroid membrane, contra-lateral cord and ventricular band This may be along the same line as the division of the cartilage or further posterior, in which case limited dissection beneath the perichondrium underlying the mid-portion of the cord and ventricular band is first required

5 The lesion is carefully inspected and its gross limits verified

6 External perichondrium is separated from outer surface of thyroid ala on the involved side, as far as the posterior border and from upper to lower borders

7 Inferiorly, the line of excision is usually carried along the upper edge of the cricoid arcus and as far posterior as the crico-arytenoid joint capsule, which is incised if the arytenoid is to be removed The inferior cornu of the thyroid ala is separated from its attachment to the cricoid, on the outer surface of the lamina During this part of the dissection care must be exercised to avoid entering the thin-walled pyriform sinus A horizontal segment of the cricoid arcus and lamina may be included if necessary

8 Superiorly, the line of excision is usually at the upper border of the thyroid ala, although a horizontal segment of the upper portion of the ala is often left *in situ* for support The soft tissues are divided along a line downward and pos-

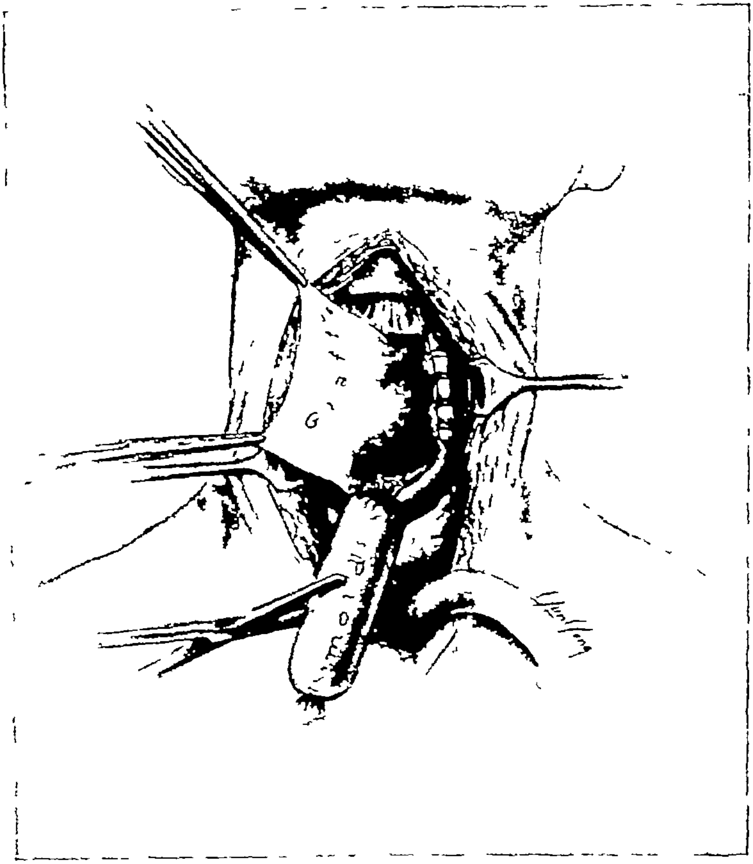

Fig 3 Extended fronto-lateral technique of partial laryngectomy Placement of split-thickness skin graft is shown Following introduction of the latex-covered foam-rubber mold the free anterior portion of the graft is brought across the anterior surface of the mold and sutured to the external perichondrium of the remaining portion of left thyroid ala.

contralateral cord and ventricular band have been removed, or if the arytenoid on the side of greatest involvement has been included, a split-skin graft about 0 015 inches in thickness should be used This is obtained with the Brown electrodermatome, usually from the area just below the clavicle, and is sutured to the mucosal edge posteriorly, above and below on the side from which the thyroid ala has been removed Anteriorly, after repair of the mucosal edge on the contralateral side as above, or suture of a second portion

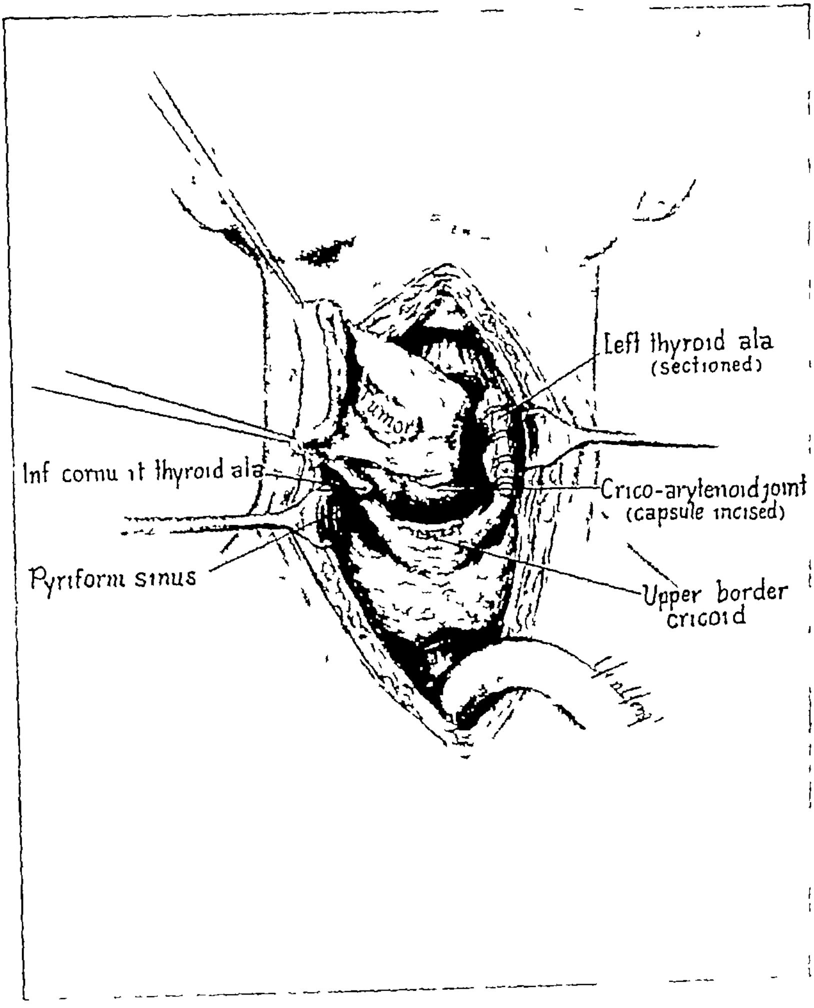

Fig 2 Extended fronto-lateral technique of partial laryngectomy Left thyroid ala cord and ventricular band have been divided and the mucosal edge on this side anchored forward by mattress sutures of No 00000 chromic catgut brought through external perichondrium On the right the inferior and superior lines of excision have been completed, the capsule of the crico-arytenoid joint and the attachment of the inferior cornu of the thyroid ala have been divided

covered with latex (condom rubber) and long enough to extend from the tuberculum of the epiglottis to the first tracheal ring is introduced and anchored in place by two through-and-through sutures of No 32 alloy steel wire Laterally and anteriorly, the mold is covered by the external perichondrium of the ala which has been removed *b* If greater portions of

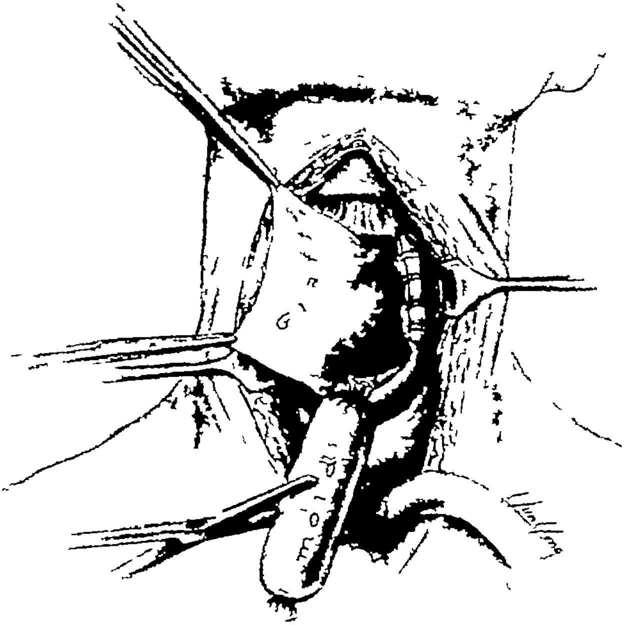

Fig 3 Extended fronto-lateral technique of partial laryngectomy Placement of split-thickness skin graft is shown Following introduction of the latex-covered foam-rubber mold the free anterior portion of the graft is brought across the anterior surface of the mold and sutured to the external perichondrium of the remaining portion of left thyroid ala.

contralateral cord and ventricular band have been removed, or if the arytenoid on the side of greatest involvement has been included, a split-skin graft about 0 015 inches in thickness should be used This is obtained with the Brown electrodermatome, usually from the area just below the clavicle, and is sutured to the mucosal edge posteriorly, above and below on the side from which the thyroid ala has been removed Anteriorly, after repair of the mucosal edge on the contralateral side as above, or suture of a second portion of graft in the same manner, the remaining free edge of graft is brought across the anterior surface of the mold which has been introduced and anchored as above, being sutured to the external perichondrium on the contralateral side

11 The endotracheal catheter is removed, a No 6 tracheal cannula introduced, and any accumulated tracheobronchial secretions aspirated In closure, drainage is not used, except for that provided around the tracheal cannula, where the edges of the incision are brought together rather loosely

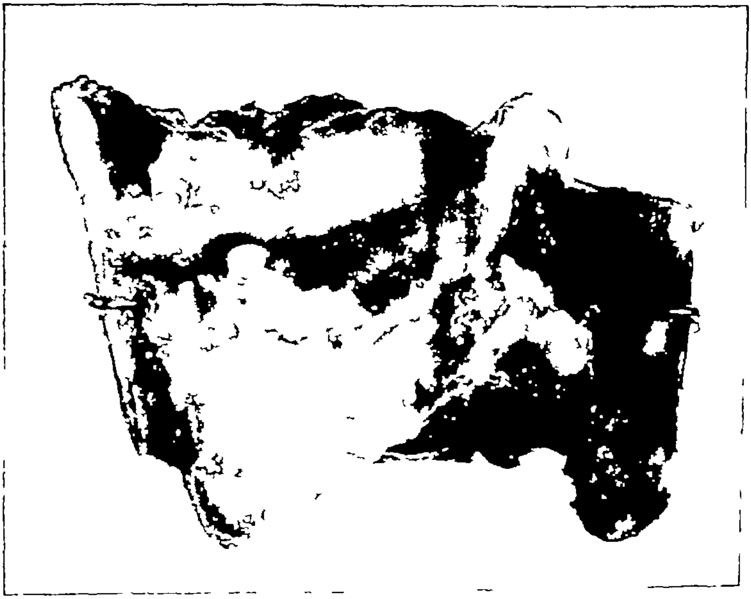

Fig 4 Representative surgical specimen removed by the extended fronto-lateral technique On the left are seen the edge of the divided left thyroid ala with corresponding portions of left cord and ventricular band On the right are the posterior border of the lower two-thirds of the right thyroid ala with its inferior cornu The entire arytenoid is included the articular facet being well shown The lesion involves the anterior commissure and entire length of the right cord with extension into the ventricle moderate impairment of motility had been observed Patient living and well after five years

POST-OPERATIVE CARE

The usual measures in the care of the tracheostomy patient are employed (humidification and catheter aspiration of secretions well below the end of the tracheal cannula) If secretions are tenacious, sterile saline 3 to 5 cc is installed through the cannula before each aspiration Nebulization of detergents such as Alevaire® or mucolytic agents and instillation of gomenol 10 per cent are useful in prevention of crusting The nursing staff should be instructed to report promptly any degree of dyspnea, however mild

With the mold in place, taking of nourishment does not appear to be an important problem Liquids are given for the first 24 to 48 hours, following which soft diet is usually well tolerated Antibiotics (penicillin or penicillin-tetracycline) are given until the likelihood of wound infection has passed, ordinarily about seven to ten days Pre- and post-operative cultures are useful in determining antibiotic susceptibilities, particularly if the hemolytic staphylococcus aureus, coagulase-positive, should be involved Demerol or codeine may be used for local discomfort, but are rarely required after the first 24 hours Ambulation is encouraged on the first post-operative day

The tracheal cannula is changed daily after the first day and the foam-rubber mold removed in about ten days Following removal of the mold, some spill-over of liquids into the larynx may be expected for a few days, and aspiration through the tracheal cannula is continued during this period as needed, to prevent the occurrence of aspiration pneumonitis Once swallowing can be accomplished without appreciable spill-over, the tracheal cannula may be removed, providing the airway seems adequate, after a trial period of corking for one or two days

SEQUELAE

As in other types of partial laryngectomy, the occurrence of excessive granulations may require direct laryngoscopic removal, although this is not likely if the skin-graft remains viable Sequestration of cartilage fragments has not been observed in any of our cases operated by this technique

Adherence of secretions to the area of skin graft has occasionally been noted for a few weeks or months after operation, but may be largely avoided by bedroom humidification

Post-operative stenosis of significant degree occurred in two of the series of 16 cases reported here Tracheostomy followed by insertion of an acrylic mold without re-opening the larynx for periods of ten and 21 days respectively was required, but in both cases decannulation was later accomplished (in 5 and 12 months respectively)

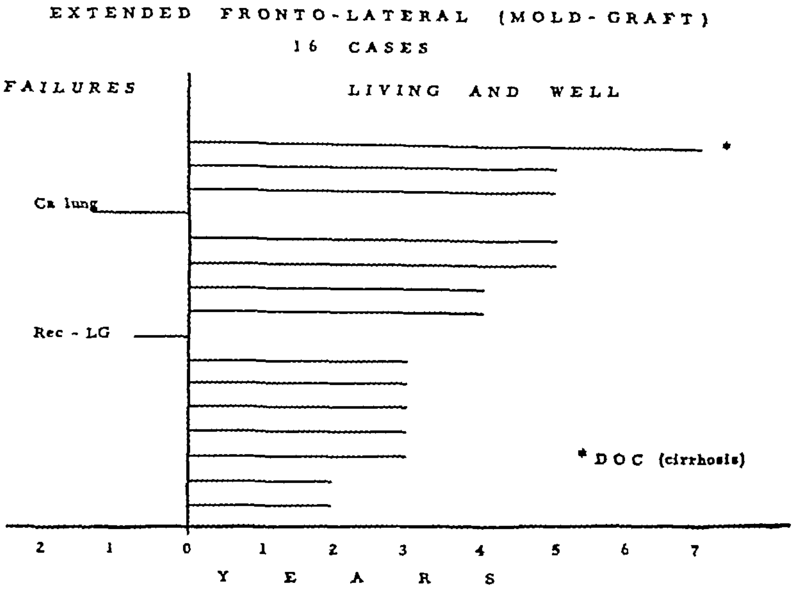

Fig 5 Results in 16 cases of partial laryngectomy by the extended fronto-lateral technique (see text)

RESULTS

Survival data in the 16 cases reported are shown in Table V Of the six patients who qualify for five-year follow-up, five (83 per cent) are apparent cures and one died 16 months after operation, of carcinoma of the lung, without evidence of local recurrence or cervical node metastasis Whether the lung carcinoma was primary or metastatic is undetermined

Of the entire group of 16 cases, only one patient developed local recurrence A laryngectomy was done, and he is living and well after four years There was no operative or post-operative mortality in this series

COMMENT

The frequency with which the "extended fronto-lateral" technique may be applied is not great During the period in which the 16 cases reported were observed, partial laryngectomy by other techniques was performed in 105 cases, *i e*, the relative frequency is approximately 1 7, however, no one would question that these patients, most of whom by previous standards would probably have been treated by laryngectomy, have been given an improved outlook for rehabilitation without appreciable increase in risk of recurrence Although the post-operative voice is, on the average, poorer than following the more limited types of partial laryngectomy, it is usually adequate for ordinary purposes of communication

As in any type of partial laryngectomy, the initial surgical exposure of the lesion should be through tissues known to be uninvolved, and the actual excision performed without haste, the margin of normal tissue surrounding the lesion being in view at all times Prompt healing is favored by preserving intact the perichondrium on at least one surface of all remaining portions of cartilage.

Our present technique differs from that of Figi in that, *1* the split-skin graft is fitted to the mucosal defect and sutured in place, rather than being fixed to the foam-rubber stent which is later to be removed, and *2* we have not found it necessary to insert routinely a second mold immediately following removal of the first, as described by Figi

Since all of the lesions treated in this series were essentially of the intrinsic type, or of only slightly greater extent, radical neck dissection was not performed In none of the cases were cervical nodes palpated initially, and none developed cervical node metastasis after operation

The "hemi-laryngectomy" of Gluck appears to have been largely abandoned as a form of surgical treatment, at least in this country Presumably this is because of the marked post-operative impairment of both the airway and the protective mechanism during swallowing The term "hemilaryngectomy," which implies removal of an anatomic half of the larynx (including cricoid) as described by Gluck, should probably not be used in referring to the type of operation which we have called, in an attempt to be accurately descriptive, the "extended fronto-lateral"

The usefulness of this procedure appears to be in its intermediate position between the more conservative types of partial laryngectomy and total laryngectomy By judicious selection of cases, it is likely that one may avoid, on the one hand, the temptation to treat by conservative operation a lesion which is slightly beyond the accepted indications, and on the other, to resort to total laryngectomy when a less radical operation would be sufficient.

SUMMARY

1 A technique of "extended fronto-lateral" partial laryngectomy is described, and results in a series of 16 cases of carcinoma of the larynx treated by this method are reported

CARCINOMA OF THE LARYNX

Contralateral Metastasis in Lesions Approaching the Midline[*][†]

NORMAN JESBERG, M D ,

Los Angeles, Calif

Statistical reports of laryngectomized patients are in close agreement as to the rate of recurrence, approximately 30 per cent of patients thus treated develop metastatic cervical lymph-node disease Of this group, approximately 35 per cent may be treated successfully by a secondary radical neck dissection In order to improve our present cure rate, we must consider what happens in these cases which develop cervical lymph-node extension

It is certain that an improvement may be expected by extending the primary operation to include the lymphatic contents of the neck, but the main difficulty is in selecting the cases which may be expected to benefit by such an extended operation Kuhn[1] has given us a statistical report on the types of cases where we may expect metastasis to occur He reported that 57 per cent of all non-cordal and diffuse growths were complicated by metastatic lymph-node disease, and that cordal growths with a moderate extracordal extension ranged up to 34 per cent Approximately 75 per cent of pyriform sinus and 78 per cent of marginal lesions were accompanied by metastasis

One cannot help being impressed by the element of unpredictability in the biological behavior of these growths For example, one patient may have a bulky, primary, extracordal growth without metastasis, and another case with a small cordal lesion may eventually manifest incurable metastatic disease The exceptional cases should not alter our plan of treatment, which is based on statistical probability,

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication May 8 1958

but we should recognize at the same time that there is a measure of individual behavior in the activity of the disease, the course it takes, and the response to therapy We should anticipate and be *prepared for the unexpected It is not* possible to make an absolute prediction on the basis of statistics, for no two cases are similar in all of the important particulars

Successful treatment by means of an extended surgical approach depends not only on anticipating what lesions may produce metastasis but also on which lymph-nodes may be involved

CLINICAL TYPES OF LYMPH NODE METASTASIS

The usual case developing clinical evidence of metastatic lymph-node disease does so in the first or second postoperative year The customary site is in the nodes of the neck on the same side as the primary growth These cases can be treated with success by a one-stage laryngectomy and ipsilateral neck dissection

In midline growths, such as those of the epiglottis, anterior commissure, interarytenoid space or postcricoid area, there is obviously a potential for bilateral metastasis, and these cases are much more difficult to manage Here one is at a loss to predict the direction or directions of neoplastic extension Until the time when one-stage laryngectomy with bilateral radical neck dissection is more feasible, one must choose either an operation including the laryngeal lesion and the lymphatics of the side of greater involvement, or wide-field laryngectomy alone

Less frequent and less to be expected is contralateral metastasis from a lesion decidedly on one side but approaching the midline Reed[2] has reported this to occur, however, in 10 per cent of the cases developing recurrence after laryngectomy If we include those lesions which produce bilateral metastasis, the figure comes closer to 20 per cent This contralateral metastasis is an occurrence which laryngectomy and neck dissection on the expected side of metastasis would

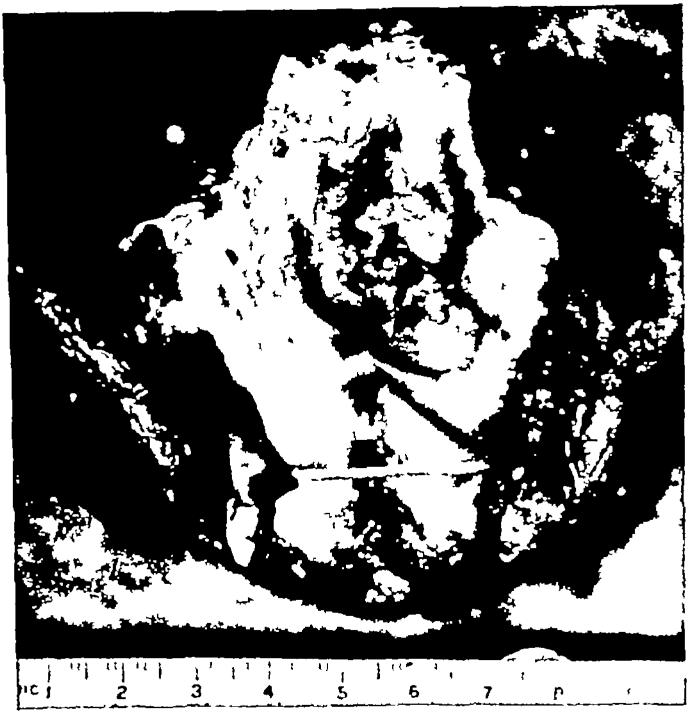

Fig 1 Photograph of the gross pathological specimen showing a large right epicordal growth involving the ventricular band base of the epiglottis and extending to the midline There is a congenital absence of the greater horn of the thyroid cartilage on the right

be powerless to cure I have had two cases which presented this problem

CASE REPORTS

Case 1 C H a 66 year-old white male was first seen April 3, 1951 and complained of progressive hoarseness of one-and a half year s duration and increasing difficulty in breathing and pain around the right ear of two months duration Examination of the ears was negative Examination of the larynx showed a large proliferating neoplastic lesion of the right ventricular band and base of the epiglottis The breath space was narrowed so that the true vocal cords could not be visualized There was no palpable cervical lymphadenopathy

Tracheotomy followed by laryngoscopy and biopsy was done The biopsy report was transitional epidermoid carcinoma Grade II Wide-field laryngectomy was performed under local anesthesia on April 30 1951 The surgical specimen is shown in Fig 1, and demonstrates a large right ventricular band and epiglottic base lesion which extends to the midline of the epiglottis The entire hyoid bone strap muscles, larynx and upper tracheal rings were removed The only other abnormal finding was that there was a congenital absence of the greater horn of the thyroid cartilage on the right

Convalescence was prompt, and he was discharged from the hospital on the ninth postoperative day He did not learn esophageal speech, due to a marked nerve deafness, but he progressed satisfactorily otherwise

On June 20, 1952, two hard, freely movable, metastatic nodules were palpated under the anterior border of the left (contralateral) sternomastoid muscle The nodules were approximately 2 centimeters and 1 centimeter in diameter Since they were freely movable and since he was otherwise a good surgical risk, a left radical neck dissection was advised This advice was declined, and the patient did nothing until July 6, 1953 when he presented himself for radiological treatment The metastatic neoplastic masses were then large, fixed and attached to the skin, 8000 r were given to the left side of the neck and as might be expected the response was not favorable The metastatic masses continued to get larger, and he died on January 26, 1955 At no time during the three-and a half years he was known to have metastatic disease in the left side of the neck did it become clinically manifest on the right side, the side of the epicordal primary growth

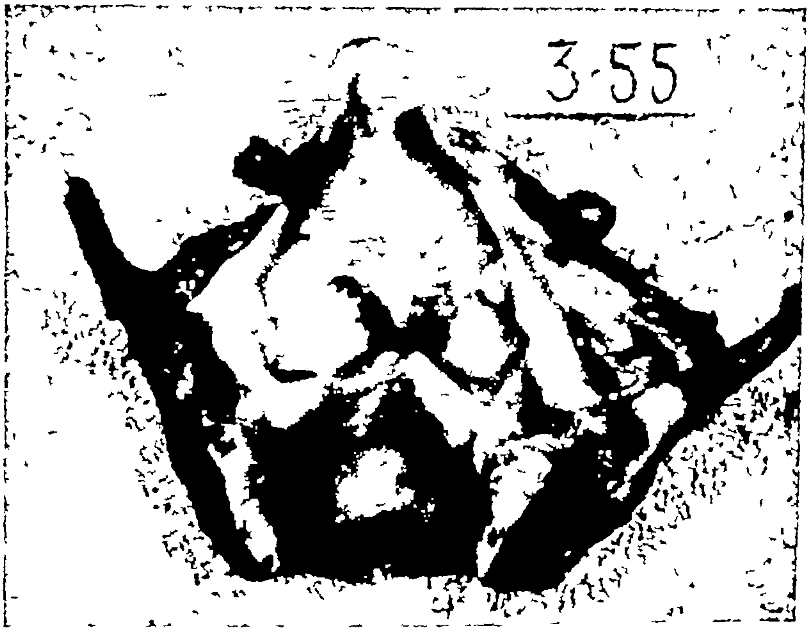

Fig 2 Photograph of the gross pathological specimen showing a growth of the right periarytenoid region extending into the ventricle There is a small cyst just below the anterior portion of the right aryepiglottic fold

Case 2 H V R, an 81 year-old white male, was first seen April 4 1955, and complained of hoarseness of six weeks duration He had been in good general health most of his life but had had a 'slight stroke two years before without any residual symptoms Examination of the larynx showed decreased motility of the right true vocal cord On a subsequent examination, a diffuse surface irregularity was observed around the right vocal process of the arytenoid cartilage and the posterior portion of the true cord Laryngoscopy with biopsy was not done until July 15 1955 at which time there was a diffuse peri arytenoid hemorrhagic, surface lesion extending into the right ventricle The pathological report was squamous carcinoma superficial (ungraded) There was no palpable cervical lymphadenopathy

Wide-field laryngectomy under local anesthesia was done on August 2 1955 The hyoid bone strap muscles larynx and upper tracheal rings were removed The lesion (see Fig 2) surrounded the right vocal process and measured 2x1 centimeters It appeared to be flat and superficial however on microscopic examination there was deep invasion around the right arytenoid cartilage extending into the deep intrinsic musculature It approached but did not reach the midline of the inter arytenoid space The microscopic diagnosis was Grade III epidermoid carcinoma He was discharged from the hospital on the eighth post-operative day and did well until January 1957 when a hard fixed metastatic neoplastic mass was palpated in the area of the left (contra lateral) deep superior, cervical lymph node In view of his age and rather feeble general condition and in view of the fixation a radical neck dissection was not advised He remained comfortable but slowly became worse and died on July 7 1957 Although the solitary metastatic mass in the left side of the neck enlarged at no time was there any clinical evidence of metastatic lymph node disease on the side of the primary laryngeal lesion

DISCUSSION

One could explain contralateral metastasis by the presence of anatomical variations in the lymphatic drainage system, however, Willis[3] has provided us with a pathological explanation, based on the disturbed dynamics of the lymphatic drainage system in the presence of neoplastic disease He suggests that the volume of primary neoplastic tissue may produce an obstruction in the normal lymphatic flow, forcing retrograde carriage of tumor emboli and crossed deposition to the opposite side He further states that this crossed metastasis may antedate lymphatic spread to the ipsilateral side One would expect this to occur in moderate to large volume tumors which approach the midline This was the situation in both of the cases reported In the epicordal case, the lesion was large and extended to the midline In the peri-arytenoid case, the growth appeared to be very superficial, however, on pathological examination it was found to extend deeply around the right arytenoid cartilage, although not reaching the midline posteriorly In each of these cases, a one-stage laryngectomy, with ipsilateral neck dissection, would have failed to encompass the disease

SUMMARY AND CONCLUSIONS

1 A report of two cases of diffuse unilateral carcinoma of the larynx, which produced contralateral metastasis, is presented

2 These cases confirm the incidence of contralateral metastasis previously reported by Reed

3 An explanation for this occurrence, based on retrograde embolic deposition, has been provided by Willis

AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY HOME STUDY COURSES

The 1958-1959 Home Study Courses in the basic sciences related to ophthalmology and otolaryngology, offered as a part of the educational program of the American Academy of Ophthalmology and Otolaryngology, will begin on September 1 and continue for a period of ten months Detailed information and application forms may be secured from Dr William L Benedict, the executive secretary-treasurer of the Academy, 15 Second Street, S W, Rochester, Minnesota Registrations should be completed before August 15

AN OBJECTIVE APPROACH TO THE COMPLAINT, LUMP IN THE THROAT[*][†]

G ARNOLD HENRY, M D ,

Toronto, Canada

Patients complain frequently of a lump in the throat This term sums up for them a number of vague, uneasy complaints which are annoying and, sometimes frightening

The physician in his office, or at the bedside, notes the complaints and clinical findings of his patient, and supplements his knowledge by laboratory studies With this picture in his mind, he may consult the literature

Modern systematized medicine usually assumes the diagnosis and recounts the symptoms, signs and laboratory findings accompanying the condition In many instances, the two pictures are readily superimposed, however, in a complaint such as this, the results are likely to be confusing Without a definite plan of investigation, the physician frequently succumbs to the easy and popular view, and labels the patient a neurotic

A few years ago, the author became interested in this complaint One hundred and seventy-five patients were studied objectively over a five-year period The results of that survey will follow

Reference to the medical texts showed this complaint to be associated mainly with functional disturbances Some authors exercised considerable imagination in determining the causes, others took a more objective approach

Thomson and Negus,[1] in discussing sensory affections of the pharynx, note that hyperalgesia and paraesthesia may lead patients to complain of soreness, irritation, burning, choking, dryness, etc, and a sensation of foreign body in the throat Most cases, they feel, are found among the hysterical and neurotic, but abnormal sensations are also met in the anemic, gouty, dyspeptic, alcoholic and hypochondriac The nose, throat, lingual tonsil, ears, teeth, refractive errors, etc, may be a cause of reflex irritation Lederer[2] says that, in a large proportion of so-called hysterical cases, some local lesion will be found to account for the symptom, if the pharynx is carefully examined

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication May 26 1958

In the literature, Tremble,[3] among others, directed attention to the lingual tonsil Mills[4] reported cases in which the nasal sinuses were the cause Morrison[5] stated that osteoarthritis of the lower cervical spine was a frequent cause of lump in the throat According to Boreadis and Gershon-Cohen,[6] osteoarthritis in the region of the vertebral foramina, with narrowing and roughening, is very important Inman[7] believes there are two separate kinds of sensation one caused by local inflammation over the arthritic process, and the other along the whole length of the peripheral nerve

Lindsay,[8] in discussing functional diseases of the upper swallowing mechanism, notes that a tonic spasm of the pharyngeal musculature may occur in disorders of the central nervous system, such as tetanus or brain injuries, as well as in acute local infections A tonic spasm probably occurs also in some psychogenic disorders (cricopharyngeal spasm, globus hystericus)

Pastore, Aldrich, Richards and Lindsay,[9] in a panel discussion on "A Lump in the Throat," covered the organic, psychic and physiological aspects of the subject

Clerf[10] stated that spasm of the cricopharyngeus frequently may be called a lump in the throat The latter may be caused, also, by organic lesions in the esophagus or by reflex action from more distant parts, associated with pharyngitis, arthritis, or straight autonomic stimulation This latter cause was developed by Hilger,[11] who pointed out that disturbances of the autonomic nervous system cause neurovascular changes in a number of areas These are evident in the hypopharynx as a pain and a lump Sjoberg,[12] in experimental work on cats, showed that a high bilateral vagotomy caused paralysis of the vocal cords and pharyngeal paralysis There was also a strong contraction of the cricopharyngeus and cardiospasm This, he claimed, was due to a sympatheticotonic contraction at both levels of the esophagus

A comprehensive study of the group was carried out under a wide variety of headings These may be arranged as to age and sex, site and duration of the lump, associated complaints, clinical findings, management, treatment and results of treatment Notes were made on the estimated psychogenic element involved in each case

TABLE I—AGE AND SEX OF 175 PATIENTS

Female		116
Under 40 years of age	65	
Over 40 years of age	51	
Male		59
Under 40 years of age	19	
Over 40 years of age	40	

TABLE II—SITE AND DURATION OF LUMP

Site of Lump—	
Cricoid Area	107
Vallecular Area	68
Duration of Lump on First Visit—	
Under 1 month	53
Under 2 months	91
Under 1 year	143
After 1 year	32

It will be noted that two out of three cases in this series were female Contrary to general opinion, they were more likely to be under the menopausal age Males with this complaint were more frequently over forty years of age

The lump was localized most commonly at the cricoid level in the midline In the remainder of the cases, it was situated higher, usually about the vallecular level, to one side or other of the throat Most of the patients were sufficiently impressed with their complaint to seek early advice

Lump in the throat is the expression the patient finds best describes the vague, disturbing sensation which warns him all is not well in this region of his body The associated complaints may be equally difficult to describe

In order of frequency, the following symptoms were noted A feeling of dysphagia, soreness, fullness, and foreign body Cough, hoarseness and bleeding were present in lesser numbers

Dysphagia, to the point of actual interference with the swallowing of fluids or solids, was not common, although occasionally seen with loss of weight It was usually described as difficulty with a dry swallow—their own secretion

TABLE III—ASSOCIATED SYMPTOMS

Dysphagia	60
Soreness Pain	57
Fullness Pressure	43
Feeling of Foreign Body	28
Less frequently—Cough, Hoarseness, Bleeding	

TABLE IV—CLINICAL FINDINGS

Pharyngitis	66
Post Nasal Discharge	37
Cervical Arthritis	23
Esophagitis	21
Malignancy	15
N Y D	30
Foreign body, cysts, elongated styloid process, hyperthyroidism, anemia, alcoholism, tobacco	

Soreness and pain were of a vague, nagging nature, usually about the location of the lump They occurred relatively more frequently in the ventricular area When present at the cricoid level, they occasionally radiated substernally

Fullness was usually associated with those who felt a foreign body or secretion might be present in the vallecular area Pressure was particularly noted in the vallecular area, or in patients with a large thyroid lobe

In order of frequency, pharyngitis, post nasal discharge, arthritis of the lower cervical spine, esophagitis and carcinoma of the hypopharynx and upper esophagus, were the most common findings Found less often were foreign body, cysts, particularly in the vallecula, elongated styloid process, lack of movement of a vocal cord It was noted in patients with hypothyroidism and sideropenic anemia Patients with hyperirritable throats, as well as those who used alcohol and tobacco to excess, were noted in the series

Pharyngitis was the most common finding, noted usually in the lingual tonsil and the region of the lateral pharyngeal bands Recent or active inflammation, rather than hypertrophy, was the important finding Frequently, there was an area of hyperemia in the region of the lateral pharyngeal band just medial to the posterior pillar of the tonsil

In most instances, alleviation of the offending cause by antibiotics or other therapy stopped or relieved the complaint Patients often stated that previous sore throats had caused the same complaint Occasionally, post nasal discharge accompanied the pharyngitis, but the two findings were not regularly associated

Patients with post nasal discharge fell into two groups those with profuse, and those with dry, crusty secretions, such as are frequently seen with a low-grade posterior sinus infection Suppurative antral and ethmoidal infections were a factor in a few cases, and treatment of the sinus infection removed the complaint Patients in the group were temporarily relieved of the lump by swallowing

A number of patients with obvious allergies or irritations to paints, chemicals and detergents were seen who, at times, had this complaint

Arthritis of the cervical spine was observed radiologically in a number of cases The lower three cervical vertebrae were more commonly involved On the whole, other significant findings were not present, although the patients occasionally complained of soreness in the back and sides of the throat and in other areas, such as the shoulders and arms Patients with severe arthritis did not complain of a lump in the throat

A number of patients felt that a foreign body might be present, accounting for their symptoms Where the history warranted, radiological studies and direct examination were carried out Sometimes, in indirect examination of the hypopharynx or direct examination of the esophagus, evidence of injury by a passing foreign body could be seen Only in a relatively small number was a foreign body found It would seem that, for a foreign body to be interpreted as a lump, it must be small and relatively non-irritating Injury to the retropharyngeal soft tissues with thickening may, in its early stages, feel like a lump

TABLE V—ESOPHAGEAL EXAMINATION 42 CASES

Negative		8
Upper Esophageal Cancer		7
Foreign Body Trauma		5
Diverticulum		1
Esophagitis		21
Cricoid and Cardiac Levels	10	
Cricoid Level	9	
Throughout	2	

Two instances will be mentioned briefly to show that these latter factors cannot be ignored A man was sent to my office with a lump in his throat and an accompanying pharyngitis and "flu" ear The night before, while eating a green salad, he had a stinging sensation in his throat Beyond the signs described, nothing further was evident by indirect examination in the region of the hypopharynx A week later, he returned with a greatly swollen arytenoid and pyriform fossa A small metal staple, probably the one used to close the plastic bag containing the greens, was seen on X-ray

The second case was sent to me a week after she had complained of a lump and history suggesting a foreign body There was no longer the complaint of a lump Instead, there was a massive swelling of her lower retropharyngeal tissues A huge, superior mediastinal abscess was drained through the neck.

Forty-two patients were examined esophagoscopically Early upper esophageal cancer, foreign bodies and foreign body trauma, and diverticula were found in a small number of cases to be the cause of the complaint

The remaining cases, constituting half of the group, were labelled esophagitis They did not include inflammatory changes associated wi the first half of the group Ten of the cases showed a circular band of hyperemia and esophagitis extending an inch or more down the esophagus from the cricoid level with a similar diffuse, and usually less apparent, area present at the cardia Nine cases showed esophagitis only at the upper or cricoid level, and included three with web formation Two cases had more or less diffuse esophagitis throughout with the greatest involvement in the upper area

The group with esophagitis at the cricopharyngeus and cardia probably represent spasm at the two levels The second group seemed to be associated with a number of factors, such as reflex spasm, allergic and other irritants, sideropenic anemia

RADIOLOGICAL FINDINGS

Many of these cases had radiological studies including the chest, cervical spine, barium bolus and occasionally, spot films This was carried out in every case before esophagoscopy Studies of the lateral cervical spine showed the soft tissues and largeal cartilages, as well as the cervical spine A number of interesting pictures of osteoarthritis were obtained Barium studies in most cases gave evidence of postcricoidal cancer, although there was a tendency sometimes to miss a fair-sized lesion in this area Definite evidence of cricopharyngeal spasm was not obtained, although, in a few instances, the radiologist suspected a hesitation in the bolus entering the esophagus

The management of a patient with lump in the throat is important. With such a vague complaint, the patient frequently suspects the worst The functional and emotional element is a varying factor in all cases Nearly everyone, when carefully questioned, can relate stresses and strains in their daily life In this series, clinical findings of significant value were found in the majority of cases Treatment of the known causes, with allowance for the overlying functional factor, should be the keynote of therapy

The history and examination must be thorough Treatment will be based on the examination findings Where there is no response to therapy in a month or so, thorough radiological studies should be made If the results are negative and supported by clinical findings, a further waiting period is justified Continuation of the symptoms at the cricoid level or lower should be followed by esophageal examination

As soon as possible, a confident attitude must be struck, and the patient given to understand that the examiner is familiar with his complaint He is told that it is seldom serious and that the necessary steps to safeguard his health have been taken It is well to let him know that, while most patients respond readily, others may have trouble for a considerable period of time The advice of the family physician is available in most cases, the internist is frequently consulted, the neurologist occasionally, and the psychiatrist rarely

The treatment of pharyngitis, inflamed lingual tonsils, lateral pharyngeal bands, postnasal discharge, foreign bodies and injuries caused by their passage, need not be labored Treatment for the hypothyroid and anemic is essential Advice regarding alcohol, tobacco and obesity is important

Esophagoscopy is more than a diagnostic procedure The stretching of the cricopharyngeal sphincter, breaking down of adhesions in arthritis cases, and removal of webs is beneficial The application of dilute silver nitrate seems beneficial in prolonged esophagitis In addition to medication for presenting conditions, thiamin chloride is frequently used, sodium iodide for dry throats and, in cricopharyngeal spasm, antispasmodics

The results of therapy were good in the pharyngitis cases Most cases fell into the cured or improved group, with few failures Improvement usually meant that the patient was cured of the complaint, but that it tended to recur with additional pharyngitis The results were much the same for postnasal discharge

The arthritis group was much harder to estimate, both as to their validity and the result of treatment It should be noted that the diagnosis is made, primarily, radiologically A like group of patients without complaint would, doubtless, show characteristic osteoarthritis Mostly, they were improved, or no better About half of the esophagitis cases were cured, the remainder falling about equally into the improved and the no better category

Patients with a legitimate foreign body or a vallecular cyst treated, did well The vague foreign bodies and the N Y D group were mostly improved, with some cured and others no better

Where the lump was an early symptom of carcinoma or a stenosing lesion, the progress of the patient was that of the disease The complaint, however, became lost in the more serious presenting symptoms

SUMMARY

Lump in the throat best describes the patients' summation of a number of vague complaints in this part of the body Vague symptoms are frequently the reflection of similar clinical conditions which may easily be overlooked

The complaint may be present with pharyngitis, postnasal discharge, moderate cervical arthritis and esophagitis It may occur with early retropharyngeal swelling, reaction to a foreign body lodged or passed, or a cyst in the vallecula When it occurs with new growth or stenosis, it is an early sign Emotional disturbances are capable of causing the complaint, and frequently affect the duration and intensity of the presenting symptoms A number of general systemic conditions play an important part

CONCLUSIONS

There has been a tendency to place the patient with the complaint, lump in the throat, in the realm of the neurotic In many cases, there is a varying element of truth in this belief

An objective approach to the problem uncovers significant clinical findings which are the primary cause in the majority of cases Satisfactory management of these patients embodies practice of the true art and science of medicine

DOES IRRADIATION OF INFANTS AND CHILDREN CAUSE CANCER OF THE THYROID?*†

Shirley Harold Baron, M.D.,
San Francisco, Calif.

The possibility that cancer of the thyroid in children and adolescents might be related to previous irradiation of the head, neck, or thymus in infancy or early childhood, should be of great concern to otolaryngologists, the majority of whom have prescribed some form of ionizing radiation as an adjuvant in the treatment of recalcitrant ear, nose and throat diseases.

Duffy and Fitzgerald,[1] in 1950, suggested that irradiation of the thymus in infancy might be an etiological factor in cancer of the thyroid in children and adolescents. Clark,[2] in 1955, impressed with this possibility, reviewed his cases of cancer of the thyroid in this age group. He discovered in his 13 cases that all had been subjected to previous irradiation: three, to the upper chest for an enlarged thymus; three, to the neck for cervical adenitis; five, to the head and neck for enlarged tonsils and adenoids; one, to the face and anterior chest for sinusitis and peribronchitis; and one, to the anterior upper chest for pertussis.

Disturbed by this startling report of Clark's, I reviewed two cases of cancer of the thyroid in children that I had seen that year (1955) and found that they both had had irradiation for an enlarged thymus in infancy. Subsequently, I encountered two more cases, and an additional three cases were reported to me by two colleagues. The following are the case reports.

Case 1. D. R.—Female, 18 years of age. Born Feb. 1, 1940. Pertussis Aug. 8, 1940. Chest X-ray Sept. 5, 1940, possibility of an enlarged

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication May 26, 1958.

thymus" Given 204 r of X ray radiation therapy to thymus (102 r, Sept 13 1940, and 102 r, Nov 29 1940) Mass in isthmus and left lobe of thyroid noted on Nov 10, 1951 (11¾ years of age) Surgery done on July 9, 1952 (12 years, 5 months of age) Diagnosis Papillary carcinoma of the thyroid, with extension to the pretracheal fascia and regional lymph nodes, supplementary X ray therapy between July 30 1952, and Sept 5, 1952 X ray chest, Aug 12, 1952, showed pulmonary metastases, which have progressively increased to the present however, patient appears well and has no complaints Interval between irradiation and diagnosis of cancer, 11 years, 10 months

Case 2 S O—Female 12 years of age, born June 11, 1945 Papillary carcinoma surgically removed on April 6, 1954 (8 years, 10 months of age) Supplementary X ray therapy Chest X ray films were clear at that time, chest X rays Dec, 1957, and Mar 1, 1958, suggest metastases Patient appears well and has no complaints

In 1955, when I reviewed this case, the pediatrician stated that this child had had irradiation both to the thymus and nasopharynx, however, in 1958, a record of prior irradiation could not be found, hence, there is no certainty that this patient had had prior irradiation

Case 3 R W—Male 18 years of age Irradiation to thymus for respiratory difficulty at four months of age, mass in thyroid discovered at age 15 Surgery right radical neck dissection and total thyroidectomy for papillary adenocarcinoma Postoperative complication cerebral edema and partial blindness which persists, feels well

Amount of irradiation in infancy could not be obtained, but there is no question that it was given Interval between irradiation and diagnosis of cancer 15 years

Case 4 M M—Female, 11 years of age Irradiation to thymus at eight months of age Total of 800 r (four treatments of 200 r each measured in air) were given in a two week period Jan 5, 1948, using 200 kv 50 cm distance and ½ mm of copper and 1 mm of aluminum filtration Total thyroidectomy and left radical neck dissection, Sept, 1952 (age 5 years 4 months), supplemented with radioactive iodine, Oct, 1952 Diagnosis Alveolar carcinoma of thyroid and regional lymph nodes Present condition feels well but there is evidence of lung and mediastinum metastases Interval between irradiation and diagnosis of cancer 4 years, 9 months

Case 5 S B*—Female, 19 years of age Irradiation to thymus at six months of age Total dose 450 r (150 r, 6/14/39, 150 r, 6/21/39, 150 r 6/28/39), 200 kv 1 mm copper and 1 mm aluminum filter Thyroid surgically removed 16 years of age Diagnosis Adenocarcinoma, patient is asymptomatic at present No evidence of pulmonary metastases, interval between irradiation and diagnosis of cancer 15 years

Case 6 C P*—Male 12 years of age Irradiation of nasopharyngeal lymphoid tissue at about the age of five dose not known Two stage operation for cancer of the thyroid with cervical node metastases *1* Right lobe of thyroid removed and right radical neck dissection, *2* two weeks later left lobe of thyroid removed and partial left radical neck dissection, supplementary therapy with I^{131} At present almost three years later no evidence of neck recurrence or lung metastases Interval between irradiation and diagnosis of cancer 7 years

Case 7 D J—Male 7 years of age Four X ray treatments to the thymus at three months of age exact dose not known Surgery for cancer of the thyroid with metastases to cervical nodes total right thyroidectomy with right radical neck dissection and sub-total left thyroidectomy, supplementary therapy with I^{131} At present two and one-half years later, no evidence of neck recurrence or lung metastases Interval between irradiation and diagnosis of cancer 7 years

REPORTS FROM THE LITERATURE

These seven cases (one doubtful), added to those of Clark, prompted this review of the evidence for and against the possible relationship of cancer of the thyroid in children and adolescents to previous irradiation

Duffy and Fitzgerald,[1] in 1950, reported 28 cases of histologically diagnosed thyroid carcinoma in children and adolescents, 18 years of age or younger Ten cases in this series had been subjected to irradiation to the thymus for obstructed respiratory symptoms ascribed to "enlargement of the thymus" In all cases, these were short courses of low voltage Roentgen rays administered some time between the fourth and sixteenth month of life These authors stated, "to propose a cause-and-effect relationship between thymic irradiation and the development of cancer would be quite unjustified on the basis of data at hand, when one considers the large number of children who have had irradiation to 'enlarged thymus', however, the potential carcinogenic effects of irradiation are becoming increasingly apparent, and such relationships as those of thymic irradiation in early life and the subsequent development of thyroid or thymic tumors might be profitably explored" Seven years later, Duffy[3] stated, "there is strong circumstantial evidence that therapeutic X-irradiation in infants may be an etiologic factor in thyroid cancer of childhood and adolescence"

Simpson, Hempelmann and Fuller,[4] in 1955, reported a study of the subsequent history of 1,400 of 1,722 children who received X-ray therapy to the thymus gland In 17 of these children neoplasia is known to have developed, including seven cases of leukemia and six of carcinoma of the thyroid This is a significantly higher incidence than was found among the untreated siblings of the irradiated children or in the general population In addition, nine treated children were found to have had thyroid adenoma All of these cases of cancer of the thyroid had had an amount of irradiation of 200 *r* or more

Adding to this study, two years later Simpson and Hempelmann[5] brought the total cases traced to 1,502 treated by X-ray and 1,933 of their untreated siblings Of those treated by X-ray the known cases of thyroid cancer increased to 11 Relative to their report of an increased incidence in leukemia, it is noteworthy that Court-Brown and Abbatt[6] reported an increased incidence of leukemia in patients with ankylosing spondilitis treated with X-ray, and Stewart[7] and associates speculated that diagnostic irradiation *in utero* may occasionally cause leukemia or cancer in the unborn child

Winship[8 9] started a survey of childhood thyroid carcinoma in 1948, but not until 1950 did he start to inquire about a history of irradiation In his report of 275 cases in 1955,[8] Winship stated, "Counting all the known cases in the United States of childhood carcinoma of the thyroid, almost 20 per cent have had irradiation of the thymus gland or to the neck for some other disease This is a significant percentage"

Majarakis, Slaughter, and Cole,[11] in 1956, recorded 15 cases of cancer of the thyroid in children and adolescents between five and 20 years of age Ten of these had a history of irradiation to the head and neck between two months and six years of age, with doses ranging from 200 *r* to 625 *r* In this group of nine females and six males, the interval between the therapy and the diagnosis of cancer was approximately 7 8 years

Frantz[12] told of two cases of carcinoma of the thyroid, one following irradiation for the keloid of a burn scar and the other for a giant tongue Cancer developed after 10 years in one and 15 years in the other The radiation in each case was in small doses

In 1956, Fetterman[13] reported ten cases of thyroid carcinoma in children under 16 years of age Eight of these had received prior irradiation, two for hemangiomas of the upper face and chest, two for enlarged lymph nodes, one for enlarged tonsils, and three for a presumably enlarged thymus Fetterman emphasized the importance of repeated questioning which doubled the number in his series known to have been previously irradiated, that is, in four of his eight cases a discovery of previous irradiation was made only after repeated questioning Fetterman suggested that, in the series of Ravdin and Horn,[14] and of Warren and associates,[15] more pointed questioning might have elicitied information that there had been previous irradiation in a higher percentage of cases Klopp,[16] too, felt that the incidence of previous irradiation in childhood thyroid cancer would be even higher if more correct information could be obtained by more careful questioning He related the story of one case in which previous irradiation had been denied by the patient and the father, but later information from the divorced mother in another city revealed that the patient's thymus had been irradiated in infancy

In an article from the Johns Hopkins Hospital, which is in the process of publication with Dr Samuel Asper[17] as the principal investigator, the following is being stated [27] "In a survey at the Johns Hopkins Hospital, there were found 40 thyroid carcinomas in people under 25 years of age, 17 of these had received X-ray therapy of some kind Of the 17, six had so-called cross-fire X-ray of the tonsils, two had X-ray of the tonsils and nasopharynx, four received X-ray to the thymus, two, X-ray for acne of the upper back and face, one, X-ray for an enlarged tongue, one, X-ray for a laryngeal polyp, and one received treatment by radium pack over a hemangioma, which presented over the inner portion of the clavicle

Notwithstanding all this evidence, there are a number of factors which have been presented in opposition to the belief that there may be an association of irradiation in infancy to carcinoma of the thyroid In an editorial in the *British Medical Journal*,[18] referring to the reports of Rawson and associates[19] and Bielschowsky,[20] it is stated "It could be argued, however, that the thyroid cancers in the treated children were not caused directly by the irradiation, but were in some way due to the destruction of the thymus There is evidence (Rawson, et al) that the thymus may be one of the sites of removal of circulating thyrotrophic hormone Since thyrotrophic hormone is known to play a part in the development of cancer of the thyroid (Bielchowsky), it is conceivable that the destruction of the thymus might in itself do something to provoke cancer of the thyroid by increasing the amount of thyrotrophic hormone in the blood " Counteracting this speculation is the number of thyroid cancer cases in which the previous irradiation did not involve the thymus

It is possible, too, that some of the thyroid cancers, thought to have developed after irradiation, might have been present before the irradiation Winship[10] pointed out that in his collected series of 400 cases of carcinoma of the thyroid in children, 12 had tumors at birth, these subsequently proved to be carcinomas Uhlmann[21] told of a patient who failed to respond to X-ray therapy for enlarged cervical lymph nodes, two months after treatment a biopsy revealed metastatic carcinoma of the thyroid

Uhlmann,[21] in a study of 25 patients under the age of 21 who had been referred to him for treatment of carcinoma of the thyroid during 18 years between 1938 and 1956, found that only four had had previous irradiation During the same 18 years, he administered radiation therapy to 2,500 children for hypertrophic lymphoid tissue in the pharynx and for enlarged tonsils In a follow-up of only 480 cases of these, not a single instance of carcinoma was found during a period of seven years Uhlmann measured the amount of radiation that reaches the thyroid during X-ray treatment for benign hyperplasia of the nasopharynx His customary three treatments, with a total of 375 *r* to each of two lateral fields, resulted in a maximum of 18 *r* reaching the skin above the thyroid over a period of two weeks which, according to him, is much less than the amount of radiation that reaches the thyroid during the usual fluoroscopic examination of the chest *

Uhlmann, in his report of 1956, stated that he thought it significant that in animals cancer of the thyroid had never been produced with X-rays, however, in 1957, Doniach[22] produced thyroid cancer in seven out of 21 rats, when 1,100 rads of X-ray therapy was administered to the rat thyroid followed by prolonged methylthiouracil therapy In only one of 13 animals with this same X-ray dose but without methylthiouracil, did thyroid cancer develop

---

*A measure of fluoroscopic radiation was made by the X-ray Department of the Stanford University Medical School The maximum dose of radiation at table-top was 3 2 r per minute A skillful fluoroscopist can cone down the field of exposure to a very small area in the chest thus avoiding the thyroid therefore members of the Department feel that in a well-planned fluoroscopy it would be extremely unusual to expose the thyroid to a greater amount of radiation than might be applied to the same area during therapeutic use for benign conditions

Uhlmann feels that, statistically, the correlation of irradiation and the development of carcinoma of the thyroid is untenable In addition to his own cases, he refers to other reports of 68 children with cancer of the thyroid (Dailey and Lindsay, 23,[23] Horn and Ravdin, 22,[14] and Warren and associates, 23[15]) and only one had had previous X-ray therapy

There is, on the other hand, certain experimental work referred to by Duffy,[3] which indicates that the administered irradiation is potentiated by endogenous endocrine activity in the development of thyroid cancer Such a mechanism may account for the increased risk after the use of X-rays in the infant or growing child, compared to that in the adult Duffy stated, "Doniach[22] has suggested that a small dose of X-irradiation may act as the initiating factor, and that the subsequent 'normal' growth and development of the thyroid from infancy to puberty may be the promoting factor in the production of the thyroid cancer in childhood The dose of the external X-rays, or other radiation, would not then be as important as the time at which it is administered, since the mature adult thyroid tissue is apparently reasonably resistant to the development of radiation cancer "

DISCUSSION

Bordley,[27] referring to the Johns Hopkins' survey, stated "*1* None of these cases received any of their ray therapy at the Johns Hopkins, which might lead one to believe that in institutions where great care was taken by people specially trained for this work, the instance of needless irradiation of surrounding tissues is greatly reduced, *2* In the cases where X-ray was used on the tonsils and the nasopharynx, it was believed by the investigators that the coning of the X-rays was unnecessarily large, and that the spread of the treated field was very much larger than it should have been, with pretty definite indication that the thyroid became involved in the field, *3* There has been no evidence of any malignant changes related to irradiation with the Beta ray applicator. This is perfectly natural, due to lack of penetration of the Beta rays. To my mind, it is perfectly evident that to X-ray someone because a tongue is enlarged, or because he has a laryngeal polyp, or to remove the tonsils in a child, is a rather unnecessary procedure."

Duffy[24] stated, "Although cause and effect have obviously not been proven, the possibility of radiation being a factor in the cause of thyroid and other cancers in the young is such that radiation for benign conditions in infants and early childhood should be condemned." A similar sentiment was expressed by Simpson and Hempelmann,[5] Klopp,[16] Berman,[16] Copeland,[16] Dennis,[28] and Fetterman.[13] If this be the case, what then should be the position of the otolaryngologist who has prescribed radiation as a therapeutic aid for many years? He cannot ignore the reports of the potential hazards of radiation, nor can he discount experiences such as those of the otolaryngologists of the Johns Hopkins Hospital, who have used nasopharyngeal radiation since 1924, and in whose cases it has been said,[27] there has never occurred cancer of the thyroid. A step toward the solution of this dilemma would be a re-evaluation of the indications. One might ask, "has irradiation been really necessary?" For example, could not the 2,500 cases reported by Uhlmann,[21] irradiated for enlarged tonsils and adenoids, throat infections, recurrent colds and impaired hearing, have been reduced to 250 or even 25? Does one have to resort to radiation (as reported[25]) for chronic cough, coryza, mouth breathing, snoring, nasal voice, anorexia, gagging, vomiting and choking due to postnasal drainage? Is radiation really indispensable in treating conduction deafness of tubal origin?

There is no question that much of the radiation prescribed could be dispensed with. I stated this in a previous paper,[26] and presented as an example of a certain group of patients, the case of a seven-and-a-half-year-old girl whose second adenotonsillectomy was supplemented with X-ray irradiation Her good hearing result (see Fig 1) was thought at the time to be due to the combination of surgery and irradiation, but subsequent controls, as represented in Fig 2, treated by meticulous nasopharyngeal surgery but without irradiation, produced the same good results

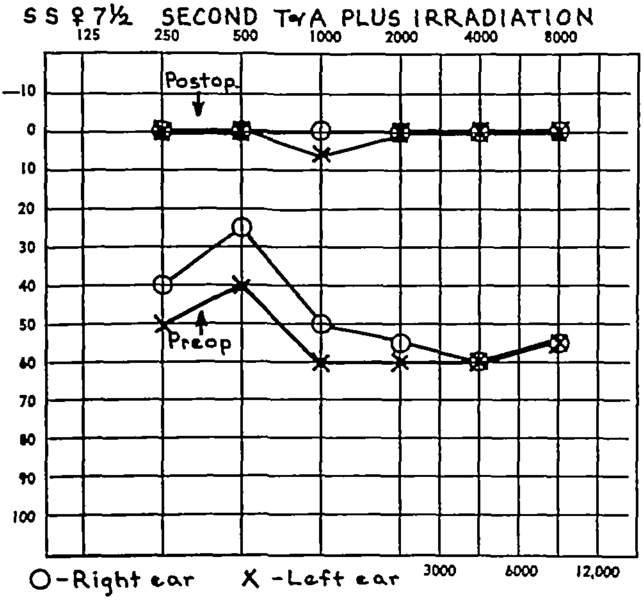

Fig 1 Pre- and postoperative audiograms of S S a 7½-year-old girl The surgery a second adeno-tonsillectomy was supplemented with Roentgen irradiation This was one of a number of cases whose good results were thought at the time to be due to the combination of surgery and irradiation but subsequent controls as represented by Fig 2 suggest that adequate surgery was responsible for the improvement.

Further evidence of unnecessary use of irradiation was pointed out in the case of a 45-year-old male (see Fig 3), who had tubal obstruction with secretory otitis conduction impairment in his only hearing ear He had had one course of 320 *r* of X-ray irradiation to both right and left sides, another course of 700 *r* four years later, and an additional 50 mg radium plaque, Monel-filtered, against each Eustachian tube for a period of eight minutes His recurrent secretory otitis and deafness did not improve Subsequently surgical removal of the nasopharyngeal lymphoid tissue and tonsil tags, nine years after the first irradiation treatment, resulted in a cure of both the secretory otitis media and the conduction deafness Irradiation could have been avoided had surgery been tried first This also demonstrated that masses of lymphoid tissue are not always melted away by irradiation in the doses used for non-malignant conditions

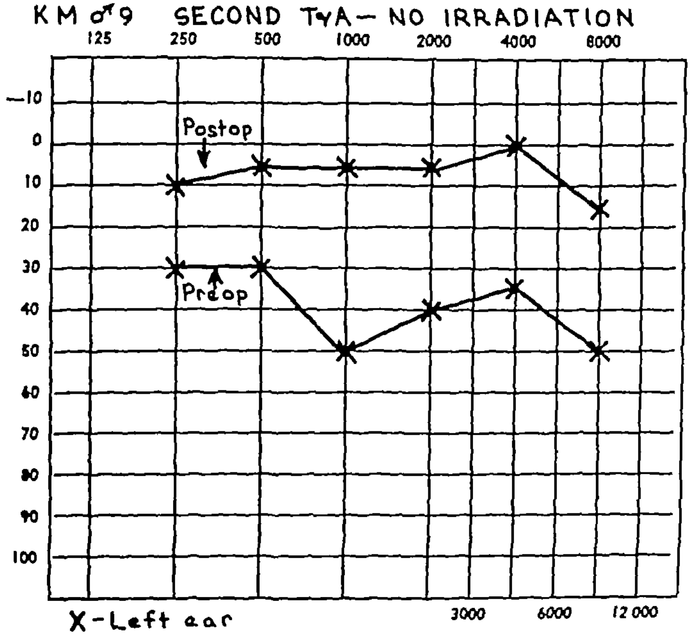

Fig 2 Pre- and postoperative audiograms of K. M. a 9-year-old boy His second adenotonsillectomy without supplementary irradiation resulted in a hearing improvement comparable to the group represented by Fig 1 who had had supplementary irradiation

In general, it can be said that if a patient with a non-malignant ear, nose and throat disease is treated by irradiation only after a fair trial of other adequate therapy, the number of individuals who would be exposed to irradiation would be very small

CONCLUSION

The few cases of cancer of thyroid in children having had prior irradiation, herein presented, in addition to those previously reported, do not permit one to conclude that irradiation of infants and children causes cancer of the thyroid to appear in later years, however, the possibility is sufficiently startling to make one suspicious of potential hazards of even small doses of radiation in children Until the evidence is conclusive, for or against this relationship, one should use great restraint in undertaking irradiation for any nonmalignant condition in infants and children For the otolaryngologist, this caution should prove no handicap, for there are very few benign ear, nose or throat diseases of

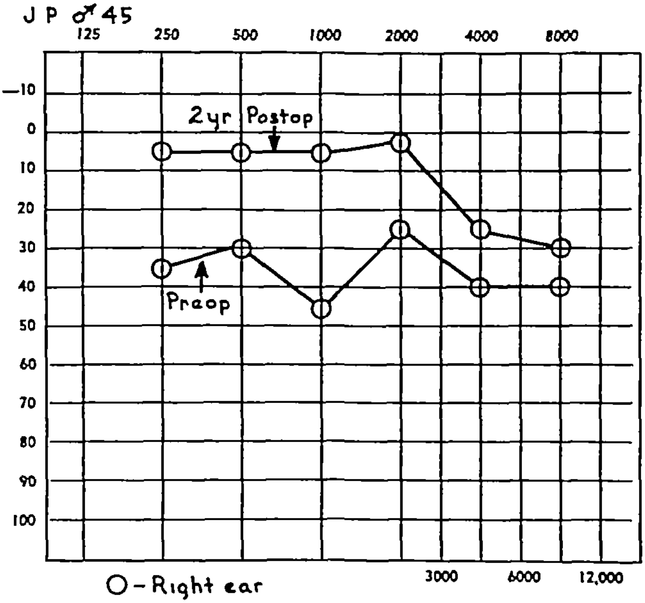

Fig 3 Pre- and postoperative audiograms of Mr J P age 45 Chronic serous otitis media in right ear Course of X-ray irradiation to nasopharynx in May 1947 and October 1951 and one treatment with radium plaque Monel-filtered in December 1951 No improvement until nasopharyngeal lymphoid tissue and tonsil remnants were removed surgically in June 1956

tube for a period of eight minutes His recurrent secretory otitis and deafness did not improve Subsequently surgical removal of the nasopharyngeal lymphoid tissue and tonsil tags, nine years after the first irradiation treatment, resulted in a cure of both the secretory otitis media and the conduction deafness Irradiation could have been avoided had surgery been tried first This also demonstrated that masses of lymphoid tissue are not always melted away by irradiation in the doses used for non-malignant conditions

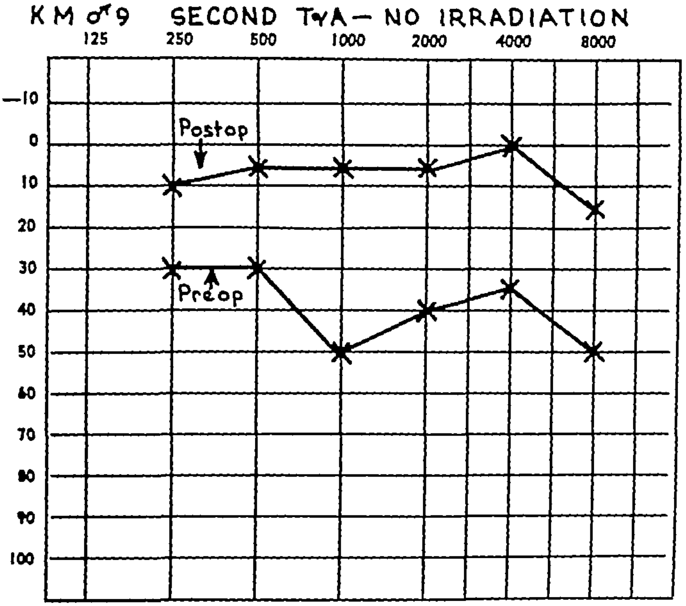

Fig 2 Pre- and postoperative audiograms of K. M. a 9-year-old boy His second adenotonsillectomy without supplementary irradiation resulted in a hearing improvement comparable to the group represented by Fig 1 who had had supplementary irradiation

In general, it can be said that if a patient with a non-malignant ear, nose and throat disease is treated by irradiation only after a fair trial of other adequate therapy, the number of individuals who would be exposed to irradiation would be very small

infants and children which absolutely require irradiation therapy

SUMMARY

1 Seven cases of thyroid cancer in children are reported, six of them are known to have had therapeutic irradiation in infancy These cases add further weight to the many similar reported cases of childhood thyroid cancer, pointing to X-ray as a major etiologic factor for thyroid cancer in young persons

2 The evidence for the relationship of irradiation and childhood cancer of the thyroid is inconclusive Some series reported show little correlation, however, in the light of reported evidence it appears not improbable that irradiation of the head, neck or mediastinum in infancy may increase the chance of getting thyroid cancer some years later Unless the etiologic connection comes to be disproved, it would appear wise not to use radiation on children if any other therapy can be found

ADDENDUM

Since presenting this subject before the American Laryngological, Rhinological and Otological Society, Inc, at San Francisco on May 21, 1958, an additional case appeared at the Stanford University Hospital, it was called to my attention by Dr Joseph P Kriss, and is being presented through the courtesy of Dr Carleton Mathewson, Jr, who is in charge of the patient

Case 8 R R 9 years of age Irradiation to thymus at three weeks of age Total of 225 *r* were given in a three-week period starting April 18 1949 using 140 kv peak 20 milliamperes filtration ¼ mm copper and 1 mm aluminum half value layer 42 mm of copper target skin distance 50 cm cone field size 10x10 cm but irradiated size 6x10 cm In June 1957 surgery consisting of a left radical neck dissection with the removal of the left lobe and isthmus of the thyroid, was done On *November 4* 1957 additional surgery which involved a right radical neck dissection and the removal of the right lobe of the thyroid was done In January 1958 the child developed dyspnea A chest X ray revealed diffuse bilateral pulmonary metastases Additional therapy in the *form of* I^{131} was given in June, 1958

Interval between irradiation and diagnosis of cancer eight years

Average interval between irradiation and diagnosis of thyroid cancer for all cases herein reported 9 8 years

ALUMNI ASSOCIATION OF THE NEW YORK EYE AND EAR INFIRMARY

The Annual Spring Meeting of the Alumni Association of the New York Eye and Ear Infirmary last April was so well received that it has been decided to expand next year's meeting, which will take place from April 20-23, 1959

Symposia and lectures on Hearing Rehabilitation, Endoscopy, and Ear Surgery will be conducted It is also planned to offer refresher courses in Mastoid and Fenestration Surgery and Stapes Mobilization Techniques

More complete information regarding the meeting will appear in a later issue of THE LARYNGOSCOPE

CYTOLOGIC DIAGNOSIS AND PROGNOSIS IN CARCINOMA OF THE MOUTH, PHARYNX AND NASOPHARYNX

EUGENE S HOPP, M D ,[*][†]

San Francisco, Calif

According to a survey reported in the *Cancer Bulletin*,[1] mouth and lip cancer comprise 10 per cent of all male cancer This same publication estimates that as high as 80 per cent of deaths from cancer of the mouth could be prevented by early recognition and prompt adequate treatment

No attempt will be made in this paper to discuss clinical findings or treatment in cancer of the mouth and nasopharynx The sole purpose of this study is to describe a valuable adjunct to the early diagnosis of cancer of these areas, and to demonstrate a means of evaluating radiation treated lesions in which repeated biopsies would prove harmful

It was in 1949 that the late Dr Morrison,[2] Dr Wu and I first published the results of the application of the Papanicolaou-Traut[3] smear technique of cytologic diagnosis to cancer of the upper respiratory tract. In that first publication we were primarily concerned with the application of the smear technique to the early diagnosis of lesions in the nasopharynx. The success achieved in this area soon led to the application of the same technique to the early diagnosis of lesions in the mouth, pharynx and even larynx. The results of the cytological studies made in these areas have been excellent. It should again be emphasized, as it was in the original paper, that this procedure is not intended to replace tissue biopsy and histological examination

ALUMNI ASSOCIATION OF THE NEW YORK EYE AND EAR INFIRMARY

The Annual Spring Meeting of the Alumni Association of the New York Eye and Ear Infirmary last April was so well received that it has been decided to expand next year's meeting, which will take place from April 20-23, 1959

Symposia and lectures on Hearing Rehabilitation, Endoscopy, and Ear Surgery will be conducted It is also planned to offer refresher courses in Mastoid and Fenestration Surgery and Stapes Mobilization Techniques

More complete information regarding the meeting will appear in a later issue of THE LARYNGOSCOPE

the cell and degree of cornification, the staining color is not specific As might be expected, greater numbers of cornified cells appear in the tongue and gingival smears, fewer in cheek and post-tonsillar smears

Fifty normal smears from adults of almost equal sex distribution and varying ages show no variation of cytology for sex, age or phase of the menstrual cycle Such studies were reported by Miller et al[6] and Montgomery[5] in 1951

In the normal smear much nuclear variation is encountered both as to size and shape and position in the cell, but the chromatin content is usually evenly distributed and the cell cytoplasm has a distinct, clearly defined border The larger cells in mouth smears range from about 70 to 100 mμ in size and the medium-sized cells range from about 35 to 40 mμ The nucleus is small compared to the size of the cell, being about 10 mμ in the large cells and 5 mμ in the medium-sized cells

Pre-Malignant Cytology Smears in ten cases of leukoplakia of the mouth were examined As noted by Weinman[9] and Montgomery and von Hamm[10] there appears to be no characteristic cell type

Malignant Cytology Mouth smears from malignant areas are usually rich in cells, the cell nucleus and nucleolus are enlarged, multiple nucleoli are frequent, and the diagnosis of malignancy may be made on the basis of thickened nuclear membranes, hyperchromasia, abnormal clumping of chromatin material and uneven distribution of chromatin bits The cell itself has ill-defined borders, may be distorted or even without a visible, true wall Clumps of these cells are characteristic, but they may be found singly Of course, the normal cytology of squamous cells, leukocytes and clasmatocytes, is also found in the malignant smear

Post-Radiation Cytology In carcinoma of the mouth and nasopharynx which is under treatment with X-ray, malignant cells usually disappear or show senile changes after about the third or fourth week of therapy There is an increase in polymorphonuclear leukocytes and in pink or red staining

Technique Various methods have been described for taking smears in the mouth and nasopharynx Gladstone[3] used both gelfoam and cellulose sponges The sponge was rubbed over the surface of the lesion and then sectioned Thirteen mouth lesions were thus smeared Two of these had a positive tissue biopsy for carcinoma and these two also had positive smears The remainder were all negative Montgomery[5] scraped the mucosa with a Woodson's No 2 metal plastic instrument, and Miller[6] and his co-workers used a wooden spatula Both obtained good smears, however, our original technique, slightly modified, still seems the simplest A tightly wound cotton applicator is rubbed over the surface of the lesion and the adjacent area The rubbing must be firm but not sufficient to produce active bleeding The cotton applicator is then rubbed on the surface of a clean, dry glass slide The slide is immediately immersed in the standard fixative solution of equal parts of 95 per cent alcohol and ethyl ether The slide is kept in the solution until ready to be stained Slides may be left in the fixing solution indefinitely or stained after a minimum of one-half hour

The staining technique follows the modified method of Papanicolaou and Traut[7] with but one exception EA 50 has been used to replace EA 36 or 25 of step No 6 More recently the technique of Pharr, Wood and Traut[8] has been followed in the staining procedure

Normal Cytology A study of the normal cytology of the respective areas being smeared is essential to the diagnosis of the malignant smear In general, the histological characteristics of the area determine the cells found in the normal smear In the nasopharyngeal smear there may be found ciliated columnar cells, columnar cells which have lost their cilia, lymphocytes and polymorphonuclear leukocytes Occasionally and particularly in infection histiocytes, epithelial cells, bacteria and erythrocytes are seen

In the mouth and pharynx ciliated cells are uncommon, and squamous epithelial cells predominate The staining of these cells varies from blue to red to yellow While the determining factors in the color range appear to be age or maturation of

TABLE II

RESULTS OF CYTOLOGICAL STUDIES IN CARCINOMA OF THE MOUTH

	Montgomery[13]	Wahl[11]	Peters[15]	Morrison[3]	Peters[11]	Silverman[12]	Hopp	Totals
Number of Patients	15	41	114	10	194	19	25	418
Positive Smears	13	41	110*	10	186**	18	24	402
Negative Smears	2	0	4	0	8	1	1	16
Positive Biopsies	15	41	114	10	162	18	25	385
Negative Biopsies	0	0	0	0	23	1	0	24

* 8 smears reported suspicious grouped with the positive

**32 smears reported suspicious grouped with the positive squamous cells This is especially noticeable in areas of ciliated epithelium where ciliated cells tend practically to disappear The staining characteristics of the cells are probably due to increased keratinization and decreased production of immature cells, with consequent increase in aged or damaged cells

RESULTS

One-hundred-and-four cases of benign lesions of the nasopharynx, mouth, tonsil, and larynx had Papanicolaou smears made without a false positive for carcinoma Peters[11] in a very recent report smeared 401 cases of leukoplakia, submucous fibrosis, scleroma and other benign conditions in the mouth and obtained three false positive smears for a total error of 0 7 per cent Silverman[12] and his co-workers at the University of California, in a fine study soon to be published, reported no false positive mouth smears in a group of 60 patients

TABLE I

	No of Cases of Carcinoma	Positive Smears	Negative Smears
Nasopharynx	12	11	1
Mouth	25	24	1

Table I records the results of the cytological studies in the nasopharynx, mouth, tonsil and larynx

Three cases of carcinoma of the mouth were studied cytologically during and after radiation treatment All smears were negative by the fourth week of therapy One remained negative and the patient showed no evidence of recurrence five years post-radiation The other two (anterior pillar and tonsil) yielded positive smears within two months after therapy and were confirmed by subsequent biopsy Silverman[12] and his co-workers have reported a case which illustrates the point very well Their patient was a 46-year-old male found on examination and biopsy to have a lympho-

ANNUAL OTOLARYNGOLOGIC ASSEMBLY UNIVERSITY OF ILLINOIS

The University of Illinois College of Medicine Department of Otolaryngology announces its Annual Otolaryngologic Assembly from September 29 through October 5, 1958 The Assembly will consist of an intensive series of lectures and panels concerning advancements in otolaryngology, and evening sessions devoted to surgical anatomy of the head and neck and histopathology of the ear, nose and throat. Interested physicians should write direct to the Department of Otolaryngology, 1853 West Polk Street, Chicago 12, Ill epithelioma of the soft palate The lesion disappeared after X-ray therapy, but a small ulceration developed a few months later The problem was to differentiate between recurrence and post-radiation necrosis Biopsy in the irradiated area could have produced considerable difficulty if the lesion proved benign The initial smear was inconclusive but suspicious Repeat smears yielded a positive for malignancy This was then confirmed by biopsy

In Table II the statistics of several mouth smear studies have been assembled Two cases of carcinoma of the mouth were first discovered on routine smear by Peters[11] One had been thought to have an ulcerative stomatitis and the other an hypertrophy of the posterior pillar In Silverman's[12] series, four cases of mouth lesions were first diagnosed as malignant by cytologic studies

In conclusion, the smear technique is not intended to replace tissue biopsy It is a simple method of diagnosis, however, and can enable one to diagnose malignancy at an earlier stage In addition, radiation treated lesions can be kept under long term observation As Peters[11] so well stated "Repeated biopsies might be difficult, but repeated smears and occasional biopsy are possible and often desirable The reliability of the cytologic interpretation increases with the experience of the interpretor Cytology does not replace histology but supplements it"

than 150 cases of naso-sino-nasopharyngeal problems, both pre- and post-adenoidectomy, as part of a thorough investigation. This also included X-ray examination of the sinuses, bacteriological and cytological studies of nasal and sinus secretions and allergic tests. Our experiences have revealed that the information obtained by radiography of the nasopharynx is usually more complete and accurate than that obtained by other methods, and can be related to the surgical scope when operation is indicated. In addition, we have noted certain aspects in the radiographic evaluation of the nasopharynx which have not been previously discussed in the literature. We are reporting these data and experiences to emphasize the value of radiographic examination of adenoids.

REVIEW OF LITERATURE

Although the literature contains relatively little concerning the radiological investigation of the nasopharynx, nevertheless the potential value of this subject has been appreciated by a number of authors. The majority of these, as might well be expected, have been radiologists. In 1898, shortly after the clinical value of X-rays became known, Mignon[1] mentioned radiographing the adenoids in his thesis on "Radiology of the Respiratory Tract." In 1904, Scheier[2] reported the demonstration of the epipharynx and enlarged adenoids roentgenographically and the disappearance of the adenoids from the X-ray plate postoperatively. Technical progress, however, had not advanced sufficiently as yet to permit satisfactory results routinely, and little more was written on this subject for the next 20 years. In 1925, Grandy[3] described the soft tissue opacity of the adenoids in the nasopharynx and the narrowing of the airway locally. He also noted the increased airway following adenoidectomy.

Bernfeld[4] in 1927 was the first to stress the importance of the size of the nasopharynx in relation to the problem of obstruction of the airway by adenoids, the difficulty of their complete removal and the frequency of recurrences. He believed that complete resection was more difficult and recurrences of much greater frequency in patients with small epipharyngeal cavities. In 1929, Schuller[5] discussed the gen-

SOFT TISSUE ROENTGENOGRAPHY OF THE NASOPHARYNX FOR ADENOIDS [*][†]

INTRODUCTION

The accurate evaluation of the adenoids is of great importance in the proper management of naso-sino-nasopharyngeal problems so frequently encountered in infants and children Both the otolaryngologist and pediatrician appreciate that the clinical examination to determine the status of the adenoids is often difficult and unsatisfactory in these young patients Posterior rhinoscopy is usually impossible, with the result that digital palpation of the nasopharynx is the clinical method most often employed to estimate the degree of obstruction that exists in the nasopharynx, however, this diagnostic procedure is crude and fraught with serious difficulties It is questionable whether a probing finger can reach the vault of the nasopharynx behind the vomer, or determine the amount or depth of lymphoid tissue while an unwilling patient is crying and struggling Thus, information obtained in this manner is often incomplete and even inaccurate In addition, the psychic trauma which may accompany this manipulation is undesirable

In contrast, we have found that radiographic examination of the nasopharynx is a simple procedure which can be performed satisfactorily and with ease in children of all ages Roentgen ray exposure is minimal, approximately that of a routine chest examination We have used this method in more

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication May 26 1958

soft palate often brings this soft tissue density in contact with the soft tissues of the posterior pharyngeal wall, and thus reduces both the airway and the demonstrability of the adenoids We have shown, as have others,[10 13 15 18] that the soft palate is in a mid-position with the nasopharynx open during the simple suspension of respiration Phonation, swallowing and crying elevate the soft palate and diminish the nasopharyngeal airway Inspiration and expiration of air through the nose depresses the soft palate about equally and thereby increase the nasopharyngeal airway Position of the patient, whether supine, lateral recumbent, sitting or standing, plays no major role in elevation or depression of the soft palate, however, there is less elevation of the shoulders and thickening of the cervical soft tissues when the patient's head is held erect and the neck is slightly extended For these reasons our lateral views of the nasopharynx are made with the examinee erect, *1* with respiration suspended, and *2* during nasal inspiration

ROENTGEN ANATOMY

The nasopharynx is that portion of the respiratory airway situated behind the choanae and above the soft palate[5 19] The roof of the nasopharynx is formed by the basisphenoid and basiocciput, the posterior wall by the condyloid portion of the occipital bone and the adjacent anterior arch of the atlas, the floor by the superior surface of the soft palate, and the anterior boundary by the vomer and choanae medially, and the pterygoid plates laterally (see Fig 1) The roof, posterior wall and floor of the space are easily recognized on the radiograph The choanae and vomer, of considerable importance in the evaluation of adenoidal obstruction, cannot be directly identified on the film, however, an accurate estimation of the location of the choanae may be obtained since they are on the same plane as the posterior edge of the vomer The lower edge of this bone begins at the posterior margin of the hard palate (the palate bone) and extends upward and backward to articulate with the rostrum of the sphenoid at the under surface of the base of the skull The plane of the posterior margin of the hard palate can be delineated clearly on the film From this point a line drawn upward and backward to eral subject of bony deformities of the nasopharynx as demonstrated roentgenographically. He described the variations in size and appearance of this airspace, and quoted Testut and Jacob who believed that the infantile nasopharynx was comparatively small with a flat vault, while the adult nasopharynx was larger with a high angular or rounded vault. It was also noted that tumors of the epipharynx, including adenoids, caused more obstruction if the cavity was small and narrow. Moulinard[6, 7] in 1949 also believed that the infant type of nasopharynx was relatively small with an axis parallel to the base of the skull, while the adult epipharynx was larger with a more vertical antero-posterior axis. Other reports[3, 8, 9, 10, 11, 12, 13] similarly indicating the value of the radiographic appearance of enlarged adenoids have appeared sporadically in the literature. Brief descriptions of the method and its merits have been published in standard reference texts.[14, 15]

TECHNIQUE

We have observed that a lateral view of the nasopharynx at a six foot target-film-distance and with factors permitting rapid exposure (1/30 to 1/60 second) to avoid motion blurring is most satisfactory. A non-Bucky technique is preferred, since the gradations on the film are more gradual, the contrasts less and the soft tissues are shown more completely. We have used tomographic techniques in the profile view of the nasopharynx, as have others,[16] but have found that this procedure does not yield additional information. Lipiodal studies[17] have not proved of value.

Radiographic visualization of the adenoids results from the contrast between the water-density of the adenoidal soft tissue mass and the radiolucency of the surrounding nasopharyngeal airway. It is, therefore, apparent that the larger the nasopharyngeal airway, the more likely are margins of the adenoids to be demonstrated, even if enlarged. The anterior, superior and posterior walls of the nasopharynx are bony and immobile. The floor of the nasopharynx is the superior surface of the soft palate and mobile. Depression of the soft palate increases the nasopharyngeal airspace and improves the visibility of the adenoids. Elevation of the an angle of about 30° with the horizontal as it extends towards its junction with the posterior wall of the nasopharynx It is thus apparent that the largest nasopharyngeal airway is usually the anterior region just behind the choanae

The significance of the anatomical arrangement just described is further emphasized by the effects of the action of the soft palate The size of the posterior part of the epipharynx can be increased by the depression of the soft palate which occurs during inspiration or expiration The movement of the soft palate, however, is least at its attachment to the hard palate just behind the choanae As a result, the available airway just behind the choanae is least affected by the soft palate motion Because of the lack of soft palate motion in this plane, the high vault of the nasopharynx anteriorly can be considered a compensatory arrangement to furnish the largest possible nasopharyngeal airway for respiration

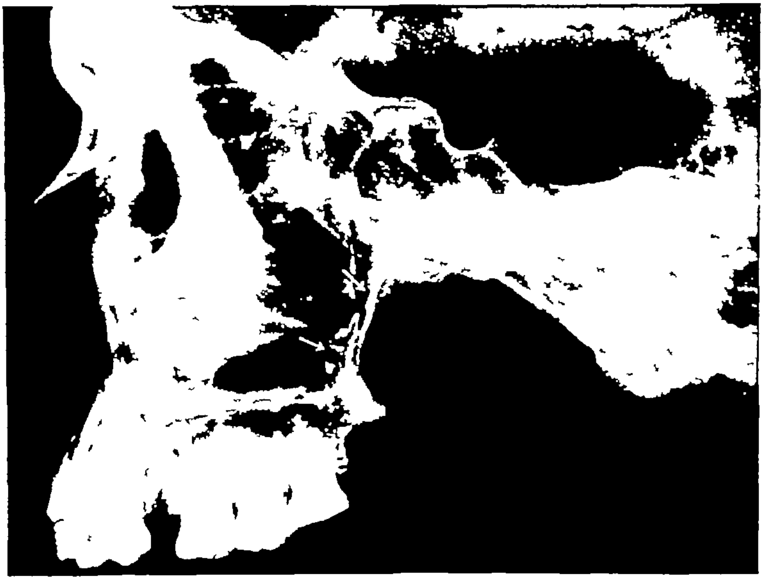

Fig 2 X-ray of dried skull Posterior margin of vomer marked with opaque paste Note close relationship to anterior margin of pterygoid plate and posterior wall of maxillary antrum

the point where the upper anterior margin of the pterygoid plate joins the body of the sphenoid corresponds closely to the posterior edge of the vomer and the position of the choanae (see Fig 2) This line lies very near the posterior margin of the antrum, and the latter also may be utilized as an adequately accurate position of the choanae

The two determinants in nasopharyngeal obstruction are the degree of adenoidal enlargement and the size and shape of the nasopharyngeal space We believe that the importance of the latter has not been sufficiently recognized Both the size and shape of the nasopharyngeal space vary considerably The major factor in this variation is the shape of the roof or fornix of this cavity Usually, the roof is highest anteriorly, just behind the choanae, where the vomer joins with the inferior surface of the body of the sphenoid bone (see Fig 2) From this point the fornix slopes downward and backward at

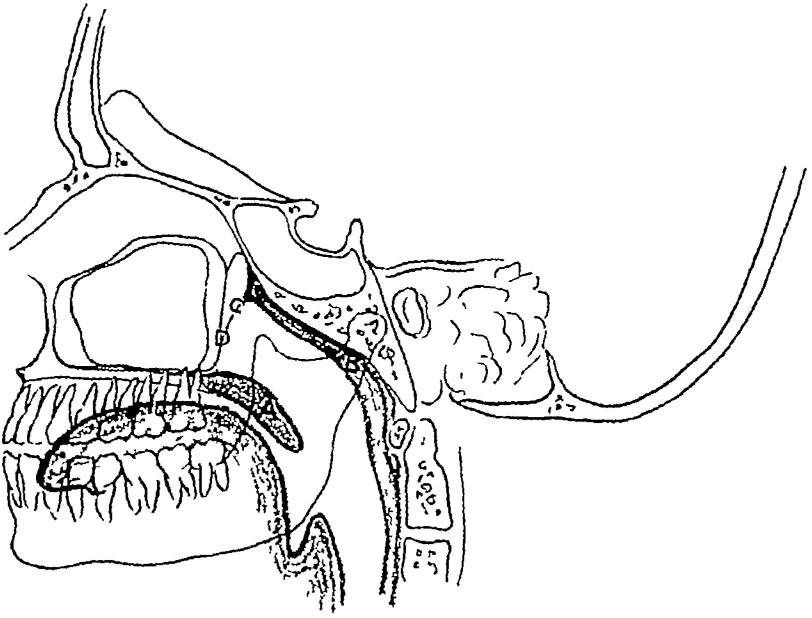

Fig 1 Diagram of anatomy of nasopharynx Nasopharynx located between soft palate (A) and mucous membrane of roof (B) The line of the posterior edge of the vomer is approximated by either the anterior edge of the pterygoid plate (C) or the posterior wall of the maxillary antrum (D)

paratively small nasopharyngeal airways, while in other instances even larger adenoids did not completely occlude comparatively larger nasopharyngeal spaces

ROENTGEN EXAMINATION OF ADENOIDS

The mucous membrane lining the roof and adjacent posterior wall of the pharynx is cast in folds and diffusely infiltrated with lymphoid tissue throughout its submucosa In areas the lymphoid tissue is relatively more abundant, and forms conglomerate nodular masses with crypt-like invaginations of the surface epithelium These are the pharyngeal tonsils or adenoids When infection occurs, there is swelling and enlargement of the diffusely dispersed lymphoid tissue and the nodular lymphoid masses, which result in thickening of the mucous membrane lining of the nasopharyngeal vault The increased width of the mucous membrane may be essentially flat if the diffusely dispersed lymphoid tissue is predominantly involved, nodular in shape if the coalescent lymphoid masses are mainly affected, or a combination of both types Usually the combined form is encountered with marked adenoidal enlargements Nodular enlargements of lymphoid tissue may occur anywhere in the mucosa of the roof The adenoids develop rapidly after birth, attain their maximum size in early childhood and begin to involute at about 8 to 10 years In most instances regression is nearly complete by 12 to 14 years of age

Radiographically, the normal mucous membrane lining of the nasopharyngeal roof is seen as a thin band of soft tissue density lying immediately beneath the inferior surface of the body of the sphenoid bone It begins antero-superiorly in the fornix just behind the choanae and extends backward to merge with the mucous membrane lining of the posterior pharyngeal wall The free surface of this mucosal band can be visualized on the roentgenogram, because it borders the air-containing nasopharyngeal cavity (see Fig 4) It measures no more than 6 mm in width in the normal nasopharynx, and runs parallel with the surface of the sphenoid bone which it covers The normal mucous membrane shows no nodularity A well defined, patent, radiolucent nasopharyngeal airway is

Patients have been encountered, however, in whom the arch of the roof anteriorly is comparatively flat rather than high, and the entire epipharyngeal vault is low (see Fig 3) The superio-inferior diameter of the nasopharynx is thus diminished and the entire nasopharyngeal airway decreased This may be partly compensated posteriorly by marked depression of the soft palate, but anteriorly behind the choanae such lowering of the soft palate is not possible The critical plane for nasopharyngeal obstruction is, therefore, to be found anteriorly just behind the choanae in patients with low, poorly arched nasopharyngeal vaults Clinically, the anterior "critical region" of the nasopharynx is the zone most difficult to explore by digital examination Thus, adenoidal tissue in this recess might not be discovered by this diagnostic method

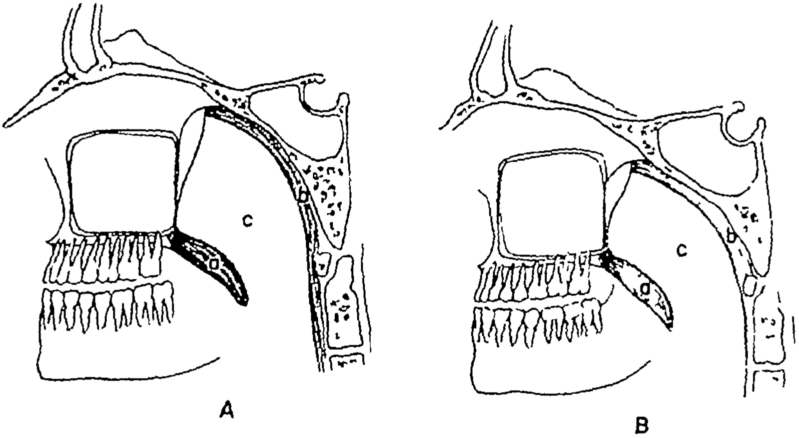

Fig 3 Diagram of nasopharynx with high vault (A) and low vault (B) Soft palate (a) mucous membrane roof of vault (b) nasopharyngeal space (c)

We have observed that usually the nasopharyngeal areas in young children are smaller than in adults, and the vault is lower and less well arched, however, considerable variations in size and height of the vault existed both in the children examined and in the adult radiographs studied for comparison This individual variation plays an important role in the matter of airway obstruction In some patients moderate enlargements of the adenoids caused complete obstruction of com-

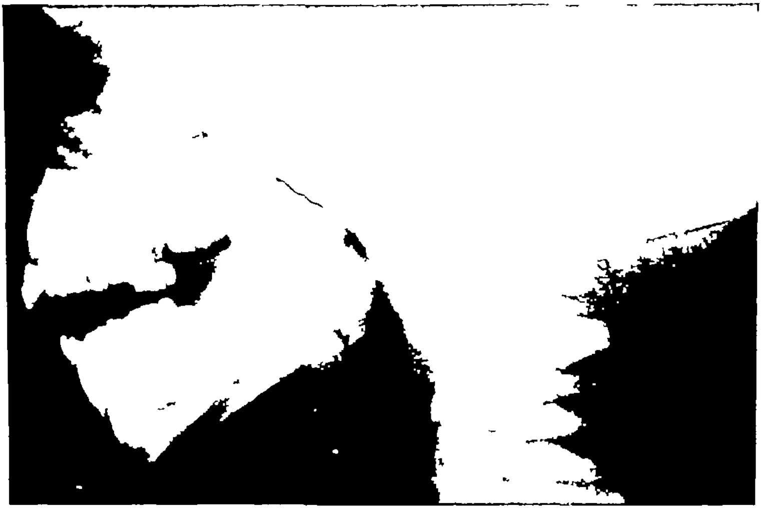

Fig 5-A. Moderately enlarged adenoids Respiration suspended

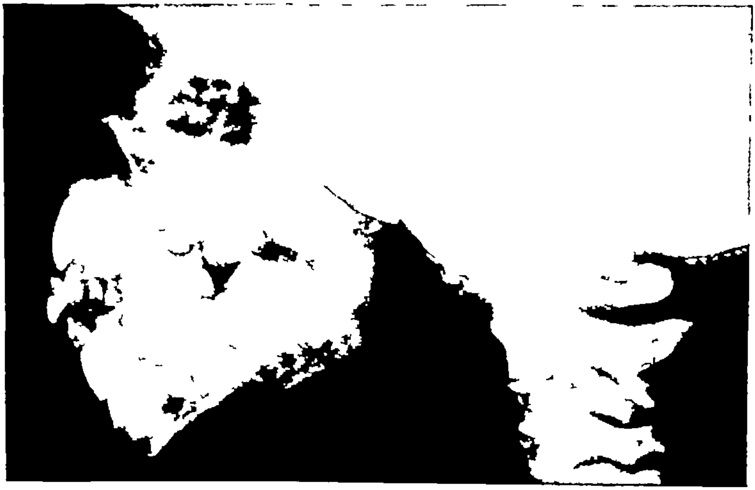

Fig 5-B Moderately enlarged adenoids During nasal inspiration

clearly delineated between the free edge of the mucous membrane of the roof and the superior surface of the soft palate which forms the floor of the nasopharynx

As the adenoids enlarge, the width of the soft tissue band under the sphenoid bone increases, resulting in a corresponding narrowing of the adjacent radiolucent airway In addition to the general increase of width, local areas of greater nodular densities may be seen at the sites of proliferation of conglomerate lymphoid masses which further narrow the airway locally The adenoids are classified as moderately enlarged when the width of the mucosal soft tissue band is greater than 6 mm and there is mild superimposed nodulation, but nasopharyngeal airway is considered adequate (see Figs 5-A—5-B) Marked enlargement is shown by a further increase in width of the soft tissues under the sphenoid bone, usually associated with local crescentic swellings of the mucosa The nasopharyngeal airway is markedly narrowed but not completely occluded (see Figs 6-A—6-B) The final stage of enlargement is characterized by complete obstruction of the airway by greatly widened and nodular mucous mem-

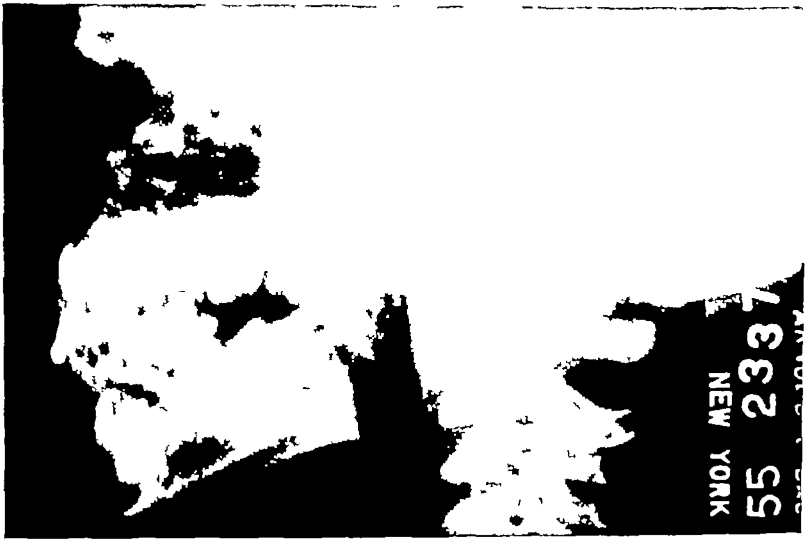

Fig 4 Normal nasopharynx

brane, which extends downward from the sphenoid bone and comes in contact with the superior surface of the soft palate (see Figs 7-A—7-B)

The importance of the mobility of the soft palate floor of the nasopharynx becomes evident in the study of cases of enlarged adenoids In each instance films are made during "respiration suspended" and during "nasal inspiration" When the major adenoidal enlargement is in the posterior part of the roof, the nasopharyngeal airway may appear occluded during suspension of respiration as the adenoids lie in contact with the superior surface of the posterior portion of the soft palate, however, on the "nasal inspiration" film the soft palate is depressed so that a distinct, although narrow airway is demonstrated (see Figs 5-B—6-B), and some nasal respiration is permitted If the adenoids are sufficiently enlarged, the airway is completely blocked at all times (see Fig 7-B) If the major adenoidal enlargement, usually nodular, is situated anteriorly in the nasopharynx just behind the choanae, the degree of obstruction cannot be alleviated by the downward motion of the soft palate since this motion is minimal at this site (see Fig 6-B) For this reason, adenoidal obstructions of the nasopharynx anteriorly are not significantly affected by nasal respiration

Radiographic differential diagnosis of enlarged adenoids is usually not difficult A widened, nodular soft tissue mass attached to the roof of the nasopharynx associated with narrowing of the nasopharyngeal airway almost invariably signifies adenoidal enlargement in young children A common source of error is the shadow of the earlobe projected into the nasopharyngeal airway Uusually, this shadow lies just below and slightly anterior to the external auditory canal (see Fig 8-A), however, if the child's head is not in a true lateral position during the filming, the earlobe may be projected into the anterior portion of the nasopharyngeal airway and cause confusion (see Fig 8-B) Identifying the earlobes in each case should eliminate this problem If doubt still exists, the earlobes may be folded up out of the area and fixed to the temples by adhesive tape prior to the filming[14]

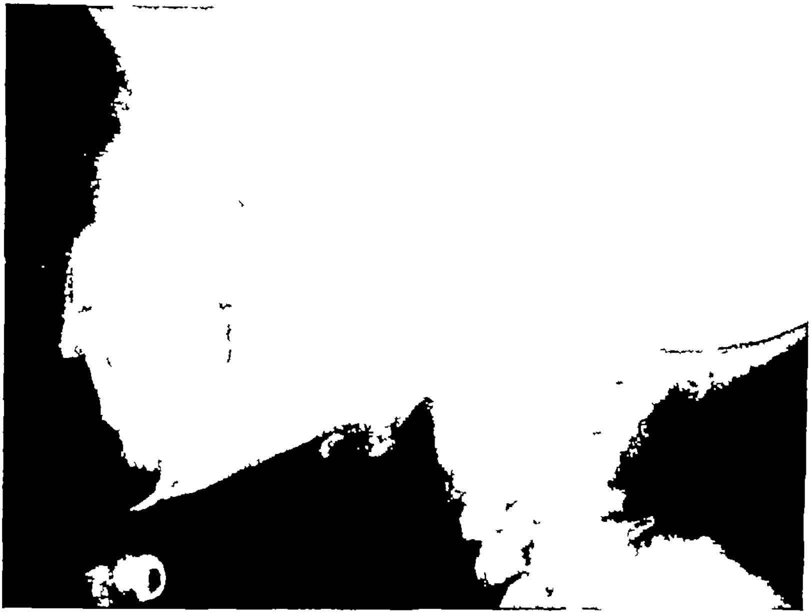

Fig 6-A. Markedly enlarged adenoids Respiration suspended

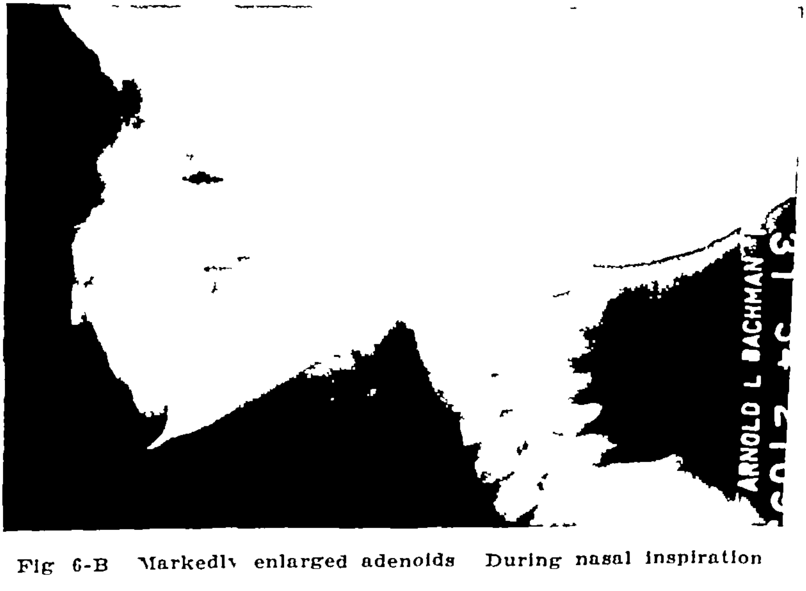

Fig 6-B Markedly enlarged adenoids During nasal inspiration

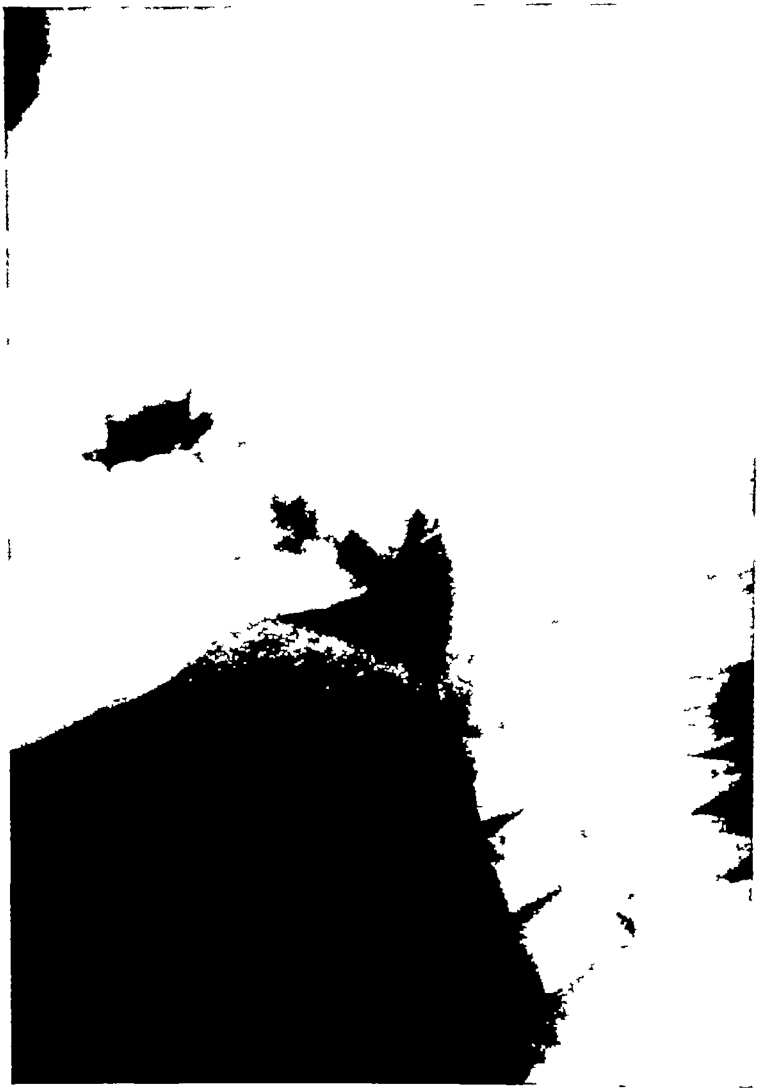

Fig 7-A. Complete obstruction of nasopharynx by greatly enlarged adenoids Respiration suspended.

Choanal and nasopharyngeal polyps, fibromas and malignant neoplasms may be observed as soft tissue masses in the nasopharynx The choanal polyps extend backward from the choanae into the anterior portion of the nasopharynx and do not arise from the vault On radiographs these soft tissue circumscribed densities may be seen separated from the mucous membrane of the vault by a thin band of nasopharyngeal airway (see Fig 9) In addition, the polyps, fibromas and malignant tumors occupying the nasopharynx usually appear after the age when the adenoids have involuted The juvenile and adolescent fibromas as a rule form huge, homogeneously dense, round and sharply circumscribed opacities quite different from the ovoid, lobulated masses seen attached to the vault in the younger children

Radiography of the nasopharynx is a useful method of assessing the success of adenoidectomy procedure Following surgery the entire thickened, lobular soft tissue density observed in the nasopharynx preoperatively is seen to have disappeared The mucosa of the roof is noted as a narrow, smooth band of soft tissue density without nodulation, and the nasopharyngeal airway is wide and patent (see Figs 10-A—10-B) Any areas of residual adenoids are easily identified as local soft tissue nodules projecting into the airway Similarly, recurrent adenoidal enlargement following surgery is apparent as band-like or nodular thickening of the mucous membrane of the vault which projects into the nasopharynx and narrows the airway exactly as do the primary adenoidal enlargements which have not been subjected to operation

In this series of cases, 46 children were evaluated for complaints lasting from several months to two years after tonsillectomy and adenoidectomy In 26 instances enlargement of adenoid tissue, usually high in the vault, could be demonstrated by roentgenography

We have indicated that the anterior area of the vault of the nasopharynx is the "critical region" physiologically This term can be applied also to the surgical considerations of this area Study of the anatomy of the vault of the nasopharynx by roentgenography reveals the reasons for the contentions

CLINICAL APPLICATIONS—CASE HISTORIES

The main possibilities in the differential diagnosis of naso-sino-nasopharyngeal problems in children which confront the otolaryngologist include the following condition *1* Adenoidal enlargement with varying obstruction and/or disease, *2* nasal infection and/or sinus infection, *3* vasomotor rhinitis and sinusitis, *4* related ear conditions, *5* occasional polyps and neoplasms For satisfactory solution of these problems, often a complete work-up is required, this must include a detailed history and careful examination, radiographic studies of the nasopharynx and the paranasal sinuses, spreads and cultures of the nasal and sinus secretions, as well as allergic investigations when the latter appear indicated The radio-that complete and direct exposure of the vault of the nasopharynx is necessary to accomplish a thorough adenoidectomy Yankauer[20] has devised a speculum, Love,[21] Baron,[22] Lothrop,[23] Senturia[24] and others have offered palatal elevators for this purpose Meltzer[25] has shown the need of using punch forceps under direct vision to remove remnants of lymphoid tissue in the fossa of Rosenmueller and high in the vault Pedersen[26] suggests the intranasal route for removal of the adenoid tissue in the area we have called the "critical region" of the vault Thus, by demonstrating the anatomy and physiology, roentgenography can be helpful in the planning of the surgical approach of a complete adenoidectomy, in addition to its diagnostic value

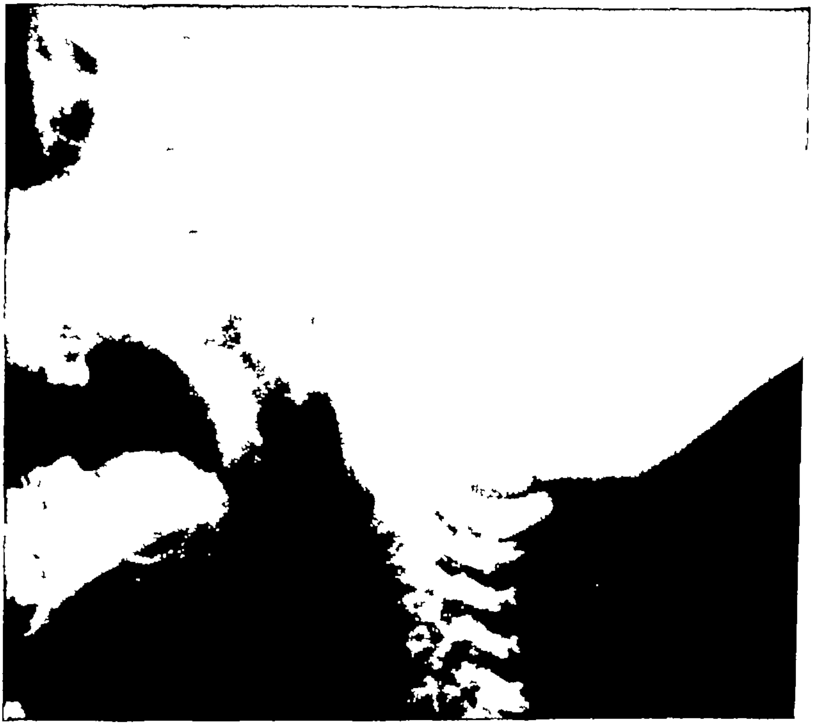

Fig 12-A Case 4 Normal nasopharynx

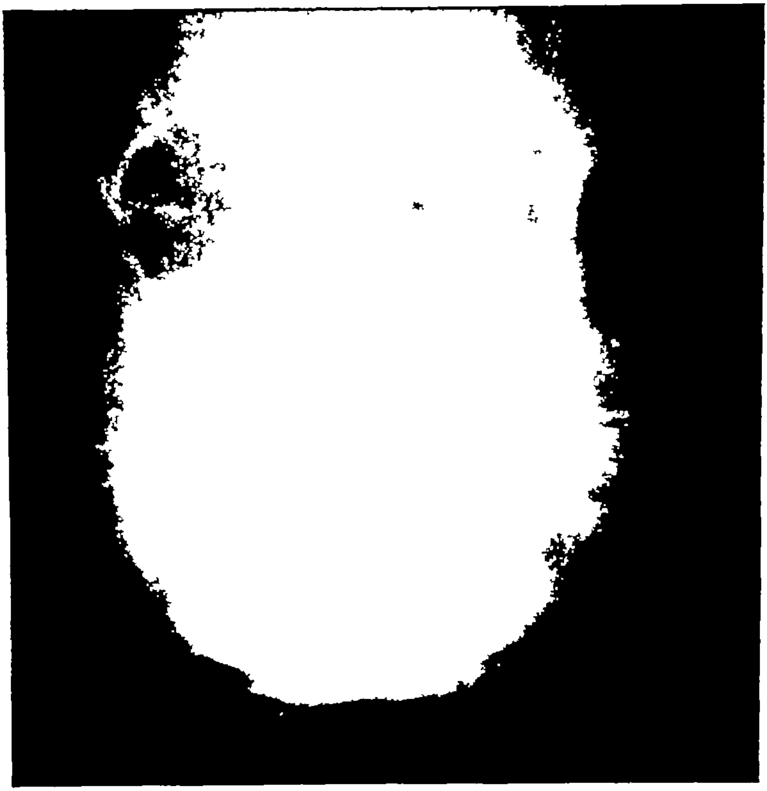

Fig 12-B Case 4 Markedly cloudy maxillary antrums

CLINICAL APPLICATIONS—CASE HISTORIES

The main possibilities in the differential diagnosis of naso-sino-nasopharyngeal problems in children which confront the otolaryngologist include the following condition *1* Adenoidal enlargement with varying obstruction and/or disease, *2* nasal infection and/or sinus infection, *3* vasomotor rhinitis and sinusitis, *4* related ear conditions, *5* occasional polyps and neoplasms For satisfactory solution of these problems, often a complete work-up is required, this must include a detailed history and careful examination, radiographic studies of the nasopharynx and the paranasal sinuses, spreads and cultures of the nasal and sinus secretions, as well as allergic investigations when the latter appear indicated The radiographic studies, while of considerable importance, constitute but one aspect of the complete investigation Often, all the elements of the work-up interlock to form a pattern which indicates the abnormality as well as the therapeutic approach A number of brief case reports will serve as illustrations

PRIMARY ADENOIDAL ENLARGEMENT WITH OBSTRUCTION

Case 1 C W, age 8, complained of constant mouth breathing nasal obstruction and nasal speech Examination revealed no abnormal findings in nose, sinuses or ears, except small amount of secretion in nasal cavities Tonsils were moderately enlarged X rays of nasopharynx showed greatly enlarged lobular adenoids filling the nasopharynx and causing obstruction during "respiration suspended" and almost complete occlusion during "nasal inspiration" Culture of nasal secretions yielded large growths of micrococcus catarrhalis and diphtheroids, a bacteriologic finding often seen in association with active adenoid tissue At operation the enlarged adenoids were removed, following which symptoms disappeared Postoperative X rays of the nasopharynx showed a clear, widely patent airway

POSTOPERATIVE ADENOIDAL ENLARGEMENT, EAR INFECTION, IMPAIRED HEARING

Case 2 C F, age 7, had tonsillectomy and adenoidectomy performed at age of two years For the following five years patient had repeated infections of the ears and upper respiratory tract Hearing became impaired A second adenoidectomy was performed eight months prior to his first visit, but hearing did not improve Examination revealed no evidence of nasal or sinus disease The tympanic membranes were congested and retracted Audiogram indicated a moderate conductive hearing impairment X rays of the nasopharynx showed enlarged adenoids high in the vault (see Figs 11 A—11 B) These enlarged adenoids were removed at a third adenoidectomy Following this operation, the tympanic membranes assumed a normal appearance and the hearing returned to a normal level

IMPAIRED HEARING UNRELATED TO NASOPHARYNGEAL OBSTRUCTION

Case 3 L G, age 8 had impaired hearing A tonsillectomy and adenoidectomy had been performed previously and an evaluation of the hearing loss in relation to adenoidal disease was requested Examination revealed no evidence of nasal or sinus disease Tympanic membranes were normal Radiographic studies of the nasopharynx showed no evidence of adenoids Direct nasopharyngoscopy revealed no lymphoid tissue Audiometric study revealed the hearing impairment to be of the perceptive type

NASAL SYMPTOMS NASAL DISEASE NO ADENOIDAL ENLARGEMENT

Case 4 J B age 3 complained of difficult nasal breathing night snorting recurrent episodes of fever Examination revealed congested turbinates and a moderate amount of thin secretion in both nasal cavities Radiographic investigation showed no adenoidal enlargement in the nasopharynx but marked clouding of the maxillary antrums (see Figs 12-A—12-B) Spreads of the nasal secretions revealed numerous cocci, and cultures yielded large growth of Staphylococcus aureus A Sensitivity tests showed that this staphylococcus was sensitive only to achromycin terramycin and chloromycetin Systemic and local tetracyclin therapy was initiated and the condition cleared rapidly

NASOPHARYNGEAL OBSTRUCTION DUE TO POLYP

Case 5 S T, age 11, complained of difficulty in breathing particularly through the left nostril, mouth breathing and nasal speech An allergic history was elicited Examination revealed a large nasopharyngeal polyp obstructing the left choana. X rays of the nasopharynx demonstrated the polyp arising from the region of the choanae and projecting into the anterior portion of the nasopharynx It was seen to be distinct from slightly enlarged non-obstructive adenoids in the vault (see Fig 9) Breathing difficulties disappeared after removal of the polyp

CONCLUSIONS

Radiographic examination of the nasopharynx is an accurate, simple and safe method for determining the size, shape and position of enlarged adenoids, and the degree of nasopharyngeal obstruction they cause For this reason it is one of the important procedures in the total investigation of naso-sino-nasopharyngeal problems in children Review of the literature suggests that this diagnostic method is utilized less frequently than it deserves It should replace the crude and inadequate method of digital palpation The anatomy of the nasopharynx with emphasis on variations in its size and shape, especially with reference to diagnostic and surgical problems, is presented The radiographic appearance of adenoidal enlargement is described Differential diagnosis is discussed and illustrative case reports are recorded

A CLINICAL LOOK AT PROGRESS IN EVALUATION OF HEARING FUNCTION *

FREDERICK R GUILFORD, M D ,
and
OLAF HAUG, Ph.D ,
Houston, Tex

INTRODUCTION

Progress in the development of hearing tests has followed a clinical need on the part of the otologist for more information which would contribute to a more complete diagnosis and hence to more adequate therapy Originally he was concerned with the problem of whether or not a hearing loss was present, thus, his early tests were those which measured acuity, or the degree to which a given patient's responses to sound varied from a normal standard The threshold of hearing was later measured as the amount by which sound had to exceed a normal threshold intensity for a given listener to hear The otologist was next concerned, because of the widely differing medical and surgical rehabilitation needs, with the type of hearing loss present This led to the differential diagnostic tests for conductive and nerve type impairments Tests designed to satisfy the above mentioned needs constitute the bulk of audiometric examinations in clinical otological practice today Methods and equipment for the measurement of discrimination ability for speech have been readily available to the clinician for several years, however, it is apparent that he has been slow to grasp the basic clinical importance of these discrimination tests Such discrimination tests and test equipment in the form of turntable and records, which can be used satisfactorily in any office, have been waiting for general clinical acceptance

It is not the intent of this paper to dwell on either the need

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication May 26 1958

for, or the technique of, various hearing tests which have both been abundantly covered in the literature Rather, in reviewing the progress of hearing testing, emphasis will be placed on the development of those audiological tests which we believe to have *basic clinical application*

Adam Politzer,[1] before the turn of this Century, recognized that non-calibrated tests such as the coin click, watch tick, Galton's whistle, whisper and spoken voice, and tuning fork tests "were insufficient as a means for ascertaining the exact condition of the function of hearing in diseases of the ear " It was recognized that these tests produced much variation in results as administered by different clinicians, with different standards It was this variability which the inventors of the modern audiometer sought to eliminate

TESTS OF ACUITY

a Tuning Fork Tests

Tuning forks, as they were first used for measuring air conduction acuity, gave some idea of the sensitivity of the ear by measuring how long the patient continued to hear the tone The use of forks representing each octave in the frequencies important for speech hearing, made possible for the first time an approximate plotting of the hearing threshold over a wide frequency spectrum The serious limitation in the use of tuning forks as tests of acuity was the uncertainty as to the intensity of the sound produced

b Pure Tone Audiometric Tests

Pure tone audiometric tests, by air conduction, represented a real advance in the precision of the measurement of hearing loss and the reliability of the results The threshold of hearing was measured as the amount by which sound had to exceed a normal threshold intensity in order for a given patient to hear While this test still serves us as a measurement of acuity for pure tones, or the *degree* of the hearing loss, it is necessary that its limitations be realized Much confusion has resulted until recent years, due to the tendency to interpret the patient's *practical communication handicap* in the light of the air conduction pattern (see Fig 1) The in-

adequacy of the procedure alone became more apparent with the introduction of bone conduction testing and the development of speech perception tests

c *Speech Reception Threshold*

In the course of investigation of the problem of communication in aircraft during World War II, Hudgins,[2] et al, developed the speech reception threshold tests as a measurement of acuity for speech It was later established that the speech reception threshold usually correlates very closely with the pure tone average of 500, 1000, and 2000 c p s, representing the speech range, and thus it serves as a check on the accuracy of the pure tone findings The speech reception test has been adequately described numerous times in the literature

DIFFERENTIATION OF CONDUCTIVE AND NERVE IMPAIRMENT

a Tuning Fork Tests

Weber, Rinne and Schwabach[3] were pioneers in the use of the tuning fork as an instrument for differential diagnosis of the type of hearing impairment present The well-known tests which they developed made it possible to differentiate conductive impairments from perceptive losses

Politzer[1] wisely predicted the continued importance of the tuning fork as a differential diagnostic instrument in his textbook "We most emphatically state that the tuning fork tests will be of lasting value in the diagnosis of disturbances of hearing"

It is interesting to note that all of our clinically applicable pure tone audiometric tests have as their basis the principles established in these early tuning fork tests Tuning forks were further refined in their application and interpretation for making more specific diagnoses of types of hearing impairments or degrees of nerve involvement This proved to be important in the selection of candidates for surgical rehabilitation

I will clarify this particular subject with an illustration from our "Otology Study" sheet (see Fig 2) This affords a graphic method of recording the results of tuning fork tests From the shape and the position of the resultant curves, one can make both a rapid assessment of the patient's hearing status and, equally important, check on the accuracy of the bone conduction audiometric findings

b Bone Conduction Audiometry

Bone conduction audiometry developed as a means of applying the methods of tuning fork testing in a more accurate and controlled fashion With the introduction of the bone conduction oscillator, the intensity of the test tone could be calibrated, regulated and maintained at a constant level In spite of the improvement in the precision in generating the tone, it was soon found, as in the use of the tuning fork, that experience was essential in the application of the tests before any degree of confidence could be placed in the test results It was all too often assumed that bone conduction testing was both easy and routine, however, problems such as placement of the oscillator, confused localization of the test tone, cross-over, and masking, made it a highly individualized and often challenging testing problem It has proven to be the most important *pure tone* audiometric test, now clinically available, for the differential diagnosis of hearing impairment

c Above Threshold Pure Tone Tests

The recruitment phenomenon was first described in 1924 by Pohlman and Kranz[4] and shortly after by Fowler,[5] in

1928 It was used to differentiate conductive and nerve type impairments, however, so many other tests more clearly demonstrated this diagnosis that they were given slight clinical acceptance

It was only after Dix, Hallpike and Hood[6] demonstrated, in 1948, the usefulness of recruitment testing for the differential diagnosis of end-organ and VIIIth nerve impairments, that recruitment began to receive more general clinical attention

d Speech Discrimination Tests

The need for tests other than pure tone for the evaluation of a patient's hearing handicap has long been recognized Oscar Wolfe,[7] in the latter part of the 19th Century said, that in order to make a differential diagnosis, it is absolutely necessary to use the *qualitative* test for speech hearing in addition to the *quantitative test* for hearing MacFarland[8] described a number of early speech hearing tests dating back to 1929

Egan,[9] in 1948, reported the development of various lists of phonetically balanced words to be used in the measurement of speech discrimination or intelligibility of speech This led to the first practical clinical test for assessing the patient's *communication handicap* as distinguished from the more limited evaluation of the quantitative degree of his hearing loss (see Fig 3)

MALINGERING TESTS

Simulated deafness was widely recognized in the latter half of the 19th Century A number of ingenious tests, employing tuning forks and stethoscopes along with careful observation of behavior, were used to diagnose non-organic hearing losses During, and following World War II, the needs of the Armed Services prompted the widespread use and refinement of several audiometric tests for malingering, such as the Stenger, Lombard and Doerfler-Stewart With the current active interest in industrial noise problems, including damage claims, it has become increasingly necessary for the otologist to distinguish the presence and extent of true organic hearing impairments from the non-organic or exaggerated overlay

Limitations of air curve audiometry Pure tone curves same, but wide difference in speech discrimination Aid must be fitted to left ear

Fig 3

TESTING THE VERY YOUNG CHILD

A problem which has demanded increasingly more of the otologist's attention has been the peculiar testing needs associated with the assessment of hearing function in the very young child This has necessitated the development of specialized motivational techniques and equipment for audiometry such as the Dix-Hallpike peep show[10] and the Pediacoumeter[11] (see Fig 4), however, Mykelbust[12] and others[13] have pointed out that observation of behavior is often as important as hearing test results This led to the use of behavioral inventories as an aid in the differential diagnosis of the delayed speech case with poor response to sound

1928 It was used to differentiate conductive and nerve type impairments, however, so many other tests more clearly demonstrated this diagnosis that they were given slight clinical acceptance

It was only after Dix, Hallpike and Hood[6] demonstrated, in 1948, the usefulness of recruitment testing for the differential diagnosis of end-organ and VIIIth nerve impairments, that recruitment began to receive more general clinical attention

d Speech Discrimination Tests

The need for tests other than pure tone for the evaluation of a patient's hearing handicap has long been recognized Oscar Wolfe,[7] in the latter part of the 19th Century said, that in order to make a differential diagnosis, it is absolutely necessary to use the *qualitative* test for speech hearing in addition to the *quantitative test* for hearing MacFarland[8] described a number of early speech hearing tests dating back to 1929

Egan,[9] in 1948, reported the development of various lists of phonetically balanced words to be used in the measurement of speech discrimination or intelligibility of speech This led to the first practical clinical test for assessing the patient's *communication handicap* as distinguished from the more limited evaluation of the quantitative degree of his hearing loss (see Fig 3)

MALINGERING TESTS

Simulated deafness was widely recognized in the latter half of the 19th Century A number of ingenious tests, employing tuning forks and stethoscopes along with careful observation of behavior, were used to diagnose non-organic hearing losses During, and following World War II, the needs of the Armed Services prompted the widespread use and refinement of several audiometric tests for malingering, such as the Stenger, Lombard and Doerfler-Stewart With the current active interest in industrial noise problems, including damage claims, it has become increasingly necessary for the otologist to distinguish the presence and extent of true organic hearing impairments from the non-organic or exaggerated overlay

Fig. 5.

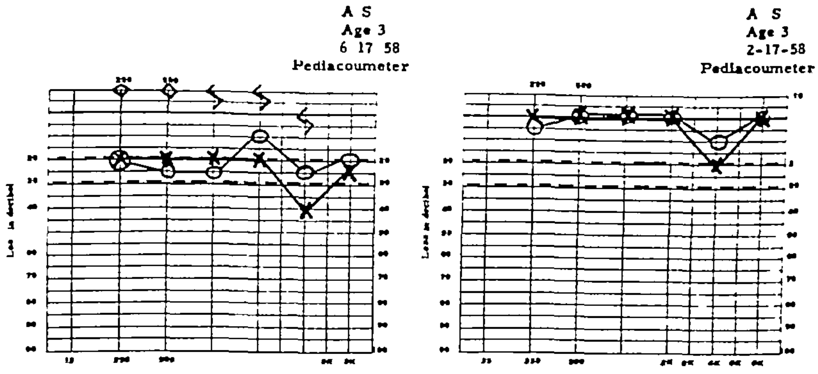
reference. The limitation in the monaural equal loudness test has been that a sloping threshold curve is necessary in order to demonstrate clearly convergence with the most comfortable equal loudness curve.

DISCUSSION

In looking back on this review of clinical progress it becomes necessary to ask ourselves—Where are we presently in the application of appropriate clinical hearing tests for adequate diagnosis? Do we have a practical group of clinical tests which may be economically applied for the accurate diagnosis of hearing problems? In the formulation of such

DIAGNOSIS OF END-ORGAN IMPAIRMENTS

Another problem in otology has been to differentiate the site of neural involvement of hearing impairment, either in the receptor end-organ or in the transmission pathways, in order to provide a more complete diagnosis than was otherwise available For this differential diagnosis, the presence of recruitment has been one of the most valuable indices



Before treatment - Restoration of hearing by medical treatment Illustrates normal threshhold possible on very young children when proper equipment and technique is used

After treatment

Fig 4

EVALUATION FOR AMPLIFICATION

The otologist is now becoming increasingly aware of his responsibility to the patient who is not a candidate for surgical or medical rehabilitation This has accentuated the need for taking various steps to evaluate the patient's requirements and suitability for amplification[14 15] For this evaluation the most useful information audiologically has been that which comes from adequate air and bone audiometry, speech discrimination scores and recruitment testing (see Fig 5)

The two most useful clinical tests for demonstrating recruitment have been the Fowler[5] binaural balance method and the monaural equal loudness method described by Watson[16]

The binaural balance method has been limited in its application in that one non-recruiting ear must be present as a ported tests has led not only to confusion in our specialty, but has also undermined the confidence of the majority of clinicians in their ability to arrive at an accurate clinical diagnosis This has resulted in the widespread practice of either relegating this important clinical function to independent non-medical agencies, or to the rejection of all but the very simplest of air conduction audiometric or tuning fork screening tests, in an effort to evaluate the patient's communication handicap

We firmly believe that the practical value of the routine application of the basic audiological tests mentioned has been adequately demonstrated, but that it needs to be more generally recognized clinically Once the basic group of audiological tests is made thoroughly familiar to the practicing clinician and the resident in *otolaryngology*, as a minimum requirement for the evaluation of hearing function, real progress will be achieved, and we will enter a new era in the assessment of the patient's handicap in communication

10 Dix M R and Hallpike, C S Peep Show—New Technique for

a group of tests, it should be stressed that not all of the old tests should be rejected and not all the new tests should as yet be accepted

Of the tests used clinically, we believe that the tuning fork, air and bone conduction audiometry, speech perception tests, monaural equal loudness and binaural balance tests for recruitment, constitute the minimum battery of audiological tests which should be applied, as indicated, in a routine evaluation of hearing handicap As we have pointed out previously,[17] facilities affording less than this complete hearing evaluation would not serve the situation for providing an accurate diagnosis and a rational plan of therapy On the other hand, more exhaustive, time consuming evaluations with clinically unproven tests cannot be at present justified from a practical point of view The basic audiological tests indicated can be adequately performed by trained personnel with moderately priced, commercially available clinical audiometers having a speech circuit or turntable If the turntable with earphones is used, only a single quiet room is necessary

A number of the newer laboratory tests of hearing function were not included in this discussion, since they have not as yet been established as practical clinical tools We recognize, however, that the development and standardization of these tests in the laboratory have been of vital significance to the clinician

Let us constantly and critically scrutinize the work of the laboratory in the development of new tests of hearing, in order to be prepared to supplant an outmoded test when a more reliable, more practical one appears, however, let us always keep in mind that the purpose of these tests is to provide an accurate diagnosis If that is being adequately done with one or more current clinical tests, why should we feel that additional and often more complex ones are necessary, which at best would only provide confirmatory evidence? We have often allowed research bulletins and special electronic equipment representatives to lead us away from our basic clinical approach to the problem The efforts of some of us to keep up with facilities for performing the very latest re-

INSTITUTE ON INDUSTRIAL DEAFNESS

Colby College, Waterville, Maine, presents the Sixth Annual Institute on Industrial Deafness, August 11-20 inclusive Please note that the course has been extended for three days in order to include engineering for noise control Its objective will be to train physicians interested in the problem, nurses, plant engineers and others in initiating and conducting hearing conservation programs in noisy industries The course includes basic otology, audiometry, noise measurement, ear protection and methods of noise control Class is limited to approximately twenty participants

The fee for the course is $250 and includes tuition, room and board The first week will constitute a complete course for doctors and nurses, and the reduced fee for this will be $200 Application should be made to Mr William A Macomber, Colby College, Waterville, Maine

MALFORMATIONS AND ANATOMICAL VARIATIONS SEEN IN THE MIDDLE EAR DURING THE OPERATION FOR MOBILIZATION OF THE STAPES *

J V D HOUGH, M D ,
Oklahoma City, Okla

INTRODUCTION

The purpose of this thesis is to present some of the variations and abnormalities which may be seen in the middle ear during transaural tympanotomy Mobilization of the stapes is the most frequently performed contemporary operation, using this exposure The conditions here reported and discussed were observed in the course of 500 such procedures

The importance of minutiae increases as the otologist's scope broadens, and his field of operation is seen with greater magnification Numerous procedures[74,130,140,149,169,170] to rebuild, alter, or bypass the conductive mechanism of the middle ear have produced a pressing need for more information regarding the variations seen when the eardrum is lifted and the complex mechanism of the middle ear is viewed Microscopic vision and intense light have revealed structures which have stimulated otologists for decades Now, the operator may engage in micro-orthopedics and plastic revisions of delicate proportions Variations of as little as a fraction of one mm or a few degrees have become more

this discussion to include those abnormalities of the middle ear which are so often found in association with other anomalies of the external or internal ear or other branchial derivatives

These malformations, limited to the middle ear, are documented here by actual photographs taken at the time of operation In order not to distort the color photographs by labels, sketches of anatomical structures of interest, are mounted beside each photograph, and the structures identified by appropriate pilot lines The photographs were taken through the Zeiss operating microscope, using daylight Kodachrome film The light and the objectives were fixed The F-setting of the camera was 22 The pictures were taken in 1/50th of a second The prints were enlarged in color directly onto a celluloid background

All of the literature available to me, both foreign and domestic, concerning embryology, physiology, anatomy, and malformations of the ear has been reviewed for the past 100 years Local hospital and university libraries and national service organizations have aided in obtaining this literature Photostats and microfilms have been secured of rare and nontransferable articles from such services as the National Library of Medicine, the Armed Forces Medical Library, etc

ORGANIZATION OF MATERIAL PRESENTED

A presentation of the visual experience of these variations and malformations requires some discussion as to the significance of what is seen First, a discussion of fundamental embryology of the area will be given Next, consideration of the individual variations seen in the following structures of the middle ear will be given *1* Muscles and Tendons, *2* Bones and Joints, *3* Nerves, *4* Vessels, and *5* The Round Window Photographs and drawings of ears, demonstrating some of the variations and abnormalities, will then be presented in the same order A brief explanation regarding the purpose of presenting each photograph will be given Comments that seem appropriate will be offered regarding surgical significance, etiology, embryology, and case history important than ever before A slight distortion or the absence of a landmark can be a pitfall for the newly trained surgeon, and sometimes an experienced operator may find his way down an unmarked road into a disastrous result

The report of variations found in the middle ear, or even a segment of it, from the outset is doomed to be incomplete Exhaustive studies of only one small part,[10 14 17 16 18 23 11 13 15 9 35 12 20 19] such as the stapes, have occupied men over long periods of time Study of variations of the ear is, however, important enough to justify the effort from a purely didactive biologic standpoint, but this justification is now reinforced by the currently evident clinical application, furthermore, thoughts regarding the development processes and theories of function may be stimulated in the minds of the readers

In the past the discovery of middle ear anomalies unassociated with other known defects of closely related structures has been extremely rare[5 6] Almost all of the reports in available literature have been of patients with atresia of the external ear with or without other defects of the entire hearing organ[54 110 91 28 34 118 40 77 94 76 111 25 99 95 60 100 71 101,107 53, 103 119 72 104 105 55 57 70 106 96,122 2 22 87 107 108 133 159 114,126 45 123 124 125 79 113 92 154 6 112 21 69 132 68] It is, however, my opinion that isolated *malformations of the middle ear are not nearly* so rare as has been previously thought, indeed, I am sure that many of these have been observed repeatedly although not yet reported A large number of variations and abnormalities have been observed by me in 500 operations, so it seems reasonable to assume that these are not rare The otologic surgeon, therefore, must constantly remember that a normal external canal may be approached and a normal tympanic membrane reflected only to unveil architectural and mechanical problems of several types

SOURCES OF MATERIAL

The reported variations and anomalies listed in this thesis were all found during the course of 500 transaural tympanotomies, most of which were done for the purpose of mobilizing the stapes There will be no attempt to broaden the field of expansion of the head, which tends to separate the primitive external ear from the middle ear. Mesodermal tissue separates the two epithelial layers during the ossicular development. Near the end of the second month of fetal life, the ectoderm thickens at the bottom of the groove and grows toward the middle ear. This solid meatal plate remains closed until the seventh month, at which time it splits and forms a canal. The innermost portion of this plate becomes the superficial layer of the tympanic membrane.

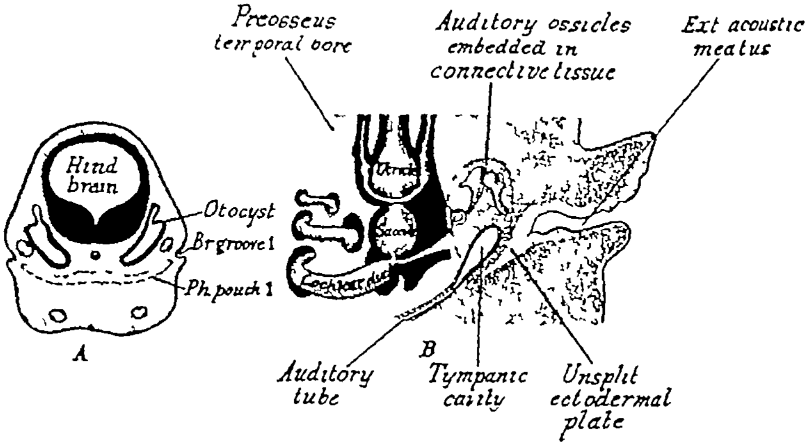
THE MIDDLE EAR

The tympanic cavity and the auditory (Eustachian) tube actually represents a drawn-out first pharyngeal pouch. The second pharyngeal pouch may also be merged with it.[53] The surrounding tissue of the first and second branchial arches constitutes the primordia of most of the other tympanic structures, such as ossicles, muscles, tendons, and connective tissue.

The first pharyngeal entodermal pouch appears late in the third embryonic week (3 mm stage) and expands rapidly. For a time it is in contact with the ectodermal membrane of the external first branchial groove (primitive external canal). This long open tube undergoes a bottleneck constriction near the end of the second month. The constricted portion lengthens and becomes the auditory (Eustachian) tube, whereas the blind outer end of the pouch expands to form the tympanic cavity. At eight weeks (23 mm stage), the tip of the flat tympanic cavity lies alongside the ectodermal tissue of the first branchial groove, which is the future external canal. These two cavities are separated by mesenchyme which later becomes the manubrium of the malleus and the middle fibrous layer of the tympanic membrane. Above, medial and posterior to the area of the future expansion of the tympanic cavity, the other ossicular and muscular elements are being developed from the mesenchymal tissue. As these structures progress to maturity, the unused surrounding mesenchyme disintegrates and the entodermal-lined tympanic cavity expands. This expansion is in pace with the concomitant development of the cartilaginous otic capsule and the external

Finally, general discussion under the headings of, first, etiology, and second, diagnosis, of malformations of the middle ear will be presented

Embryology—(see Fig 1) Drawing from diagram in Arey, "Developmental Anatomy," W B Saunders Co, 1940



Progressive association of the primordia of the external, middle and internal ears illustrated by partly schematic sections *A* At six weeks *B* at three months

FIG 1

THE EXTERNAL EAR

The external ear is formed by a modification of the tissues of the median portion of the first branchial groove and its neighboring first branchial arch (mandibular) above, and the second branchial arch (hyoid) below The auricle is formed by several knoblike structures that appear on the first two arches about the sixth fetal week These are gradually molded together to form the adult auricle

The external auditory canal in reality represents the first branchial groove The membranes (ectodermal) of this groove are for a time (fourth to the fifth embryonic week) in contact with the internal (entodermal) tissues of the first pharyngeal pouch This contact is soon lost, however, by the will be formed At this age the malleus and incus are recognizable, and the incudomalleolar joint begins to separate the two ossicles The incus is beginning to approach, but not touch, the head of the stapes for the formation of the incudostapedial joint Precartilage may be seen in the tissue of the ossicles and the otic capsule

In the eight-week-old embryo (23 mm stage), the stapes is cartilaginous, and its base is pressed hard against the otic capsule The remaining visceral bar connection becomes a strong mesenchymal band This band attaches to the lateral mass of the otic capsule, thus connecting it with the stapes head This will become the stapedius muscle A very small stapedial artery is still present The malleus is still connected to Meckel's cartilage, and the incudomalleolar joint has developed an articulating surface The joining of the long process of the incus with the stapes head has occurred

The embryo, at the age of nine weeks (30 mm stage), has true cartilage forming the stapes and the otic capsule, except in the vestibular region of the capsule against which the stapes rests This area is called the lamina stapedialis This portion of the capsule actually has two cellular zones The more superficial is mesenchyme which lies against the perichondrium of the base of the stapes The deeper layer is fibroblastic and blends with the mesenchyme supporting the epithelial labyrinth Actually this lamina stapedialis fuses with and becomes a structural part of the footplate of the stapes, therefore, it may be said that a part of the otic capsular wall contributes to the formation of the stapes

Between the 12th and the 14th fetal week (50 and 75 mm stage), the crura of the stapes become bowed, and the union of the incus and stapes differentiates into an articulating joint The base of the stapes has now become a part of the lamina stapedialis and blends with the surrounding capsular tissue This blending zone gradually undergoes further change into the annular ligament Actually, an orifice as such never exists, since the stapes is histologically continuous with the marginal cartilaginous vestibular window The annular ligament is first composed of chondrogenic tissue but progressively changes to a fibrous tissue ear canal. As the tympanum expands the lining epithelium surrounds the ossicles and muscles. By the 30th week (270 mm. stage), the cavity formation of the tympanum is complete, but another month is required before the epitympanum is near completion. At term most of the expansion is finished and the cavities are almost mature.

OSSICULAR AND MUSCULAR DEVELOPMENT OF THE MIDDLE EAR

This thesis is so intimately concerned with the ossicular and muscular structures of the middle ear that a more detailed discussion will be made regarding their known developmental processes. A brief chronologic story of embryologic development has been correlated from several authoritative sources.

The stapes is the first ossicle to make its appearance. When the embryo is four-and-a-half weeks old (7 mm. stage) there is a concentration of mesenchymal cells at the cranial end of the second branchial arch, also referred to as the hyoid, or second visceral bar. This is situated lateral to the mesenchyme of the primitive otic capsule, and is separated from it. It is still connected with its branchial arch (Reichert's cartilage, or hyoid bar). When the embryo is six weeks old (12 mm. stage), the stapes is represented by a dense mesenchymal ring penetrated by a large stapedial artery.

At the end of six-and-a-half weeks (14 mm. stage), the stapes is continuous with its branchial arch (Reichert's cartilage) only at the lateral portion, which will become the future head of the ossicle. It is at this age that Meckel's cartilage of the first branchial, or visceral, arch is seen (also called the mandibular arch). This will rapidly differentiate into the malleus, the incus and the tensor tympani muscle.

When the embryo is seven weeks old (17 mm. stage) the stapes is annular in shape like a doughnut. It has moved into close apposition with the lateral wall of the otic capsule. The basal portion of the stapes abuts the otic capsule and produces a concavity in it. The stapes is still connected with its visceral branchial arch (hyoid), and it is from this remaining connection that the stapedius muscle and tendon

THE INNER EAR

The inner ear is produced from epithelium derived from ectoderm Very early in embryonic life (three to four weeks, or the 2 to 4 mm stage) there develops an ectodermal thickening called the auditory placode on the lateral surface of the head This area invaginates to form a deep pit, the orifice of which soon starts constricting and eventually closes This forms a closed sac of trapped ectodermal cells, called the otocyst This becomes separated from the surface of the head and is completely surrounded by mesenchyme At the fifth week (8 mm stage), the otocyst begins differentiation into the vestibular and cochlear portions The cochlea begins to coil at the seventh week (17 mm stage), and the vestibule has developed the primitive utricle, saccule, and semicircular canals The surrounding mesenchyme becomes the otic cartilaginous capsule which begins ossification at about the 17th week of fetal life (125 mm stage) The elaborate embryologic differentiation of this highly specialized structure will not be traced further, as it is not needed for the purpose of this thesis The differentiation has been completed, and the organ is mature at birth

VARIATIONS—MUSCLES AND TENDONS

"Malformations of the muscles of the middle ear, especially their partial or complete lack, have been observed only when associated with other severe malformations"[93] Again, this condition is not so rare as has been previously considered During the course of 500 operations, I have found five patients with a total absence of the stapedius muscle, tendon and pyramidal eminence (see Figs 16, 5, 6, 7, 8) In one patient (see Fig 13), the muscle band was not much more than a condensation of soft tissue

The significance of abnormalities or absence of the stapedius muscle has been the object of highly specialized scientific investigation[160, 117, 90, 163] Apparently the stapedius muscle has the ability to reduce or dampen sound transmission en route from the tympanic membrane to the cochlea Some believe a reflex action may enhance certain sounds as well as

When the embryo is 16 weeks old (112 mm stage), the ossicles are still cartilaginous Ossification then appears first in the incus along the anterior aspect of the long crus

By the 17th week of embryonic life (125 mm stage), bone makes its initial appearance in the body of the malleus It is also at this time that ossification begins in the otic capsule

At about the 19th week of embryonic life (150 mm stage), ossification begins in the stapes by the appearance of a single center on the obturator surface of the base From this center, ossification spreads over the base and along each crus

At about the 28th week of embryonic life (225 mm stage), ossification has occurred throughout most of the ossicles The usual evacuation of the stapes is beginning to occur along the obturator margins This progresses until the crura are reconstructed into channeled troughs, the head is hollowed to form a cylinder, and the base becomes a thinned bilaminar plate This exceptional differentiation is found only in the stapes The malleus and incus, like all of the other bones of the body, progressively become thicker through the development of endochondral bone whereas the stapes becomes thinner, loses bulk and disposes of its marrow tissue Cartilage remains throughout life on all articulating surfaces of the ossicles Cartilage still covers, and will persist, on the vestibular surface of the base of the stapes Cartilage still remains and will persist throughout life in the rim lining of the oval window

By about the 35th week of embryonic life (345 mm stage), the stapes has assumed adult form, as have also the malleus and incus Mucous membrane has lined the spaces of the middle ear and is draped over the tympanic surfaces of the ossicles

At term (367 mm) the adult form of the ossicles is present and their relationships are established The ossicular muscles are fully developed and the mechanism of sound transmission is established for life's sojourn on earth midal eminence during the operation for mobilization of the stapes without bone removal from the external canal wall is quite variable. Although frequently it may be seen in its entirety (see Fig. 2), usually the chorda tympani nerve must be dislocated, and some canal wall bone must be removed before it can be completely inspected (see Fig. 27).

Variations in the length of the stapedius tendon are great. Some are extremely long (see Fig. 31). Some are almost too short to see (see Fig. 4). The unusual projection of the stapedius pyramidal eminence and the extremely short tendon seen in this photograph are extremely rare. The manipulation of the stapes in an operation for mobilization of the stapes can be interfered with by this close proximity. Visualization of the movement of the stapedius tendon is sometimes used to identify certain slight motions of the head of the stapes during mobilization.[130, 140] The size, location, and exposure variations are important in this light.

The attachment of the stapedius tendon is to the neck of the stapes in about three-fourths of ears. Occasionally, it is attached to the head or to the posterior crus (see Figs. 17, 2, 3). Usually the tendon is attached to a spine on the stapes.[24] One writer believed that the spine was the result of a traction process, whereas another felt that the spine was perhaps due to ossification of a certain portion of a tendon.[142] It is my belief that neither is true, since I have observed several cases in which a rather long spine was projecting in a different direction from the line of the tendon, and the tendon was attached to its distal end. If this spine had resulted from either a traction process or a tendon ossification it would have been in line with the tendon.

Discussion of middle ear muscles in this thesis will not include the tensor tympani muscle because it is not usually observed in trans-aural tympanotomy.

BONES AND JOINTS

Variations of the ossicles in an otherwise normal auditory organ are rare.[93, 26] The stapes is probably the most frequently affected ossicle,[93] but the vast majority of reports in the reduce certain intensities[163] Others believe that it is not a muscle of "attention," but a protective adjustor[90] The extent of the true value of the stapedius muscle is certainly not known, but now we can at least be sure that it is not absolutely necessary for serviceable hearing This is proved by an example of the return of hearing in a patient with ankylosis of the stapes and concomitant absence of the stapedius muscle (see Fig 5) After mobilization of the stapes, this patient's hearing returned to a good serviceable level This patient seems to have had no difficulty with tolerance to intense sounds, pitched either high or low and, therefore, does not seem to miss the "protective" mechanism

A case has been previously reported of ossification of the stapedius tendon producing stapes ankylosis[142] This has not been observed in this series, but embryologically one might expect this change rather frequently The stapedius head is joined to the hyoid bar rather late, and this tissue eventually attaches to the otic capsule and becomes the stapedius muscle, tendon and pyramidal eminence, with bone being formed on both ends and around the muscle belly All these structures are derived from the same branchial tissue and one could expect, occasionally, a differential change from muscle to bone

Supernumerary muscles have been reported in the bony facial canal[4 30] This muscle is without insertion and apparently is purposeless Other small muscle fibers have been seen in the substance of the temporal bone, but none has been observed in the middle ear, and none was found in this series

Variations in the direction from the insertion of the stapedius tendon into the stapes anteriorly to its origin in the pyramidal eminence posteriorly are frequently found They are of interest only in that they might hide a certain view of the posterior crus and footplate of the stapes by such a location In the majority, the tendon extends directly posteriorly and approximately parallel to the posterior crus (see Fig 2) In a few instances, it will be directed inferiorly and posteriorly (see Fig 3), and very rarely it will be directed superiorly and posteriorly The visualization of the pyrastapes had almost fallen short of union, and the stapes had turned its head up for a slight distance advantage. Indeed, the union of these two bones, which are embryologically derivatives of separate branchial arches, would make one wonder that much greater variation does not occur. The usual incudostapedial joint is found with the lenticular process of the incus placed slightly more anterior than the head of the stapes. This allows the posterior rim of the head of the stapes to be clearly seen. Frequently the lenticular process is placed squarely on the head and occasionally more posterior than the head of the stapes (see Fig. 2).

The head of the stapes may be extremely hollowed-out or solid, and may be as a rounded knob on a pedestal, or merely a flattened surface on the top of an arch formed by the crura. The normal and the usual is somewhere between these extremes. Bone erosion may produce a variety of knobs, spines, and holes in the head or the neck of the stapes.

The neck of the stapes may be thick or thin, solid or hollow, strong or weak.[24] Its length does not always determine its strength. A long slender neck may well stand a great amount of pressure which might be exerted on it during operative maneuvers.[130,140]

The head of the stapes is usually tilted slightly forward in relationship to the crural arch, however, it frequently meets the arch in a true perpendicular manner, and is occasionally tilted slightly posterior.

The clinical significance of these variations is obvious.[3] If the articulating surface is markedly tilted, efforts to perform a mobilization of the stapes by pressure exerted through the incus will frequently cause distortion and lysis of the joint, whereas recognition that there is a moderate tilt in one of the above directions will allow the surgeon to apply force in a direction that will allow for the tilt. It has been my experience that the two most dangerous positions in this respect are a tilting of the head of the stapes downward or forward. In some instances, mobilization through the incus is impractical. Picks in the head of the stapes are sometimes used to mobilize a fixed footplate. If the incus is placed unusually literature associate ossicular deformities with other severe head and branchial arch deformities In reviewing the literature, many of those reported were found in animals [26,24]

THE STAPES

"In spite of the importance of the stapes, no single element in human anatomy has suffered more chronic neglect This is a strange instance of disregard, since the stapes has great clinical importance in otosclerosis It passes through developmental stages of extreme interest, and is grossly the most captivating bone in the human skeleton For all of its unique fascination as the smallest essential bone and as the most exquisitely fashioned unit, this ossicle has not only been forgotten by investigators in anatomy and otology, but the descriptions of it in standard textbooks of anatomy have become stylized and debased through the years They are inaccurate and fragmentary, commonly perpetrating century-old errors Illustrations are either minute or diagrammatic"[24] Bearing this quotation in mind, an objective description of the unusual anatomy of this bone will be presented, with the discussion of the variations mentioned in the literature and encountered by me in this series

THE HEAD OF THE STAPES

The head of the stapes is normally broad and shallow,[44] and its surface is elliptical and concave for articulating purposes This surface is usually in a near sagittal plane, thus permitting the use of pressure through the incus on the stapes without causing one part to slide on the other, thus producing possible joint separation (see Fig 20) Occasionally, however, the joint will be tilted forward, permitting anterior dislocation if transincus pressure is applied, also occasionally the joint face of the stapes will be facing at a downward angle as though the long process of the incus had overgrown itself, and the joint formation was an afterthought (see Fig 6) Another variation is for the head of the stapes to be tilted superiorly, thus making the articulating surface face more in an upward plane (see Fig 14) This would make one feel that the long process of the incus and the it would be a very exceptional case in which the posterior crus would be straighter and more slender and shorter than the anterior crus (see Fig 5) Actually rare specimens occur in which the anterior crus is longer than the posterior and fairly commonly the crura are equal in length and about alike in curvature (see Fig 31)

Very little reference is made in past literature to a finding which I have frequently encountered These cases are those of crural bowing, either inferiorly or superiorly They may seem to wrap around the curve of the promontory or be curved around the bony facial canal[6] (see Fig 6) Bowing of the stapes crura is probably more frequently seen in a downward direction The intimate bowing around the bony facial canal is extremely rare (see Fig 14) Bowing of the crura must be considered if stress is to be exerted in any direction during an operation

Bony projections may be seen frequently on the surface of the posterior crus A knee-like area may frequently be seen about one-third of the distance down from the head toward the footplate on the posterior crus[24] There is frequently a bony spine on either the head, neck, or high on the posterior crus for the insertion of the stapedius tendon Rarely one may see a heavy bony rod extending from the promontory or the facial canal to join the posterior crus, thus causing fixation to the labyrinthine capsule[1 52] (see Fig 18) I have observed that it is common to see bony bridges which project from the promontory and are very near one of the crura These are seldom fused with it (see Fig 17)

Severe variations of the crura are very rarely seen[23 24] They have been reported only with severe deformities of the skull Most of the severe crural deformities reported in literature were seen in animals[26 24] Isolated human anomalies are extremely rare[26] I believe these malformations are far more common than is realized Fusion of the stapes crura into a double-barreled stapes was observed one time in this series, and has been observed previously[24] This is perhaps due to variation in the primitive stapedial artery or abnormal ossification of the inner crural membrane, or due to a variation far posterior it may be impossible to engage the pick in the head of the stapes without joint dislocation. Often the head and neck of the stapes have been rendered a hollow shell by bony absorption from the obturator surface. The outside appearance may be that of a heavy solid structure, but the application of even a fine pick may break through the shell and cause the head to crumble partially.[74]

One maneuver for mobilization of a fixed stapes depends a great deal on the structure of the head and neck as well as the crura. The pressure in this maneuver is against one area of the anterior portion of the neck or head, and the line of force is in a posterior direction.[130] The head of the stapes is usually tilted slightly forward, and this is an advantage in the application of force in this direction.

THE CRURA

The stapes crura are long arched structures which fuse into one at the neck of the stapes, and are widely divergent as they meet the footplate. They are hollowed on the inside, or obturator surface, making them an inverted rounded trough, the edges of which become more pronounced as they curve to meet the footplate. This trough is usually deeper at the base of the posterior crus than at the base of the anterior crus. This hollowing out is the result of bony absorption and can produce a large number of variations. The crura may be extremely hollowed out to a very weak thin shell; on the other hand, there may be no visible evidence of erosion so that the crura are left very solid and large. This is an infantile type of crura. Bony projections, spurs and eroded-looking pits may frequently be seen, especially on the obturator surface.

The anterior crus is usually straighter and shorter than the posterior. The anterior crus averages 3.62 mm. from the head to the base. The posterior crus averages 3.73 mm. from the head to the base. The anterior crus is the more slender of the two. This description is considered to be almost an invariable one by most authors. There seems to be only one who has disagreed with this description.[75] At least one can say that plane as seen in Fig 14 In this patient there was a severe congenital malformation of the labyrinthine wall, making the area of the stapedius laminalis almost look down on its tympanic aspect This is because the window area is situated under and medial to the facial canal At the other extreme is the footplate that is flat or looking slightly upward, as seen in Fig 31

The bony overhang of the facial nerve above or the promontory below determines the direction and width of the niche in which the stapes must fit The crura are usually attached to the footplate at a slightly superior angulation *in situ*[23] This is an unusual statement since in a large majority of cases the footplate is seen mostly above the crura and behind the long process of the incus and below the overhang of the bony facial canal, thus one would expect the angle of insertion of the crura to be more inferior This is due to the fact that the vestibular window is at an angle of inclination even greater than the angle of the crura, therefore, the crura are attached to the footplate usually at an angle of less than 90 degrees from the superior edge of the footplate to the crura

The trough margins of the obturator surface of the crura extend in varying degrees out on the marginal edges of the footplate These lips may run completely around the footplate to produce a rim or tray edge as in the infantile stapes, or the trough margins may be hardly perceptible on the crura and absent on the footplate In my experience, it is unusual to see this crural trough edge extending onto the margin of the footplate Rarely a small bony ridge is seen on the tympanic surface of the footplate extending between the crura This is called the crista stapedius and is very inconstant It is reported that at times the ridge may be replaced by a crest[23]

THE FOOTPLATE OF THE STAPES

The footplate is usually rounded in an arch on its superior edge, curved with a slight point anteriorly, almost straight on its inferior edge, and gently curved on the posterior edge[24] The footplate may frequently be extremely narrow and long, being wedged into a narrow niche between the facial ridge in bony absorption In Marmozets, the crura of the stapes are often found fused for a short distance below the head[44] In Montremata, which is a true mammal of a low skeletal form, the stapes is normally absolutely columelliform (unicurate stapes)[44]

Figure 15 represents a stapes with only one crus This is the posterior crus with the tympanic side of the base being visible in the photograph The incudostapedial joint has been disarticulated in this ear, and the head of the stapes rotated posteriorly so that the basilar obturator surface of the posterior crus could be seen as it joins the footplate area The crus was fairly well developed, but there was no footplate There is a total absence of the anterior crus, thus making this a completely unicurate stapes This finding was in a patient with unilateral deafness

Complete bony union of the crura may be seen, due to massive otosclerotic mounds filling the obturator space (see Fig 19) In the case of a deep niche, the pathologic bone formation may fill in the niche for the stapes and obscure the landmarks below the stapes neck and upper arch This amount of proliferation is rare In certain anomalies, the crura may be extremely small and fragile (see Fig 14) , in other conditions the stapes may be extremely short and bulky (see Fig 4) In the short bulky stapes the obturator foramen may be very small and the stapes may be almost like a rounded blob of bone (see Fig 4) This type of stapes, obviously, has not developed even to the stage usually seen in later uterine life In late uterine life the stapes is even larger than the adult form and must undergo reduction in size by bone absorption, whereas in this patient the stapes is even smaller than usual, but it has much thickness and, therefore, represents a very early embryologic stage

The crura may join the footplate at a variety of different angles Their junction with the footplate may be at right angles or the crura may be tilted inferiorly or superiorly to the plane of the footplate Usually, the footplate of the stapes is in the vestibular window at an angle slightly off the sagittal plane of the body This may vary to an almost horizontal casionally, the otosclerotic bone is seen in mounds occupying isolated areas, or to a massive degree as mountains filling in the entire niche and covering large portions of the crura (see Fig 19)

THE LONG PROCESS OF THE INCUS

Only the long process of the incus is visible during the ordinary operation for mobilization of the stapes It projects from under the superior canal rim, usually as a long, slender, slightly convex process which bows slightly anteriorly and gradually becomes more medial toward its tip The end of the tip has a structure designed for articulation with the head of the stapes This structure is a small mass of bone which extends medially from the main shaft and bears a flat elliptical disc with a joint surface of cartilage A variety of names have been given to this portion of the long process of the incus, such as the lenticular process, the *os orbiculare* or the Sylvian apophysis[44] Some authorities have considered this a separate bone, but others have held that it is only an epiphysis of the incus[44]

The lenticular process may assume a variety of shapes which are important in present-day surgical procedures in the ear A structure much like the head of the stapes may project medially from the long axis of the process It may rest upon a small but distinct neck and may deviate anteriorly or posteriorly, superiorly or inferiorly, in order to articulate with the stapes The joint surface may be in any of the planes described under the head of the stapes variations, and are important because of the reasons listed there Bony strength of this head and neck are important, due to the possibility of fractures during various operative maneuvers

Often the long process of the incus does not have an articulating head and neck, and there is found only a flat articulating surface on the medial side of the long process of the incus

The lateral side of the long process of the incus may have a variety of bony projections A spine-like structure may be seen on the lateral surface at the very end of the process (see and the promontory It may frequently be generously wide with much of its area being superior to the crural insertion (see Fig 10) Rarely the inferior margin is seen in its completeness (see Fig 31) There may be a slight extension of the footplate, either anterior to the anterior crus or posterior to the posterior crus In one patient, I observed a marked extension posterior to the posterior crus of about 1 mm This shelf was proven to be present on mobilization by visualizing its free margin

The average length of the base of the stapes is 2 99 mm with variations of from 2 64 mm to 3 36 mm The average width is 1 4 mm with variations of from 1 08 mm to 1 66 mm [24]

The annular ligament connects the circumference of the stapes to the rim of the oval window, and is very frequently the site of otosclerotic bony invasion, especially in its anterior area [168,31] Due to the embryologic development of the annular ligament, which is derived from the same tissue that later becomes the bony labyrinth on one side and the footplate of the stapes on the other,[24] it is reasonable to assume that free cartilage or actual cartilaginous nests may devleop and remain within its substance [93 28] These nests might become osteogenic and produce bony deposits capable of causing footplate ankylosis Thin bridges of cartilage in the annular ligament presumably could become ossified in the middle decades of life much as cartilage in other regions of the body undergoes such change

The thickness of the footplate is the most variable of the areas considered An extremely thin, almost transparent, footplate is frequently seen On the other hand, a thick, strong, opaque footplate is common [131] These extremes seem to be normal variations Otosclerotic infiltration may involve a small rim area, or may when advanced, change a portion of the footplate into heavy otosclerotic bone and leave the remainder quite thin and normal The anterior areas are the most commonly infiltrated Smooth infiltration of the entire stapes and annular ligament so as to obliterate all fenestral and footplate identification may be seen (see Fig 22) Oc-rare, but because this area has not come under observation in the past as often as the epitympanum I have encountered one such frozen joint between the incus and stapes in this series

A review of the literature on the histopathology of ossicular articulation and particular discussion of the findings of foreign authors has been done[46] It was found that there were four distinct layers, almost constantly found in all ossicular articulations They are from the bone outward *1* The bony layer, *2* The layer of calcified cartilage blending with bone, *3* A layer of hyaline cartilage, and *4* The terminal or meniscoid articulating surface A very interesting finding has been the lack of disease in the joints, even in a large number of patients who had middle ear suppurative disease It has been considered, however, that actual ankylosis of the incudomalleolar joint is usually the result of inflammation

NERVES

Only the facial nerve and its chorda tympani branch needs to be considered in this thesis Marked variations of the position of the facial nerve in its horizontal course across the middle ear are extremely rare[93] Minor variations are common, and are of great importance in the region of the oval window where present-day instrumentation is common There usually is a definite bulge of the bony facial canal just lateral to and above the footplate of the stapes This bulge is usually not sufficient to hide the superior margin of the footplate Marked inferior and lateral bulging occasionally hides a part of the footplate and crowds the crura against the promontory below Obviously, this will hinder instrumentation, and may predispose to nerve injury if forceful entry to the footplate area is made The facial nerve in its bony covering may present only a very small bulge in the labyrinthine capsule wall, which will represent a nerve of small diameter, or one that is deeply placed in the bone (see Fig 18) The opposite extreme is the huge nerve and bony canal that can be seen in Fig 16 This is an unusually large fallopian ridge

Fig 24) This usually points slightly anteriorly, and gives the appearance of the bow of a ship Frequently, the opposite of this may be seen, in which the process rapidly tapers off at the end as it meets the stapes, giving a rounded-off appearance (see Fig 23) The application of various instruments for transincus pressure on the stapes will depend on the direction, topography and strength of this area Slipping-off or fracturing can result from lack of consideration of these variations

Erosion or necrosis of the lenticular process by disease will be discussed under etiology and with the presentation of the case in Fig 21 I have seen complete erosion of the lenticular process of the incus three times in this series in the presence of a normal eardrum and canal I am sure that it will be seen much more often in the future than in the past This necrosis, if complete, produces a gap in the ossicular chain and results in an air conduction hearing loss of about 60 db

A total separation of the incudostapedial joint without necrosis is reported in this series Discussion and descriptions are treated elsewhere This is the second patient reported in the literature available to me

In this series, variation in direction of the long process of the incus as it projects downward is at least 45 degrees

Bony fusion of the lenticular process of the incus with the head of the stapes and the handle of the malleus is a rare anomaly, and is presented in this series (see Fig 8) As far as I am able to ascertain, this is the first case of such abnormality reported in the literature This was a huge bony mass which involved all three ossicles Such an anomaly requires a triple arthrolysis before a mobile sound-transmitting apparatus can be obtained

A much simpler fusion at the incudostapedial joint may occur unassociated with any other abnormality Numerous reports have been made of simple joint fusion of the incudomalleolar joint, but I have found no reports of incudostapedial joint fusion The reason, I believe, is not because it is more the anomalies reported have been of the descending portion of the facial nerve and not the horizontal portions.

VESSELS

Vascular anomalies of the middle ear are extremely rare but must be constantly kept in mind. Among the anomalies, the so-called persistent stapedial artery is one of the most commonly known.[93, 30] This artery is a persistence of a primitive vessel which is a branch of the internal carotid artery. It perforates the floor of the tympanic cavity and progresses over the promontory, passes between the crura of the stapes and enters the facial canal. It later enters the cranial cavity and divides into branches to the dura.[93, 155] I have not encountered a persistent stapedial artery in this series. Although it has been commonly reported that this could be the cause of some types of tinnitus, I could find no documented reports of human cases in the literature, however, there have been many references to this anomaly in animals.[155]

Another common anomalous artery which should be mentioned, originates from the superficial petrosal branch of the middle meningeal artery. This vessel may accompany the facial nerve and may be found in the mucous membrane along the posterior wall of the niche of the oval window, passing through the crura and branching into a plexus on the promontory. I have not observed this anomaly.

Branches of the vestibular artery may be in close proximity to the labyrinthine surface of the footplate of the stapes. This artery is a branch of the internal auditory artery. Profuse bleeding from the vestibule may occur by accidental tearing of this vessel during mobilization of the footplate. If the vessel were so closely bound down to the footplate as to cause tearing of it during manipulation it would be considered to be in a very rare anatomical position. The cause of profuse bleeding in the example to follow is not known, but it is assumed to be due to the above anatomical variation. During the mobilization of a stapes footplate in one patient of this series, the following sequence of events occurred. Instrumentation was proceeding via the head of the stapes

A bony dehiscence in the facial canal wall is of great importance These are not uncommon in my experience, and invite injury to the facial nerve by either mechanical injury or inflammatory involvement[93] Usually the dehiscences are located just above the oval window[93] and are covered with a layer of connective tissue and mucous membrane[144] They are usually oval in shape and the soft tissue may bulge out of the opening slightly[50] "This is explained by the fact that the facial nerve originally lies in a sulcus of the labyrinthine capsule, which is closed to form a canal by the formation of a bony cover or a connective tissue base in late embryonic life and the first year of the post-embryonic life"[50] Defects of ossification may occur, especially in connection with a hyperplastic condition of the mucous membrane of the middle ear

The chorda tympani may be very large or extremely small in diameter It usually enters the bony external ear canal (Iter chordae posticus) on its edge just lateral to the stapedius tendon Occasionally, the nerve enters its bony canal 1 or 2 mm external or lateral to the external canal edge This was observed in three ears of this series There may be a slight variation in the location of bony entrance on the rim of the canal wall Using the right ear as an example and considering the top of the head to be the 12 o'clock position, the chorda tympani may enter its bony canal between 9 o'clock and 10 o'clock It is usually at a position just superior to the end of the fibrous annulus of the tympanic membrane As the nerve continues superiorly along the canal rim it seems to function also for a short distance as an extension of the fibrous annulus of the tympanic membrane A varying amount of bone covering is found over the nerve along the rim

No extensive hypoplasia or absence of the facial nerve or the chorda tympani was observed in this series, and I have found no reports of malformation involving the nerves alone in the literature available to me A marked hyperplasia of the facial nerve, or its bony covering or both, is reported here in Fig 14 Malformations of the facial nerve may be found in conjunction with other severe anomalies[204] Usually

PRESENTATION OF PHOTOGRAPHS AND DRAWINGS AND DISCUSSION OF ANOMALIES AND VARIATIONS OF THE MIDDLE EAR

when suddenly a profuse hemorrhage occurred from the vestibular window. This occurred as the footplate was seen to become slightly mobile. This hemorrhage was definitely a pulsating type of bleeding, and was so rapid that within a matter of seconds the entire middle ear, the ear canal, and the ear speculum were filled with blood; it was so rapid that the suction could not handle its volume. This bleeding gradually subsided over a period of four to five minutes and eventually stopped entirely, never to recur. Although mobilization attempts were discontinued, and consequently there was little postoperative hearing improvement, the profuse hemorrhage apparently did not damage the labyrinth, since hearing deterioration has not followed.

Two other vascular variations should be mentioned although neither was seen in this series. It has been reported that, rarely, there is an absence or a dehiscence of the floor of the middle ear allowing the jugular bulb to herniate upward into the middle ear; also, vascular tumors, such as glomus jugulare, may arise in this area and should be remembered in diagnostic differentiation.

THE ROUND WINDOW

Variations in the size, location and shape of the round window are interesting and sometimes clinically significant. Otosclerosis can cause complete occlusion of the round window.[89, 142] It has been found that otosclerotic occlusion of the round window causes hearing loss comparable to fixation of the stapes.[161]

In this series I have encountered no cases of complete closure of the round window but have seen several cases of extremely small windows. Identification of otosclerotic foci at the periphery of the round window has not been possible under 16-power magnification, and these small windows observed are considered to be developmental. The size of the window seemed to have little to do with the clinical restoration of hearing in this series; however, it must be pointed out that no total closures were observed. Very large windows were occasionally seen, and a variety of membranes were

Figure 2

Photograph of a left tympanic cavity presented for the purpose of demonstrating variations of the stapedius muscle and its tendon

This stapedius tendon is seen in beautiful contrast Occasionally one sees the entire stapedius tendon and the pyramidal eminence without disturbing the chorda tympani nerve or the bony external canal This tendon is of average length and is inserted directly into the head of the stapes This tendon is parallel with the posterior crus, in its usual position

Observe the excessive vascularity of the mucous membrane

Figure 3

Photograph of a right tympanic cavity displayed for the purpose of showing a variation in the tendon of the stapedius muscle

The stapes is unusually large, as is the long process of the incus, yet the stapedius tendon is relatively small The tendon is inserted directly into the posterior crus of the stapes Although this variation is not uncommon, it is the most unusual point of insertion The neck and the head are the most frequent sites for stapedial tendon insertion

Usually, the tendon of the stapedius muscle is parallel to the posterior crus of the stapes, but in this ear it is deflected at almost a 45 degree angle inferiorly Even more uncommon than this position is that of a deviation of the tendon in a superior direction

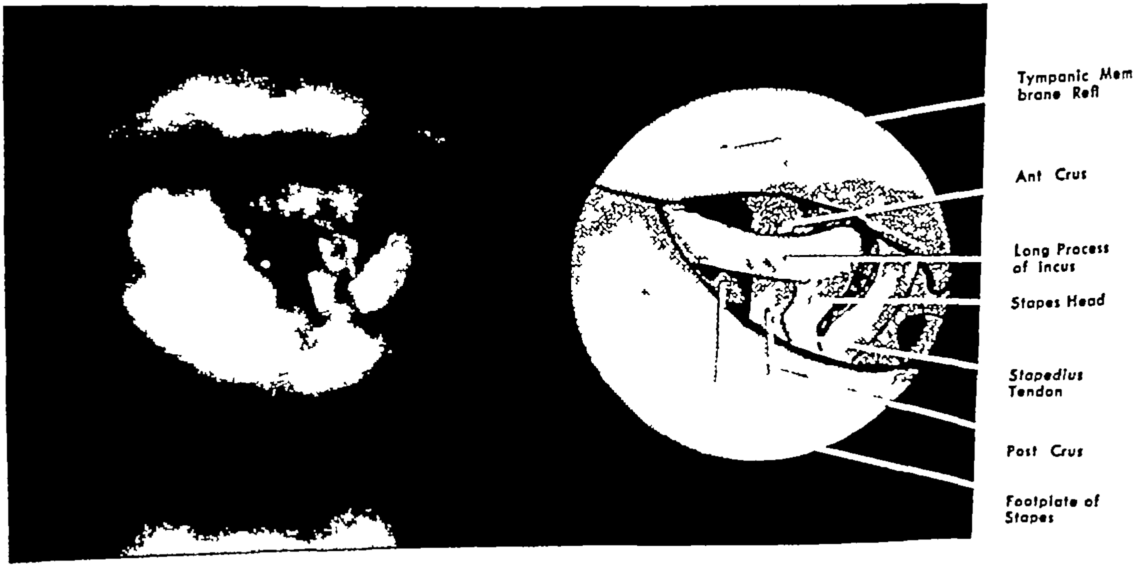

Figure 3

Figure 2

Photograph of a left tympanic cavity presented for the purpose of demonstrating variations of the stapedius muscle and its tendon

This stapedius tendon is seen in beautiful contrast. Occasionally one sees the entire stapedius tendon and the pyramidal eminence without disturbing the chorda tympani nerve or the bony external canal This tendon is of average length and is inserted directly into the head of the stapes This tendon is parallel with the posterior crus, in its usual position

Observe the excessive vascularity of the mucous membrane.

Figure 3

Photograph of a right tympanic cavity displayed for the purpose of showing a variation in the tendon of the stapedius muscle

The stapes is unusually large, as is the long process of the incus, yet the stapedius tendon is relatively small The tendon is inserted directly into the posterior crus of the stapes Although this variation is not uncommon, it is the most unusual point of insertion The neck and the head are the most frequent sites for stapedial tendon insertion

Usually, the tendon of the stapedius muscle is parallel to the posterior crus of the stapes, but in this ear it is deflected at almost a 45 degree angle inferiorly Even more uncommon than this position is that of a deviation of the tendon in a superior direction

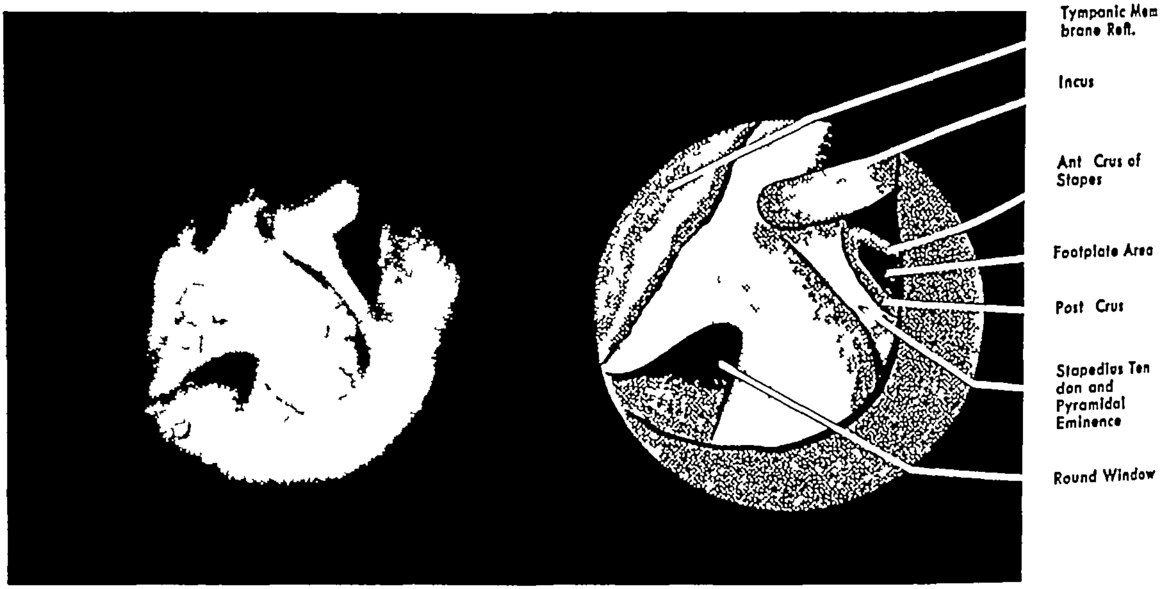

Figure 2

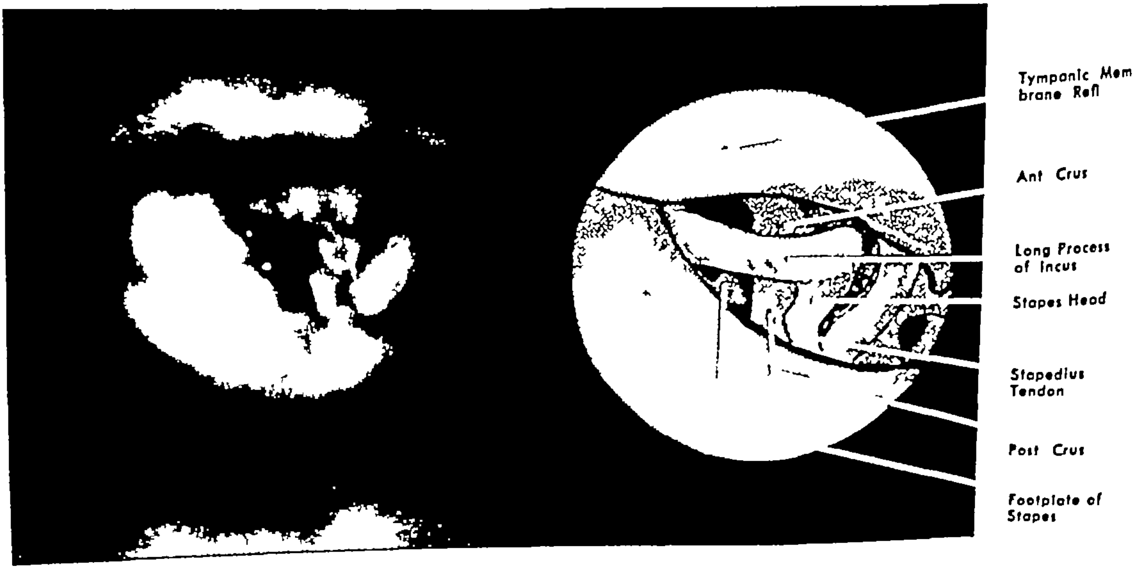

Figure 3

Figure 4

Photograph of a left tympanic cavity displayed for the purpose of showing bony and muscular variations

The long process of the incus describes an S-curve and articulates squarely with the head of the stapes

This stapes is extremely small, yet the crura are very thick An obturator foramen if present, is so small that a right angle pick could not palpate it, it could not be seen This stapes seems to be a rounded mass of bone in a very immature state Late in fetal life, the immature stapes is much larger than the mature stapes This apparent paradox is probably explained by the cessation of development in this patient somewhere between the 10th week (40 mm stage) and the 20th week (125 mm stage) of embryonic life

The footplate was present in this case but was likewise small and thick Fixation was apparently due to bony fusion to the margins of the oval window This was disrupted by mobilization maneuvers at the head of the stapes

Without the necessity of removing bone from the external canal wall, the pyramidal eminence is well seen, as is the bony ridge of the facial canal The pyramidal eminence is a continuation of the facial ridge in this ear This position and amount of projection is considered very unusual

Total absence of the stapedius muscle will be seen in Figure 5 This ear, however has an extremely short thick tendon It was so short that I first believed the stapes to be joined directly to the pyramidal eminence with bony union It was only after mobilization that I could see tendon motion

Figure 5

Photograph of a left middle ear displayed for the purpose of demonstrating muscular and bony malformations

This ear is an example of total absence of the stapedius muscle tendon, and its pyramidal eminence This is a deformity without evidence of other known head or neck malformations It was accompanied by fixation of the footplate of the stapes The problems encountered during the operation were no different from those seen in any other ear with ankylosis of the footplate margin

Much has been written concerning the function of the stapedius muscle. Five ears with congenital absence of this muscle are reported in this series In four of these patients serviceable hearing was obtained by operative restoration of mobility of the ossicular chain In none of the four cases were there symptoms which one might expect from either the loss of the so-called "protective mechanism" or the lack of the so-called "tuning-up ability," which has been ascribed to the stapedius muscle by some authorities This does not refute the theories of function of the stapedius muscle, but it establishes the fact that this muscle is not absolutely necessary for serviceable hearing Please see the pre- and post-operative audiogram of this patient following the discussion of Figure 28

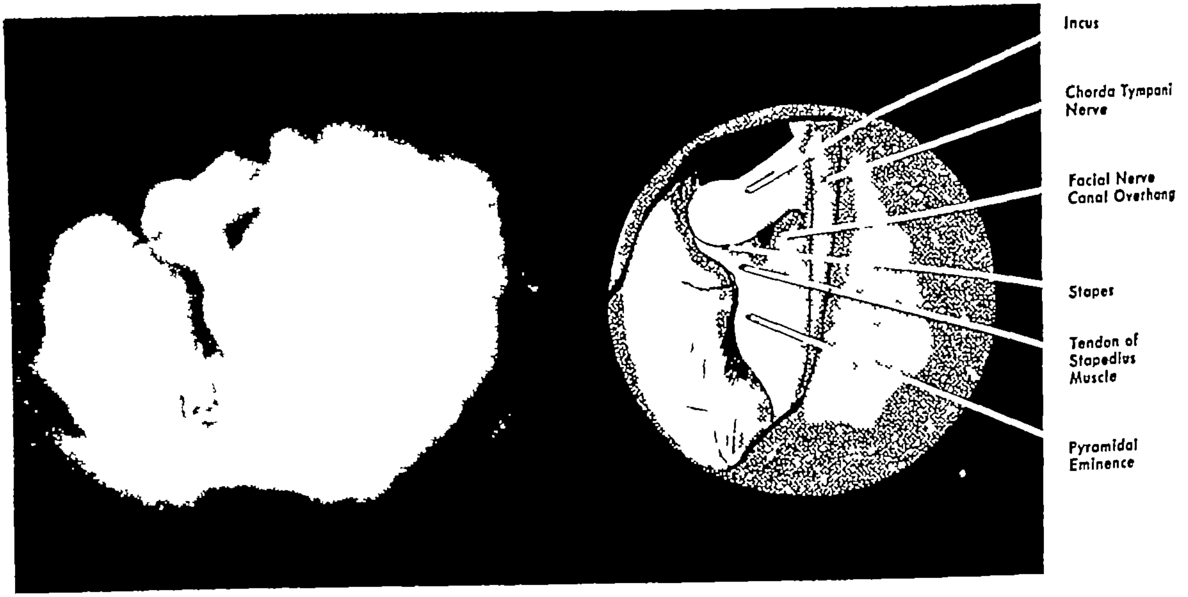

Figure 4

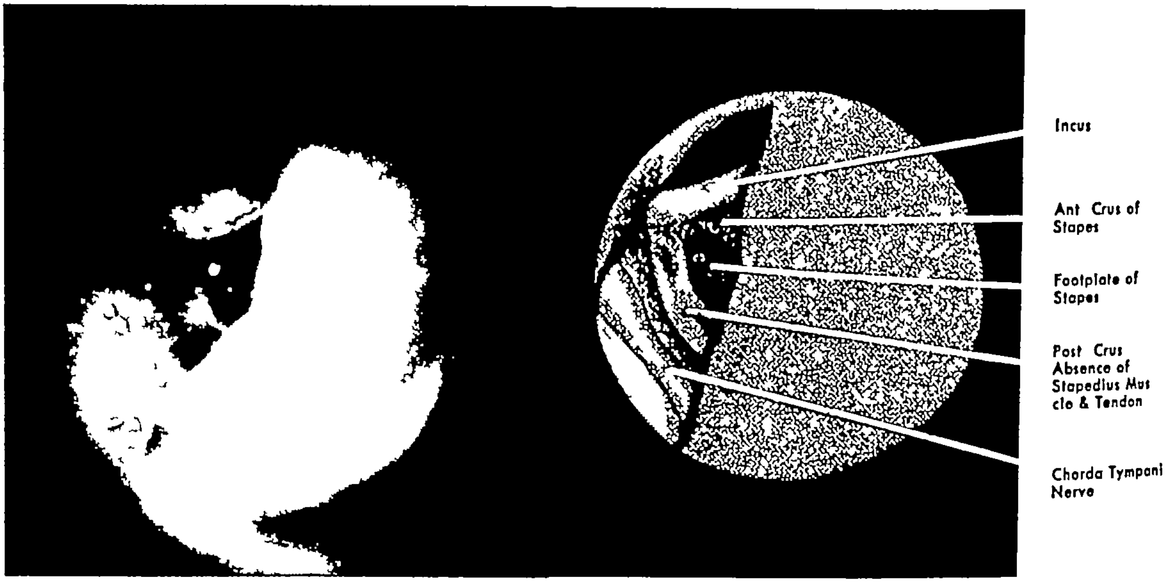

Figure 6

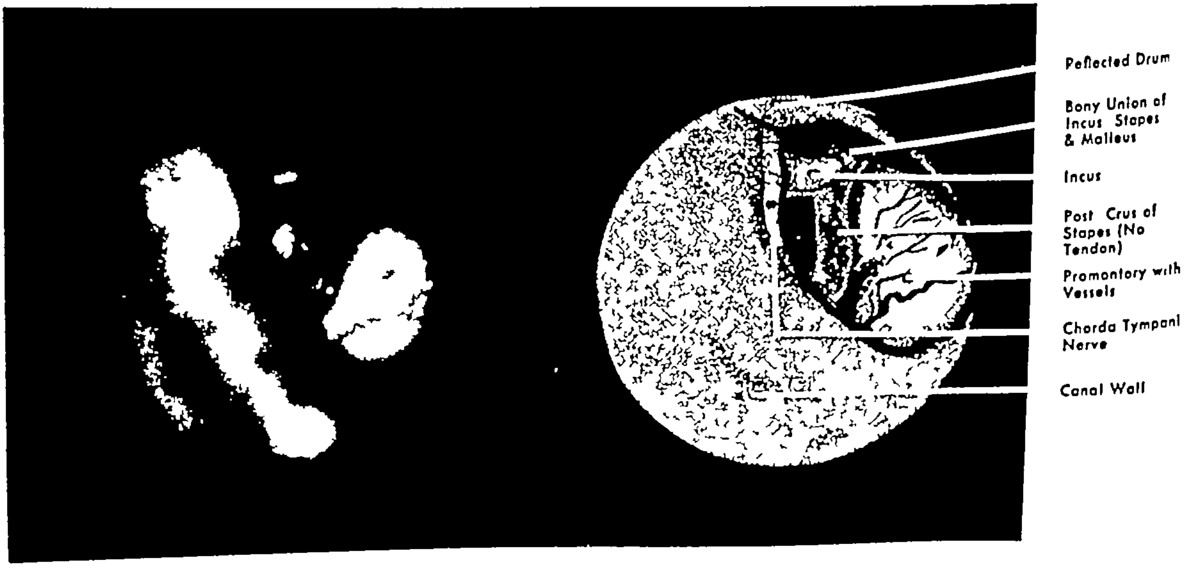

Figure 7

Figure 6

Photograph of a left middle ear displayed for the purpose of showing bony and muscular malformations

In this ear there was a bony union of the promontory to the inferior surfaces of the crura of the stapes There was a tremendous amount of longitudinal overgrowth of the long process of the incus

At operation, the crura of the stapes were gradually separated from the promontory and the stapes was made mobile For fear of possible re-attachment to the promontory, a repositioning of the incudostapedial joint was attempted The joint was purposely severed and the long process of the incus was shortened The head of the stapes was lifted superiorly so that its crura would not be against the promontory The head of the stapes was again made to rest on the inferior surface of the long process of the incus This questionable procedure proved to be worthwhile as shown by the ultimate functional result obtained Please see the pre- and post-operative audiograms reproduced following the discussion of Figure 30

The absence of the stapedius muscle, tendon, and its pyramidal eminence is again seen in this ear

Figure 7

Photograph of a right middle ear displayed for the purpose of showing bony malformations This ear also has a muscular abnormality and a variation in the position of the round window is seen

The rare malformation of triple bony union of the malleus, incus, and stapes is more clearly seen in Figure 8 and will be discussed there

The posterior crus of this stapes is clearly seen and is without its normal arch It is straight, but bends in a superior direction as it joins the footplate The posterior crus is not only without its normal arch but also is longer than the anterior crus

There is a total absence of the stapedius muscle, tendon, and pyramidal eminence in this ear This is one of five cases in this series with this abnormality To my knowledge, this abnormality has not been reported in ears without severe accompanying deformities The embryologic considerations will be given in the discussion of Figure 8

The footplate of the stapes is clearly seen just under the posterior crus The anterior crus of the stapes is hidden by the long process of the incus

Round window variations will be demonstrated in figures to follow, but an unusual variation in the position of the round window is here seen In this ear, the round window is almost completely hidden by the overhang of the bony external canal wall and is placed far posteriorly Without searching, one might be misled into believing that there is a total absence of the round window in this patient

Figure 8

Photograph of the same ear as seen in Figure 7 presented for the purpose of demonstrating more clearly the bony malformations

This ear, as previously stated represents a rare triple bony union of the lenticular process of the incus with the handle of the malleus and the head of the stapes This deformity to my knowledge, has not been reported in the past. The long process of the incus is deformed presenting a twisted S-shape The handle of the malleus is clearly seen attached to the reflected tympanic membrane and is fused with the other two ossicles by a thick bony mass

The problem of micro-orthopedics is obvious Ossicular separation was accomplished and serviceable hearing was restored The discussion of proposed embryologic significance of this deformity may be seen directly following the presentation of photographs

Figure 9

Photograph of a left tympanic cavity displayed for the purpose of showing a rare skeletal anomaly involving complete disarticulation of the incus from the stapes

This patient suffered a severe blow upon his head during his youth and reported that partial loss of hearing in this ear began at that time No other symptoms are present and the opposite ear is functionally normal

Ossicular disarticulations due to nonfatal blows on the head have not been reported in the literature available to me One would therefore hold some reservation in stating that trauma is definitely the etiologic factor but due to the history it seems to be the most likely cause

Consideration must be given to the possibility of this being a congenital abnormality An embryologic explanation is difficult due to the absence of abnormalities in other structures closely related in development The incus is derived from the first visceral arch whereas the stapes is derived from the second visceral arch During the 8th week (23 mm stage) the lenticular process of the incus and the head of the stapes unite and a true articulating joint develops A variation in growth and development possibly could produce a non-union of these bones as seen above

Figure 8

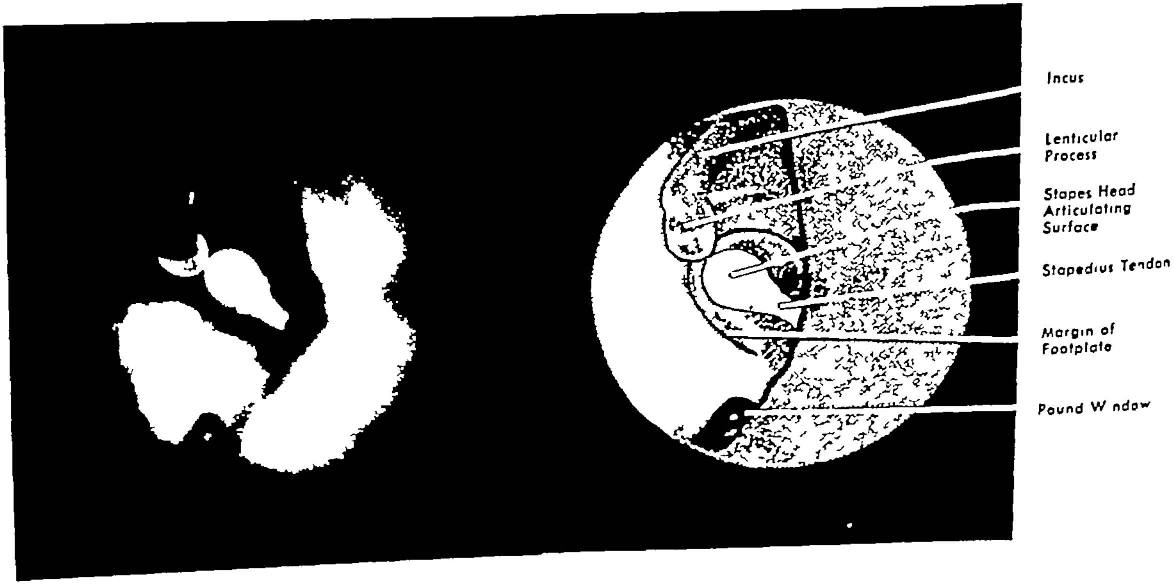

Figure 9

Figure 10

Photograph of a left middle ear (the same ear as reproduced in Figure 9) This brings the footplate of the stapes into better focus and demonstrates again the incudostapedial joint separation

This patient had a unilateral purely conductive hearing loss of 67 decibels for pure tone and 62 decibels for speech No other abnormalities of the middle ear could be found The round window was present and the membrane visible The malleus and incus were freely moveable The entire stapes was easily seen The footplate moved normally in the oval window There was no evidence of abnormalities of the external or internal ear which would account for the profound loss of hearing One may assume, with this evidence, that all of the hearing loss was due to disruption of the ossicular chain Many observers have suggested that sound reaches the cochlea by molecular transmission through the round window in the theory of "hearing in reverse" Other investigators have suggested that the cochlea receives sound by a universal transmission of energy by all of the surrounding tissues and air without any point of emphasis These theories deny the pre-eminence of transmission via the tympanic membrane and ossicular chain through the oval window to the cochlea Some observers ascribe only protective function to the tympanic membrane and ossicular chain It is not the purpose of this thesis to discuss theories of sound transmission, but the disarticulation presented in this patient caused consideration as to its functional significance

This cochlea had the opportunity to receive sound transmitted through either the round window or the oval window There was no mechanical barrier at either window Both avenues of entry were perfectly normal, yet there was a loss of 67 decibels for pure tone This type of hearing loss has been produced experimentally in animals by disruption of the ossicular chain continuity and testing cochlear potentials by the Wever-Bray phenomenon This patient, however, represents a human example of the sound transmitting ability of the ossicular chain Figure 11 will demonstrate a return of that function in the same patient by restoration of the ossicular chain

Figure 11

Photograph of the same left tympanic cavity as seen in Figures 9 and 10, displayed for the purpose of demonstrating operative correction of the incudostapedial joint separation previously seen

The articulating surfaces of the head of the stapes and the lenticular process of the incus were roughened by the use of small picks A small shaving of bone was removed from the edge of the bony external canal wall and teased into position between the articulating surfaces of the two ossicles The hearing was instantly restored to normal and there was no regression in six months Please see audiogram of this patient directly following the presentation of photographs

Round Window

Figure 10

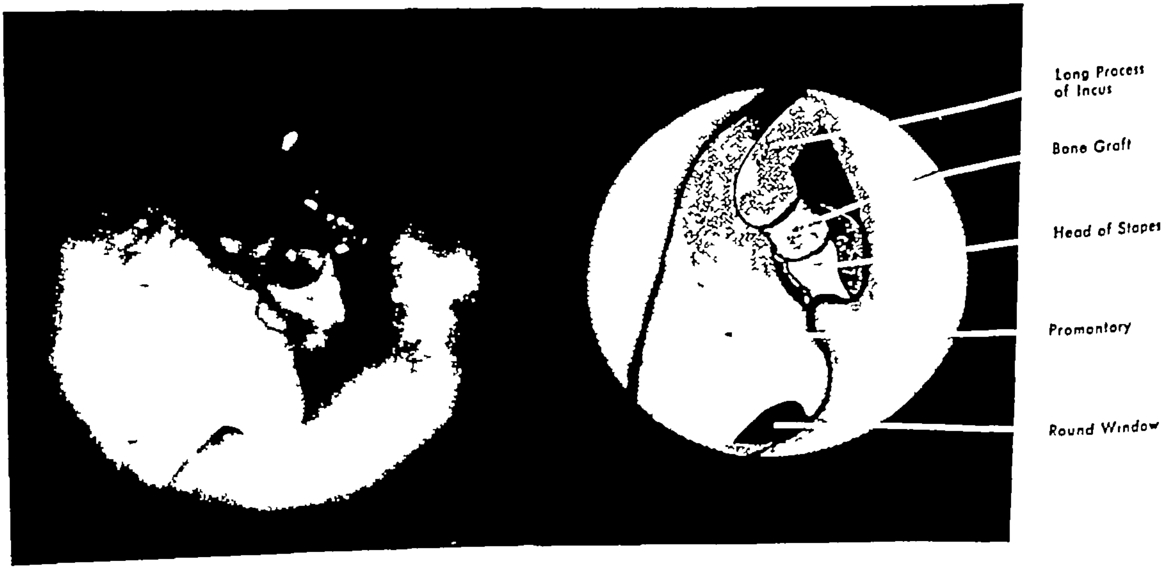

Figure 11

Figure 14

Photograph of a right tympanic cavity seen in Figure 13 after removal of mesenchymal tissue strands

The two crura of the stapes can be seen wrapped around the facial canal like the claws of a bird on a limb The crura are bony but are extremely fragile The are rounded off as they meet a very indefinite footplate The oval window area is apparently recessed high up beneath the bony ridge of the facial nerve There is a total absence of an oval window A total absence of the oval window has been considered extremely rare In literature available to me there were no human cases reported of this abnormality during the past 100 years An attempt was made in this ear to find the oval window with the use of sharp probes but only solid bone was encountered

The stapedius tendon and pyramidal eminence are easily seen, but are very small

A large bony spicule is seen projecting from the annulus to the promontory

This malformation would have been overlooked and misdiagnosed without trans-aural tympanotomy This patient's deafness has been considered to be due to a variety of conditions such as hypertrophy of the tonsils and adenoids Eustachian tube obstruction on the basis of allergy adhesive otitis media and congenital perceptive deafness This patient had undergone tonsillectomy and adenoidectomy radium application to the nasopharynx Eustachian tube insufflation and allergic management for the relief of deafness The microscopic examination of this middle ear presented a correct diagnosis and initiated the planning of a rational surgical procedure for restoration of hearing

Figure 15

Photograph of a right tympanic cavity displayed for the purpose of demonstrating marked congenital malformations of the ossicles

This is an ear of a 7 year old girl with a purely conductive deafness present presumably since birth.

The incus appears fairly normal but its body apparently placed more anteriorly than usual

The head of the stapes has been purposely disarticulated and rotated posteriorly so that the posterior crus and the footplate area are in view

There is a total absence of the anterior crus of the stapes in this ear In animals, malformed unicurate, or columelliform, stapedes have been reported, but this is the first unicurate human stapes reported as far as I can determine, without accompanying external or inner ear deformities

The footplate of the stapes is not present, but in its place is solid otic capsular bone There is no oval window due to the lack of differentiation of the lamina stapedialis described in the embryologic discussion of Figures 13 14 15, and 16 The end of the posterior crus is clearly seen in the photograph Audiometric findings of this patient may be seen directly following the presentation of photographs

Figure 15

Photograph of a right tympanic cavity displayed for the purpose of demonstrating marked congenital malformations of the ossicles

This is an ear of a 7 year old girl with a purely conductive deafness, present presumably since birth

The incus appears fairly normal, but its body apparently placed more anteriorly than usual

The head of the stapes has been purposely disarticulated and rotated posteriorly so that the posterior crus and the footplate area are in view

There is a total absence of the anterior crus of the stapes in this ear In animals, malformed unicurate, or columelliform, stapedes have been reported, but this is the first unicurate human stapes reported as far as I can determine, without accompanying external or inner ear deformities

The footplate of the stapes is not present, but in its place is solid otic capsular bone There is no oval window due to the lack of differentiation of the lamina stapedialis described in the embryologic discussion of Figures 13, 14, 15, and 16 The end of the posterior crus is clearly seen in the photograph Audiometric findings of this patient may be seen directly following the presentation of photographs

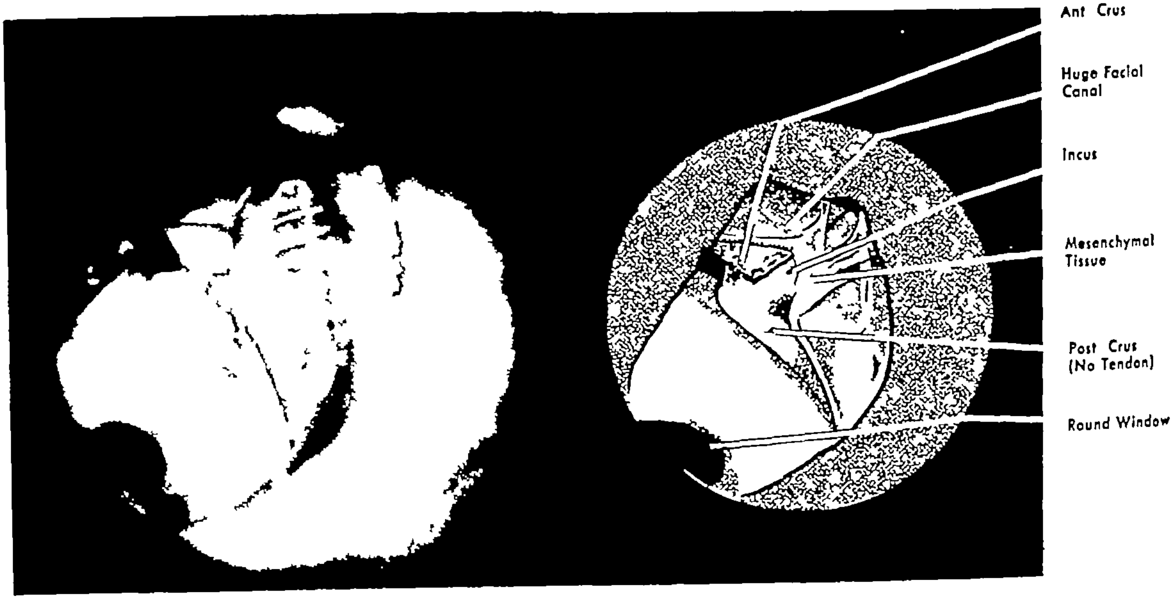

Figure 16

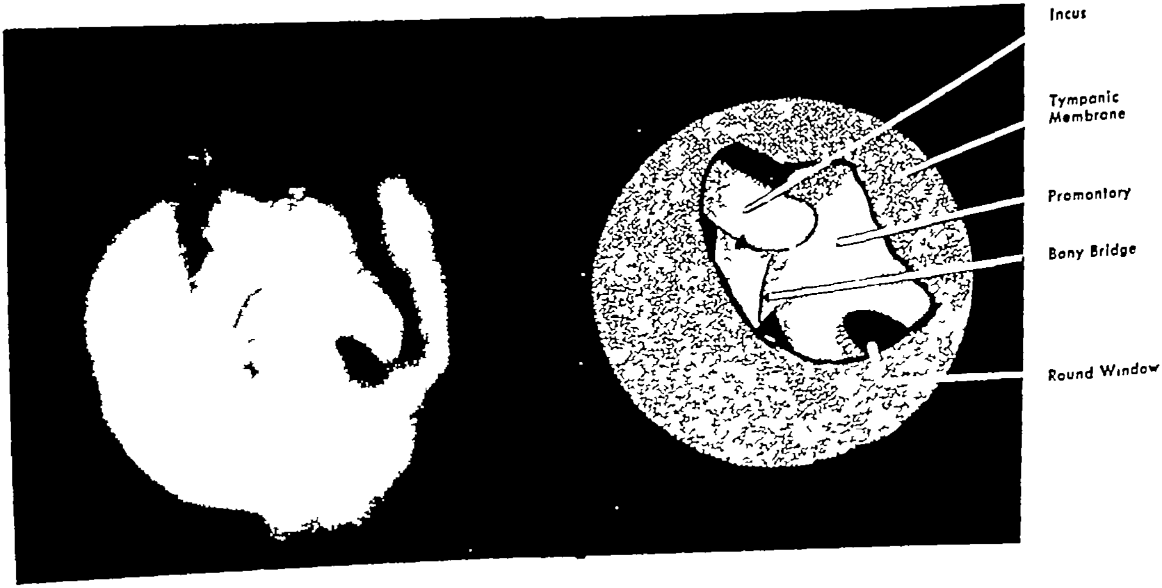

Figure 17

Figure 16

Photograph of a left tympanic cavity displayed to show marked bony malformation and absence of the stapedius muscle and tendon

This is another ear representing a congenital conductive deafness without accompanying external or internal ear malformations

There is a total absence of the stapedius muscle, tendon, and pyramidal eminence

The long process of the incus articulates with the poorly developed head of the stapes The anterior and posterior crura of the stapes are easily seen disappearing into a very narrow niche between the bulge of the bony facial canal and the promontory The crura are very small and end as free stumps in the area of the oval window

This is the third ear with complete congenital absence of the oval window reported in this series There is no evidence in this ear of differentiation of the lamina stapedialis and the surrounding capsular area into a footplate for the stapes or an oval window

The report of these cases lends evidence to the theory that the stapes footplate is derived from both the second visceral arch and the otic capsule

The bony canal for the facial nerve is extremely large in this ear and one can see strands of mesenchymal tissue superficial to it

Trans-aural tympanotomy was necessary for a correct diagnosis in this patient A bypass of the oval window area by the creation of another labyrinthine fenestra will be necessary in order to improve this patient's hearing

Figure 17

Photograph of a right middle ear displayed for the purpose of showing a bridge of bone

A projection of a bony process from the promontory to the area of the facial nerve, or pyramidal eminence, is very common This ear demonstrates, perhaps, a larger than usual example of this bony variation This process is frequently so near the posterior crus of the stapes that bony union is considered to be present It has been my experience that usually, as was true in this case, there will be no union, although sometimes this process makes a true bridge across this area

Figure 18

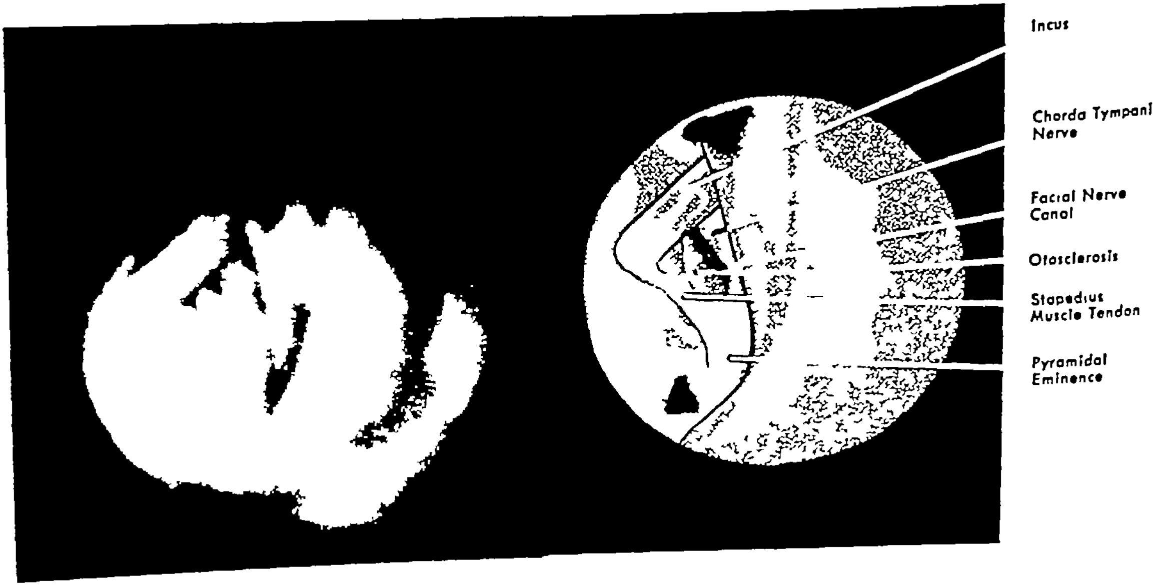

Figure 19

Figure 18

Photograph of a left middle ear displayed for the purpose of showing *bridges of bone producing fixation of the stapes Also seen is a narrow* and deep niche for the stapes, and a stapedial head with an unusual shape

A very high promontory, which bulges superiorly, has produced a very narrow deep niche for the stapes A small bony process extends from the promontory to the posterior crus of the stapes Another bridge of bone extends from the posterior crus to the bulge of the bony facial canal Lysis of these bridges can be accomplished if good exposure can be obtained

Figure 19

Photograph of a left middle ear displayed for the purpose of showing a large amount of otosclerotic overgrowth It also demonstrates an extremely short stapedius tendon, an exceptional view of the pyramidal eminence, and an unusual view of the ridge of the facial nerve canal

In this ear, otosclerotic bone has completely filled the niche for the stapes Masses of it have covered most of the crura so that only the head of the stapes seems to remain uncovered The footplate and crural landmarks have been lost

Figure 20

Photograph of a right tympanic cavity showing a usual view of the long process of the incus, head of the stapes, and footplate following the elevation of the chorda tympani nerve from its bed This is shown for comparative purposes

The incus is articulating with the head of the stapes in the most usual slightly anterior position The lenticular process is well formed and appears normal The long process of the incus is slightly curved medially and posteriorly and has no rough ridges on its lateral surface The articulating surfaces are in a plane fairly square with the head of the stapes and footplate, permitting pressure, if necessary, through the incus on the stapes for mobilization purposes

The amount of bony overhang of the canal seen in this ear is normal

The footplate of the stapes is partially obscured by the thin cob-web strands of mesenchymal tissue This is a common finding

The tendon of the stapedius muscle inserts normally into the head of the stapes

Figure 21

Photograph of a right tympanic cavity displayed for the purpose of showing a variation in the long process of the incus

This ear demonstrates an absence of the lenticular process of the incus, perhaps from necrosis There is a noticeable lack of scar tissue in the middle ear The tympanic membrane is normal in this ear and there was no past history of middle ear disease given by the patient Nevertheless, one must consider the strong possibility of inflammatory disease producing such a picture

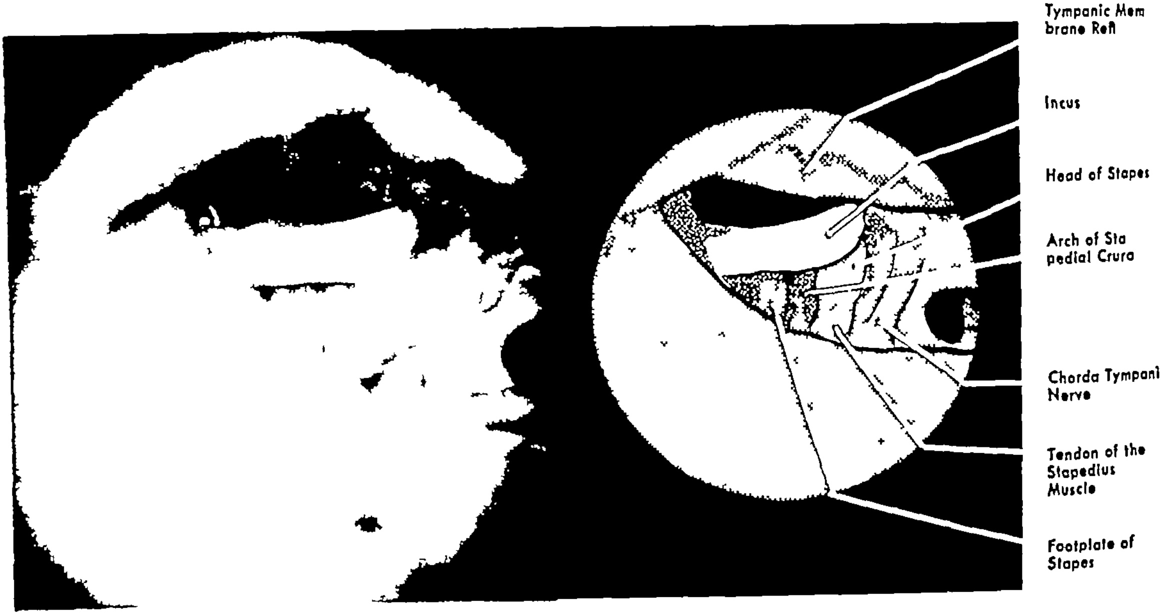

Figure 22

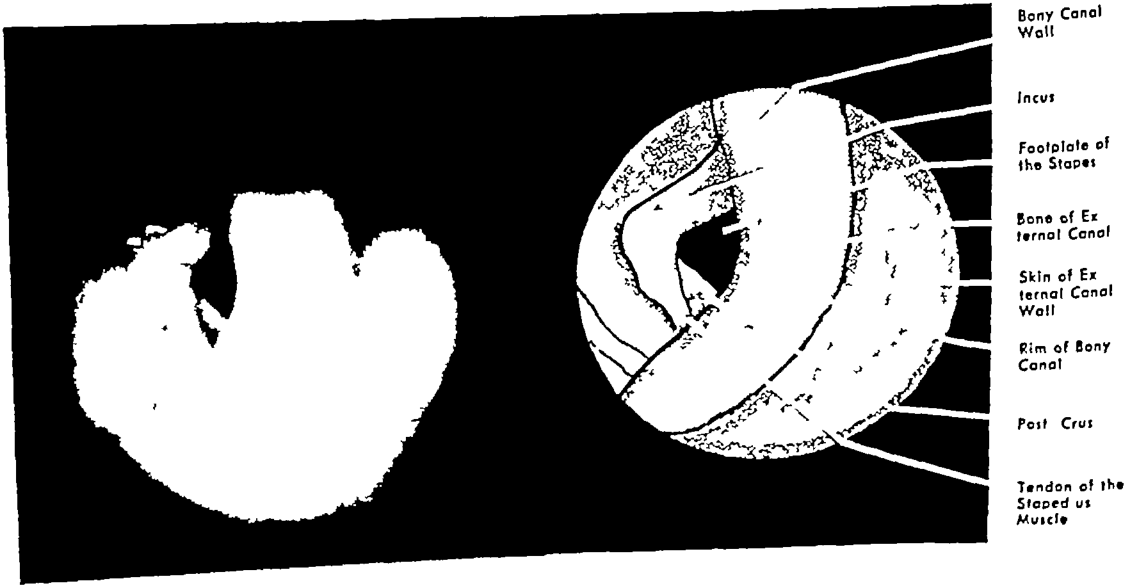

Figure 23

Figure 22

Photograph of a right middle ear presented for the purpose of showing variations in the long process of the incus

The long process of the incus becomes visible at a lower level in this ear and points more directly inferiorly than usual The most striking feature of this process of the incus is its length The shaft is bowed, causing it to appear comma-shaped It is turned upward at the end somewhat like the bow of a ship Despite its length, it does not extend too far beyond the head of the stapes and its articulating surface even faces somewhat inferiorly This articulating surface must be considered if pressure through the incus is to be exerted on the stapes for the purpose of mobilization If the direction and pressure are faulty, dislocation is likely to occur

The footplate of the stapes is clearly seen and is apparently infiltrated with otosclerotic bone The crural arch of this stapes is extremely large

Figure 23

Photograph of a left tympanic cavity presented for the purpose of demonstrating variations

The long process of the incus is turned medially at its tip and is rounded at this extremity Articulation with the head of the stapes is far anterior, but the articulating surface is tilted only slightly anteriorly

The tendon of the stapedius muscle is inserted into the small neck of the stapes These findings are not considered unusual but are variations within the range of normal

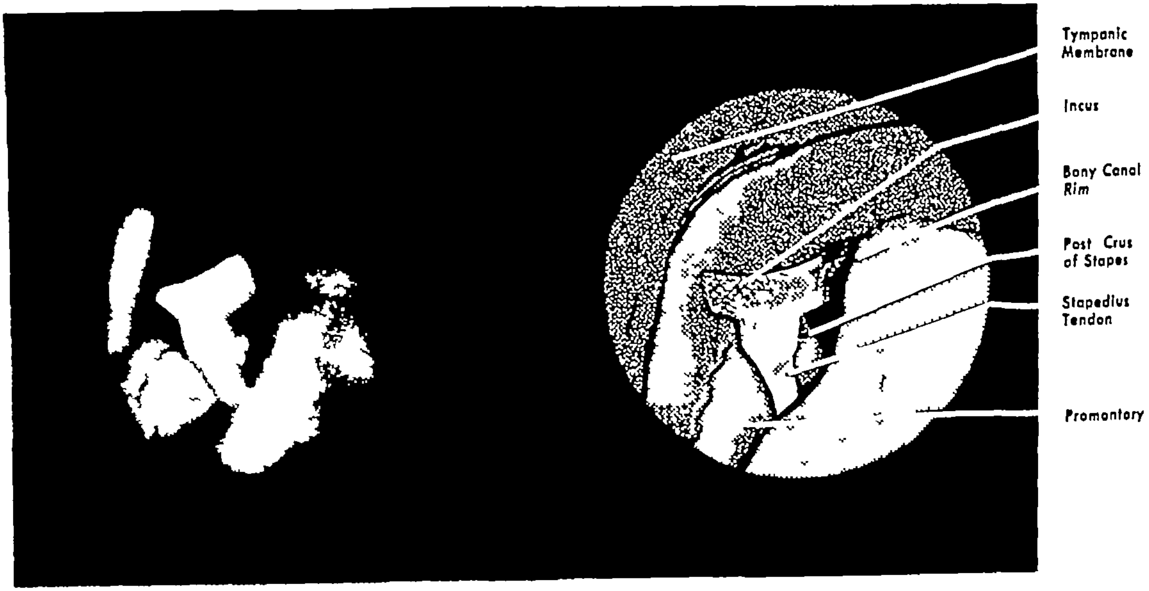

Figure 24

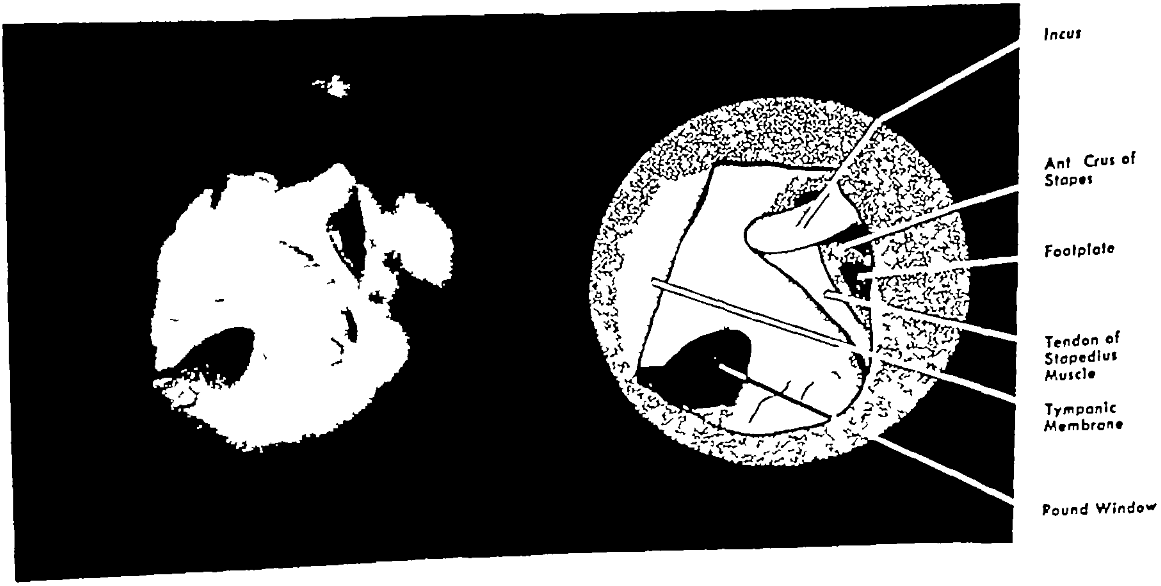

Figure 25

Figure 24

Photograph of a left tympanic cavity presented for the purpose of demonstrating variations in the long process of the incus

The long process of the incus has a sharp bony projection on its lateral surface in this ear This turns up like the bow of a ship, and presents a rough lateral surface which must be considered if instrumentation is to be done in this area The lenticular process of the incus articulates with the head of the stapes in its usual slightly anterior location The stapedius tendon inserts into the head of the stapes from an inferior direction thus exposing the posterior crus

Figure 25

Photograph of a left tympanic cavity presented for the purpose of showing variations in the long process of the incus

This view is not uncommon, but shows an uptilted long process of the incus in comparison to the slight medial downward turn seen in Figure 23

The head of the stapes is placed far forward and the lenticular process of the incus is resting on its posterior aspect The long process of the incus actually hides from view the head of the stapes Please compare with Figure 24

The stapes is tilted inferiorly and, therefore, the articulating surface is angulated This position must be considered before pressure is attempted through the incus if a mobilization of the stapes is contemplated

The stapedius tendon is exceptionally well seen without disturbance of the chorda tympani nerve or the bony external canal The tendon inserts high on the head of the stapes in this ear

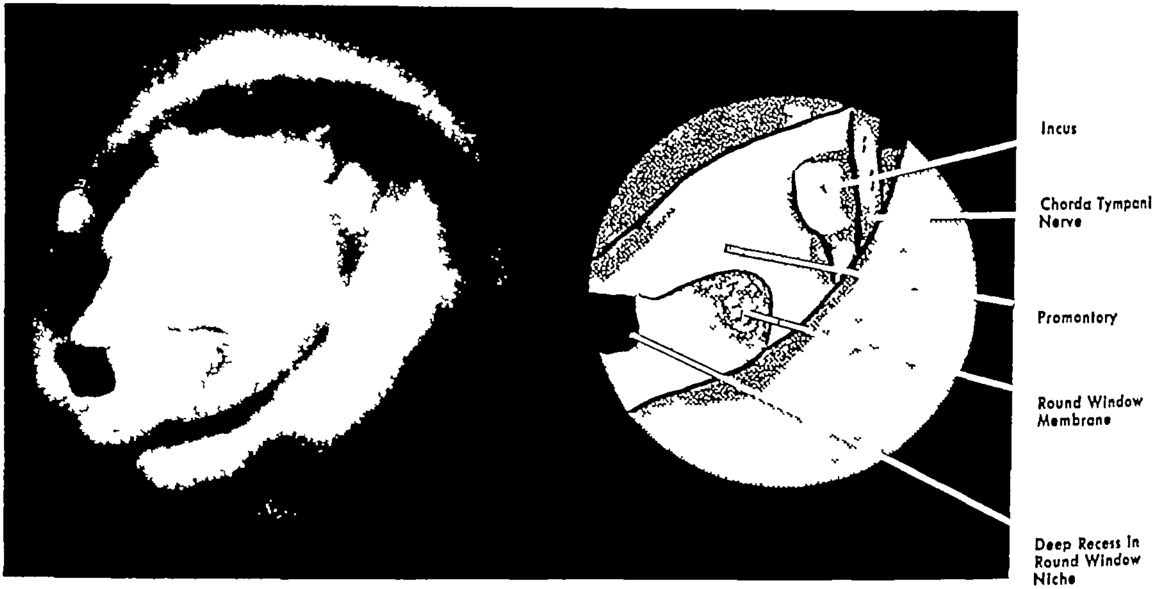

Figure 26

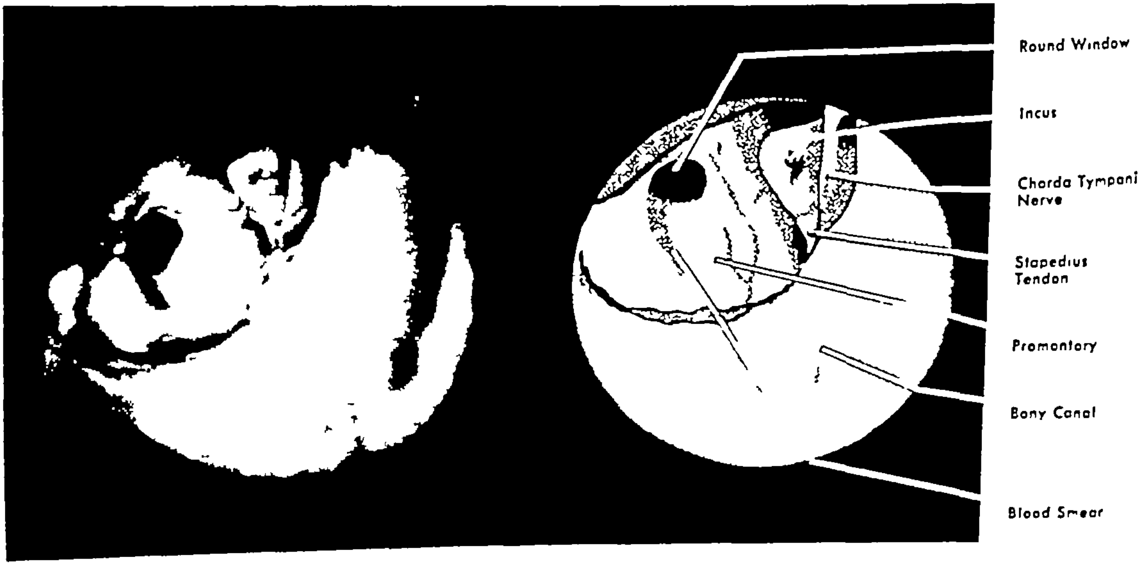

Figure 27

Figure 26

Photograph of a left middle ear displayed for the purpose of showing *round window variations*

This round window membrane is seen clearly and is facing in the posterior, inferior and lateral direction It is also on the usual posterior, inferior aspect of the promontory A large wide niche is present and a very deep depression, or second window, is present at its inferior margin I believe that most of the deep depressions commonly seen in this location are rarely in direct communication with the labyrinth

Figure 27

Photograph of a left middle ear displayed for the purpose of showing round window variations

This round window is without a niche and is situated unusually far anteriorly It is actually as far anterior as the oval window The membrane is facing posteriorly, laterally, and slightly superiorly The window is placed on the summit of the promontory

This photograph also shows the usual view of the incus seen on lifting the tympanic membrane The area hidden by the chorda tympani nerve, the moderate amount of bony overhang, and the barely visible stapedius tendon is considered to be average exposure of the middle ear

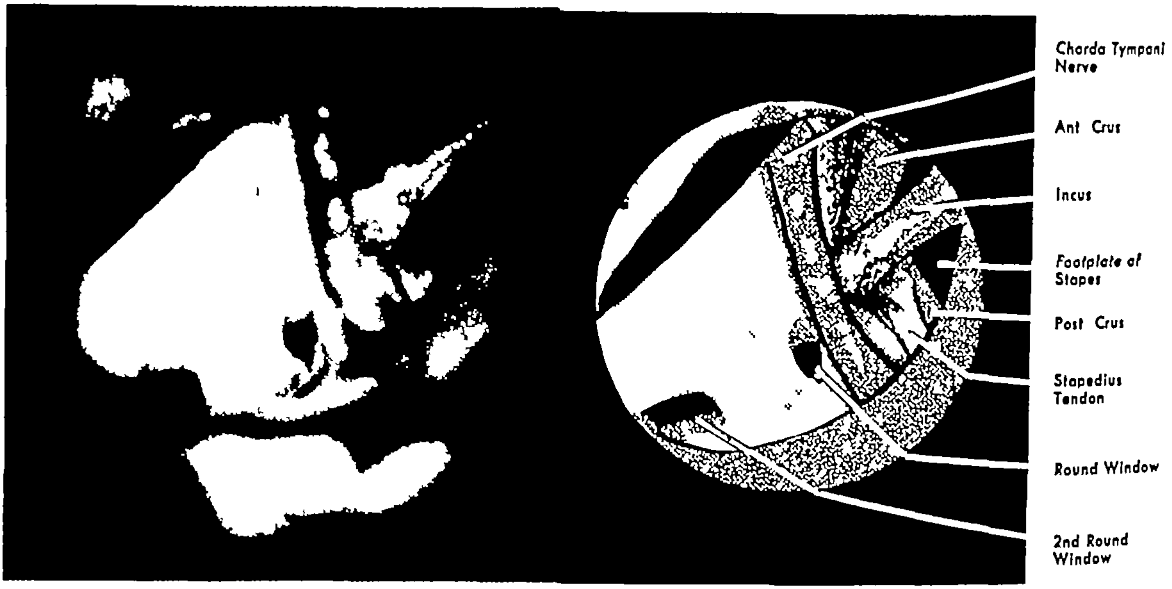

Figure 28

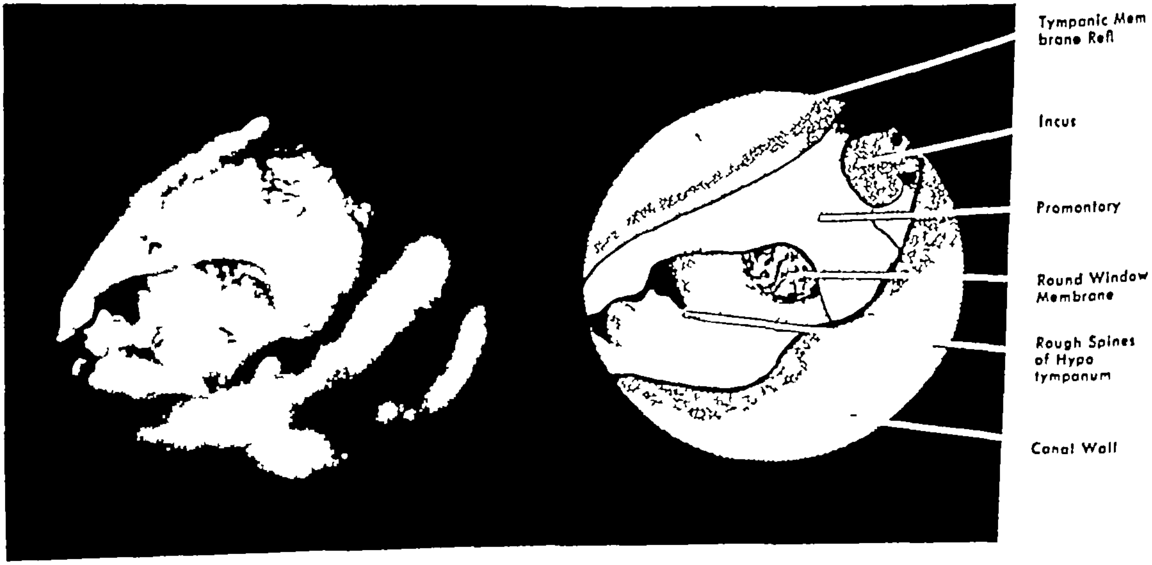

Figure 29

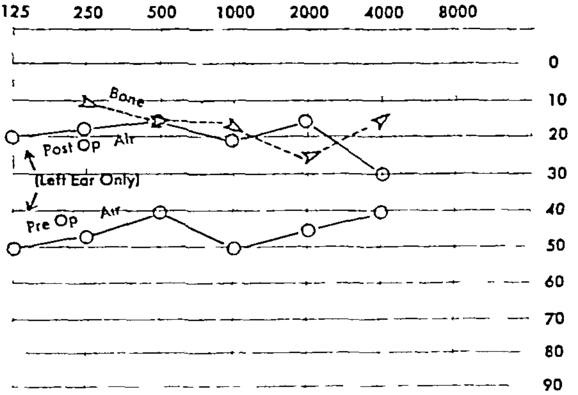
Figure 28

Photograph of a left middle ear displayed for the purpose of showing variations in the round window

This is a view of two round windows which have no niche and are apparently completely separate Membranes are thought to be present in both The small superior window faces upward and laterally, whereas the inferior window faces posteriorly and inferiorly

A large avascular promontory may be contrasted to Figure 31



Pre-operative and Post-operative
Audiogram of patient shown in Fig 5.

Figure 29

Photograph of a left middle ear displayed for the purpose of showing variations of the round window

A large round window niche is seen in this ear and multiple rough projecting bony spines are seen inferiorly These are frequently seen in the hypotympanum

The large round window membrane is clearly seen covering the fluid of the labyrinth The membrane is facing laterally, inferiorly, and posteriorly This position on the posterior inferior aspect of the promontory is the usual position for the round window

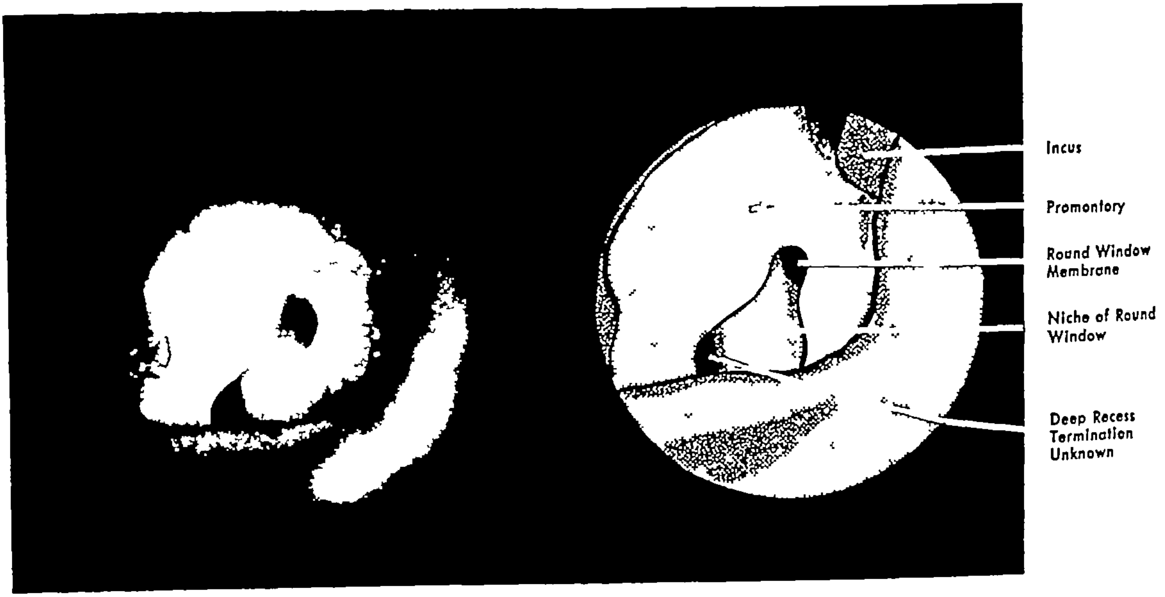


Figure 30

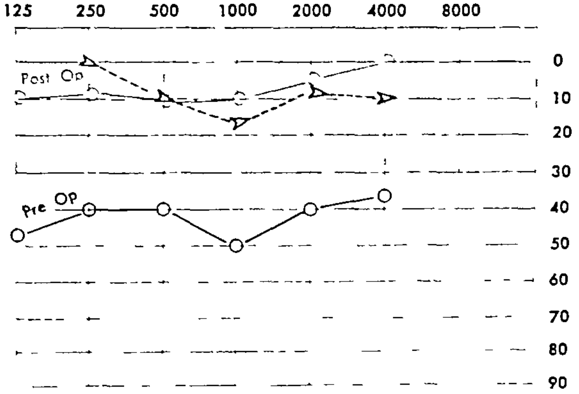
Tympanic Membrane Refl
Ant Crus
Incus
Footplate Note Inferior Margin Vascularity
Round Window
Tendon of Stapedius Muscle

Figure 30

Photograph of a left middle ear displayed for the purpose of showing variations in the round window

This could be called the double-barreled round window The upper window has a definite membrane which is extremely small and faces inferiorly and slightly laterally The lower window may, or may not, have a definite labyrinthine connection with a separating membrane These two depressions are located in a well defined niche which does not merge into the hypotympanic recess inferiorly as was seen in Figure 29



Pre-operative and Post-operative Audiograms of patient shown in Fig 6.

Figure 31

Photograph of a right middle ear displayed for the purpose of showing variations in the round window, the stapedius tendon, the stapes, and vascularity

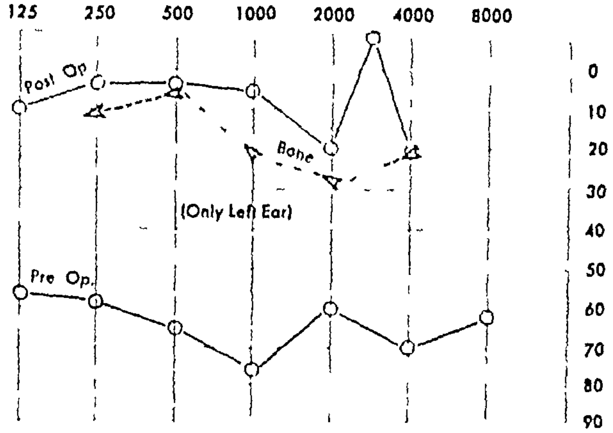
This is a very large round window and is situated in the usual promontory position but is without a niche The membrane of this window is facing mostly in a lateral direction and is unusually superficial

The stapedius tendon is quite long and is attached directly to the head of the stapes It is well seen in its entirety, including the pyramidal eminence This is unusual unless a portion of the external bony canal wall has been first removed The stapedius tendon is also directed slightly superiorly This is not too unusual, but is still in its most infrequent position

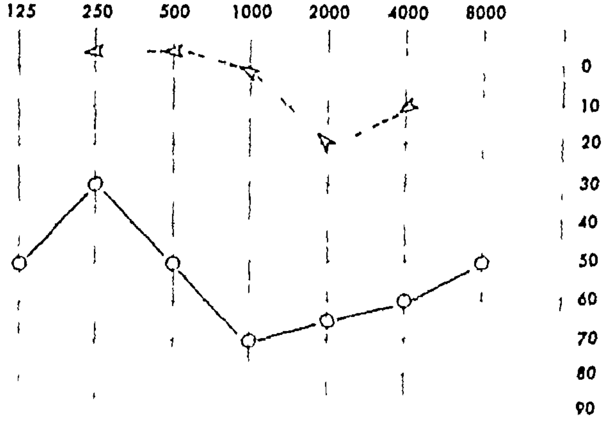
The stapes is located in a very shallow niche and its crura are turned slightly inferiorly An unusual view of the entire stapes is seen The crura are unusual in that they are approximately the same length and are similarly arched A rare view of the entire lower margin of the footplate is seen

The incus articulates with the head of the stapes in the more infrequent posterior position

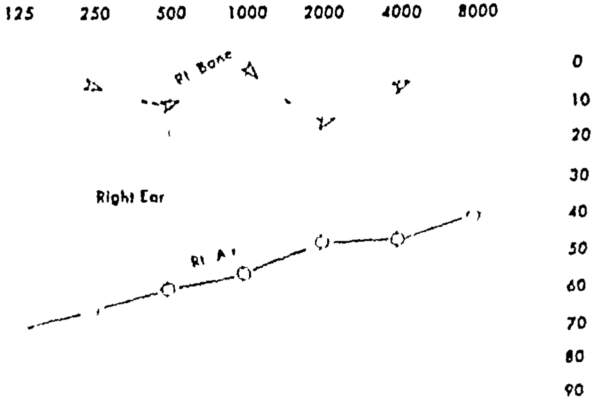
More vascularity than usual is present in this ear The amount of vascularity is extremely variable and this ear does not represent the most extreme vascularity that may be seen Note the large number of vessels over the promontory and the blood-filled appearance of the crura This may be compared to Figure 30



Pre-operative and Post-operative
Audiograms of patient shown in Figs 9 10, 11



Audiogram of patient shown in Figs 13 and 14



Audiogram of patient shown in Fig 15

observed in numerous places in the bony orifice of the round window (see Figs 29, 22) In a majority of patients, what appeared to be residual strands of mesenchymal tissue formed bizarre patterns over the window (see Fig 29)

The usual round window could be seen easily immediately upon opening the middle ear in about the 8 or 9 o'clock position and on the inferior posterior slope of the promontory (see Fig 26) The round window membrane is usually seen clearly, and is facing posteriorly, inferiorly and laterally It is seen to move with good amplitude on normal footplate motion The round window may be seen high up on the promontory in a very anterior position, with the membrane facing in a superior, posterior, and lateral direction (see Fig 27), or it may be seen located far posteriorly so that it is almost entirely hidden by the external canal wall (see Fig 20) An inferior 7 o'clock position is also possible

The round window usually is located in the superior anterior end of a wide, long, excavated bony niche (see Fig 26) This niche usually is roughly bean-shaped and may have bony projections or spines in the lower end (see Fig 29) This may be continuous, with the same rough bony topography frequently seen in the hypotympanum The lower end of this niche may, on the other hand, be smooth and present another rounded depression, or tunnel, which gives the appearance of being a second round window (see Fig 30) Dissection to find the termination of some of these so-called double windows has not been possible, but this finding is frequent enough that postmortem investigation may soon give further light

Many ears are seen in which there is no niche for the round window (see Fig 28) The labyrinth tunnel orifice ends without elaboration on the promontory in a variety of positions as described above The true round window membrane almost invariably, however, is recessed a short distance in this tunnel Superficial tympanic mucous membrane may bridge over the exterior of the orifice, but investigation usually reveals that this is a pseudo round window membrane, and the true round window membrane will be found in a deeper position

EMBRYOLOGIC DISCUSSION OF FIGURES 7 AND 8

The stapes is derived from the second visceral (branchial) arch, and even after differentiation is well under way (16 mm. stage), the head of the stapes is still attached to the original branchial arch. This remaining connection eventually attaches to the otic capsule and becomes the pyramidal eminence and the stapedius muscle and tendon. One would assume that premature separation of the stapes from the second visceral arch occurred in this ear, therefore, total absence of the muscle is observed and no trace of its origin or insertion can be found.

The malleus and incus are derived from the first branchial arch and appear first at the 13 mm. stage as one mass. By the 25 mm. stage, the malleus and incus are easily identified and are separated by a distinct incudomalleolar joint. It is about this time that the long process of the incus gradually nears and finally joins the head of the stapes in an articulation. The triple bony union, seen in Fig. 8, represents disturbed differentiation during this development. Since the connection of the head of the stapes, with its second visceral arch, detaches and joins the otic capsule to become the stapedius muscle, one might expect it occasionally to be misdirected and to join the handle of the malleus. This would explain the triple bony union seen, but this explanation would also require that tissue differentiation be directed into bone instead of muscle.

Improper development of the first branchial arch in the formation of the malleus and incus is another possibility. These two bones are at first one mass and it is conceivable that an isolated area in the region of the long process of the incus and the handle of the malleus might remain fused and eventually unite with the stapes.

The normal attraction of the stapes head for the incus might also be duplicated in the handle of the malleus, therefore, all three might fuse together in a triple union. The lack of articulating surfaces could be the result of immaturity

EMBRYOLOGY

The malformations seen in Figs 13, 14, 15, and 16 are difficult to explain embryologically, due to the very thin fragile crura of the stapes The immature stapes normally is large and bulky All of the other variations would be explained by growth distortion beginning during the eighth to the twelfth embryonic week By this time, the union of the incus and stapes has occurred, the stapedius muscle is attached, and the footplate of the stapes is beginning to be blended with the lamina stapedialis of the otic capsule The process has not been completed in these patients, and the annular ligament has not differentiated to produce the oval window As a result there is solid otic capsular bone throughout the region of the oval window in these ears

DIAGNOSIS

In all the cases specifically discussed in this thesis the external canals and tympanic membranes were normal The consideration of diagnosis is then in this light One may, however, suspect a malformation of the middle ear in some patients prior to operation The following observations may suggest middle ear anomalies *1* Cases of unilateral conductive deafness seem to have a higher percentage of abnormalities *2* Conductive deafness observed since birth or early childhood, either bilateral or unilateral, should suggest the possibility of middle ear abnormalities even in the presence of a normal tympanic membrane Conductive deafness of this type is greater than that which would be due to any other acquired pathologic process [-3] *3* The absence of Carhart's notch in the bone conduction curve may be of diagnostic significance [-3] A 50 to 65 db air conduction loss is present in most patients, and both the air and bone conduction curves present a typical flat audiogram through speech frequencies [-3] In the patients reported here, Carhart's notch was present often, but the characteristic flatness of the air conduction curve was observed in every case *4* Congenital deformities of the middle ear should be anticipated if the patient demonstrates *other anomalies* *This is particularly true of* deformities of the branchial arch derivatures *5* History dat-

EMBRYOLOGIC DISCUSSION OF FIGURES 7 AND 8

The stapes is derived from the second visceral (branchial) arch, and even after differentiation is well under way (16 mm stage), the head of the stapes is still attached to the original branchial arch This remaining connection eventually attaches to the otic capsule and becomes the pyramidal eminence and the stapedius muscle and tendon One would assume that premature separation of the stapes from the second visceral arch occurred in this ear, therefore, total absence of the muscle is observed and no trace of its origin or insertion can be found

The malleus and incus are derived from the first branchial arch and appear first at the 13 mm stage as one mass By the 25 mm stage, the malleus and incus are easily identified and are separated by a distinct incudomalleolar joint It is about this time that the long process of the incus gradually nears and finally joins the head of the stapes in an articulation The triple bony union, seen in Fig 8, represents disturbed differentiation during this development Since the connection of the head of the stapes, with its second visceral arch, detaches and joins the otic capsule to become the stapedius muscle, one might expect it occasionally to be misdirected and to join the handle of the malleus This would explain the triple bony union seen, but this explanation would also require that tissue differentiation be directed into bone instead of muscle

Improper development of the first branchial arch in the formation of the malleus and incus is another possibility These two bones are at first one mass and it is conceivable that an isolated area in the region of the long process of the incus and the handle of the malleus might remain fused and eventually unite with the stapes

The normal attraction of the stapes head for the incus might also be duplicated in the handle of the malleus, therefore, all three might fuse together in a triple union The lack of articulating surfaces could be the result of immaturity

EMBRYOLOGY

The malformations seen in Figs 13, 14, 15, and 16 are difficult to explain embryologically, due to the very thin fragile crura of the stapes The immature stapes normally is large and bulky All of the other variations would be explained by growth distortion beginning during the eighth to the twelfth embryonic week By this time, the union of the incus and stapes has occurred, the stapedius muscle is attached, and the footplate of the stapes is beginning to be blended with the lamina stapedialis of the otic capsule The process has not been completed in these patients, and the annular ligament has not differentiated to produce the oval window As a result there is solid otic capsular bone throughout the region of the oval window in these ears

DIAGNOSIS

In all the cases specifically discussed in this thesis the external canals and tympanic membranes were normal The consideration of diagnosis is then in this light One may, however, suspect a malformation of the middle ear in some patients prior to operation The following observations may suggest middle ear anomalies *1* Cases of unilateral conductive deafness seem to have a higher percentage of abnormalities *2* Conductive deafness observed since birth or early childhood, either bilateral or unilateral, should suggest the possibility of middle ear abnormalities even in the presence of a normal tympanic membrane Conductive deafness of this type is greater than that which would be due to any other acquired pathologic process [-3] *3* The absence of Carhart's notch in the bone conduction curve may be of diagnostic significance [3] A 50 to 65 db air conduction loss is present in most patients, and both the air and bone conduction curves present a typical flat audiogram through speech frequencies [-3] In the patients reported here, Carhart's notch was present often, but the characteristic flatness of the air conduction curve was observed in every case *4* Congenital deformities of the middle ear should be anticipated if the patient demonstrates other anomalies This is particularly true of deformities of the branchial arch derivatures *5* History dating back to accidental or operative injury must not be overlooked as a cause of middle ear damage producing conductive deafness.

In many instances, there will be no warning of significant variation or abnormality of the middle ear even after careful history, physical examination and audiologic tests have been employed. The use of a highly maneuverable operating microscope with direct lighting and magnification up to 40 diameters is necessary to study these interesting structural variations. One must be able to change both the position of the patient's head and the direction of vision through the microscope in order not to overlook the unusual changes in these minute structures. Insistence upon good binocular visualization and a routine of systematic inspection prepares the mind to attempt a rational surgical maneuver which will be best designed to fit the need.

ETIOLOGY

The word variation is used here in the sense that it is an all-inclusive term indicating any deviation from normal. It, then, includes a vast variety of conditions. In this sense, variations seen in the middle ear may be either congenital or acquired in origin.

CONGENITAL DEFORMITIES

Congenital deformities may be due to disturbed embryologic development on the basis of hereditary defects. Examples of this are the Treacher-Collins[164] syndrome, or severe varieties of otocephaly[7, 68, 133, 169] These cases do not fall in the group of isolated middle ear defects.[7] These malformations usually involve several of the branchial derivatives.[7] In all of the available literature I could find no single case of middle ear deformity without other accompanying deformities in which there was a definite family history; furthermore, in the cases reported in this thesis, there were no histories of similar conditions being present in other members of the family. In any of the more major deformities seen in the middle ear which do not have an obvious origin, we must logically, however, consider heredity to be a strong etiologic possibility.

Congenital deformities may be due to intra-uterine fetal injuries. Deformities in certain cases have been ascribed to maternal viral disease, such as mumps, rubella[139] and poliomyelitis.[138, 61, 83] Fetal position in utero has been considered to be a factor in the production of congenital deformities. One investigator reported changes in the inner ear and central nervous system in the newborn with abnormal fetal positions.[110] He examined six patients with abnormal position and five of the six had histologic changes. In two, changes were found in the inner ear, and in one there was a severe disturbance in the development of the inner ear and middle ear. Collaboration of investigators with obstetricians might in the future shed light on this suggestion. All of the cases found in the literature in the above categories had multiple defects outside the middle ear. None of the cases reported in this thesis have known accompanying deformities outside the middle ear, and none of the conditions reported here could be traced directly to intra-uterine injury as a possible etiologic factor.

Variations in the middle ear may be produced by congenital deformities due to alteration of developmental processes by a variety of unknown causes before birth. The vast majority of variations have no obvious cause. Tardy or delayed resorption of mesenchyme in the middle ear has been considered to be due to hormonal or enzymatic imbalance.[63] If hormonal and enzymatic factors are effective in altering the resorption of this tissue, it is reasonable to assume that these factors might affect other developmental processes. Diabetes,[82] radiation,[81] dietary deficiencies, incompatible blood types[84] (RH factors), eclampsias, maternal and fetal hypoxia,[85] and excessive use of drugs might conceivably produce changes in the normal pattern of development. An unusually high incidence of abnormalities of the ear occurs in persons born prematurely. The conditions listed above are only presumptive possibilities, and thus far there has not been a well documented case reported in which these factors have been proven to cause isolated middle ear malformations.

osteogenesis, or osteoporosis, making possible the formation of bony projections and bridges which could fix the ossicle in place It was thus suggested that irritation produced by vibratory activity in areas where bone is in contact with bone could be a stimulus promoting the formation of bony bridges It has been my frequent observation that most stapedial crura rest against the promontory to some degree These, with few exceptions, have no bony fusion, and yet the structures are so much in contact developmentally that the mucous membrane seems to make no attempt to grow between them, but rather appears to surround in certain areas the individual crus and the promontory as one unit This proximity may remain for a lifetime without bony union These facts cast considerable doubt on the theory of vibratory activity producing bony bridges Reports of ossification of the stapedius tendon causing stapedial fixation have been made[143] Bony bands extending from the promontory, or facial ridge, to the crus of the stapes, thus producing stapedial fixation, have been reported[52] Vibrations and inflammatory irritations have been suggested as possible etiologic factors[52 97] Attention has also been directed to the posibility of bony bridges (not otosclerotic) which could, in places, cross the annular ligament The lack of proper differentiation from chondral tissue into a fibrous ligament could be responsible for stapes fixation in these ears In this event, the primitive chondral tissue would develop into bone

Infection with its pathologic sequelae is well known in the middle ear, and will be discussed only briefly in the light of these observations Among the 500 cases considered in this thesis, there was an unusual lack of adhesions observed in the middle ear, even though a frequent history of childhood earaches and suppuration was obtained This was an unexpected finding and points up the fantastic ability of the living cell to restore order out of chaos and purpose out of destruction This ability may, however, serve to blind the otologist The tympanic membrane may return to normal appearance and, in a few isolated cases, lead one to believe that all suppurative disease in the middle ear has also been resolved without an aftermath of scar tissue In these cases, one may lift the tympanic membrane only to uncover an extensive network of thick scar bands True, scar bands should not be confused with the tiny strands of unresolved mesenchymal tissue which are so frequently seen around the malleus, the incus, and especially in the region of the stapes[63] These strands are present to some degree in the majority of middle ears and apparently hamper sound transmission very little (see Fig 20) In cases of delayed, or incomplete, development, this tissue may be much more in evidence (see Fig 13)

Atrophy and necrosis of bone, possibly due to infection, can be suspected in certain cases such as Fig 21 Presumption that infection can produce such change is based upon the frequently seen erosion of the ossicles in chronic mastoiditis and chronic otitis media The lenticular process of the incus seems to be a particularly vulnerable area of osteolytic attack The total erosion of this end of the long process produces a separation of the incus from the stapes and results in a conductive deafness due to interruption of the ossicular chain Isolated erosion, or atrophy, of this process separate from any other bony involvement is difficult to understand Why the head of the stapes and the crura, or the malleolar head is not also eroded by the same pathologic process, is a valid query Perhaps it is because the long process of the incus projects a greater distance from any base source of soft tissue blood supply than any part of the other ossicles They may be the most vulnerable portion for inflammatory destruction It thus may become the first part involved and, if the pathologic process is controlled, destruction occurs only in this area Perhaps this deformity is common and is only now being seen

Otosclerotic bone in this series could be seen in the great majority of cases Foci of otosclerotic bone usually were seen near the anterior end of the footplate of the stapes The amount of bony overgrowth varied from that which was barely distinguishable to large mounds which enveloped the base of the anterior crus of the stapes Fairly frequently, otosclerotic bone was seen covering a portion of the footplate, or even infiltrating and distorting it in its entirety Occasionally, the surrounding bony capsule of the labyrinth, the annular ligament, and the entire footplate could be seen to be osteogenesis, or osteoporosis, making possible the formation of bony projections and bridges which could fix the ossicle in place It was thus suggested that irritation produced by vibratory activity in areas where bone is in contact with bone could be a stimulus promoting the formation of bony bridges It has been my frequent observation that most stapedial crura rest against the promontory to some degree These, with few exceptions, have no bony fusion, and yet the structures are so much in contact developmentally that the mucous membrane seems to make no attempt to grow between them, but rather appears to surround in certain areas the individual crus and the promontory as one unit This proximity may remain for a lifetime without bony union These facts cast considerable doubt on the theory of vibratory activity producing bony bridges Reports of ossification of the stapedius tendon causing stapedial fixation have been made[143] Bony bands extending from the promontory, or facial ridge, to the crus of the stapes, thus producing stapedial fixation, have been reported[52] Vibrations and inflammatory irritations have been suggested as possible etiologic factors[52,97] Attention has also been directed to the posibility of bony bridges (not otosclerotic) which could, in places, cross the annular ligament The lack of proper differentiation from chondral tissue into a fibrous ligament could be responsible for stapes fixation in these ears In this event, the primitive chondral tissue would develop into bone

completely overrun by massive invasion of the pathologic process In these cases it was impossible to distinguish the anatomical edge of the footplate, or indeed, to differentiate the footplate from the otic capsule On rare occasion, the otosclerotic bone was seen in such huge mounds that it practically covered both crura and footplate, almost to the point of obliterating the obturator foramen of the stapes (see Fig 19)

Many other diseases, such as diabetes, syphilis, tuberculosis, cholesteatoma, etc, can produce destructive changes in the middle ear None of these was a factor in any of the cases reported in this series

CONCLUSIONS

In the past the discovery of middle ear malformations unassociated with other known defects has been extremely rare A large number of variations and malformations of the middle ear have been observed by me in 500 trans-aural tympanotomies It is reasonable, therefore, to assume that these are not rare

Variations and malformations must be considered in operative procedures of the middle ear, otherwise, a slight distortion or absence of a landmark can produce a mechanical pitfall or an uncharted course for the surgeon

Trans-aural tympanotomy in patients with unexplained deafness of a conductive type is a rational diagnostic, and sometimes corrective, procedure

The study of variations and malformations leads to a better understanding of the physiology of sound conduction, and offers evidence to support or deny certain functional theories

Investigative efforts in embryology, histology, genetics, pathology, and other basic sciences may be stimulated by the observation of malformations and variations in the middle ear

AMERICAN RHINOLOGIC SOCIETY

The Annual Program Meeting of the American Rhinologic Society will be held at the Palmer House, Chicago, on Friday, October 17, and Saturday, October 18, 1958 The speakers will include Ralph Riggs, M D, "Maxillary and Pre-Maxillary Approach to Septal Surgery", Jules Masserman, M D, "Relationship of Olfactory Factors in Neurosis in Animals" A paper on the "Physiology of Respiration" will be presented by David Cugell, M D, "Heat and Moisture Exchange of the Respiratory Mucous Membrane," by Irving Cramer, M D, "Second Golden Decade of Rhinologic Surgery—The Advances of the Past Ten Years," by Harvey Gunderson, M D A discussion entitled "Concepts of Nasal Physiology as Related to Corrective Nasal Surgery," by Maurice H Cottle, M D, "Bone Transplants" by Robert Ray, M D

There will be a panel discussion on Hump Removal, Roof Repair and Nasal Process Corrections

The meeting will start at 1 30 p m on October 17 and adjourn at 4 00 p m on Saturday, October 18, 1958 For further details write Robert M Hansen, M D, Secretary, 1735 No Wheeler Ave, Portland 12, Ore

DEVELOPMENTAL ANATOMY OF THE TEMPORAL BONE AND AUDITORY OSSICLES IN RELATION TO SOME PROBLEMS IN ENDAURAL SURGERY *†‡

BARRY J ANSON, Ph D ,
Chicago, Ill
and
THEODORE H BAST, Ph D ,
Madison, Wis

INTRODUCTION

The bones of the human skull are developmentally dissimilar to a striking degree, each apparently following an individualized route to maturity the frontal ossifies from two centers which appear in the eighth fetal week, the zygomatic from a single center, appearing in membrane bone in the second month, the sphenoid from 19 centers, the temporal bone from 14, the first one of which is formed in the fourth month, the last about five weeks later

Most remarkable of all are the auditory ossicles, which are made over for new uses, transformed from branchial to

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication March 10 1958

acoustic function Quite as extraordinary as the way in which the separate elements of the auditory apparatus originate, grow and attain maturity, is the independence enjoyed by each as it follows a developmental course that finally leads to interdependent adulthood Time tables here are as different from one another as the developmental history and adult condition of the parts when compared with corresponding features in the morphogenesis of a typical long bone

OBSERVATIONS AND DISCUSSION

1 *Otic Capsule*

In the human embryo of five weeks (8 mm), the auditory apparatus is represented merely by an epithelial vesicle which has lately been freed from the parental ectodermal layer (the future integument)

The surrounding mesenchyma is undifferentiated, there being as yet no histological prediction of change into precartilage for an otic capsule, however, no sooner has precartilage formed an encapsulating investment than deorganization of the newly-formed tissue begins around the parts of the endolymphatic (otic) labyrinth A reticulum becomes vacuolated, then the vacuoles coalesce to produce the communicating spaces of the perilymphatic (periotic) labyrinth These changes take place in a six-week period (between the fifth and the eleventh week)

In the fetus of nine weeks (40 mm), both the otic (endolymphatic) and periotic (perilymphatic) labyrinth of the internal ear are formed, the otic capsule is a cartilaginous envelope for the labyrinthine ducts and surrounding canals and scalae In the area of the future middle ear, the ossicles are formed in cartilage and lodged in mesenchyma Growth in cartilage then continues through another period of six weeks

The otic capsule of a fetus in the fifth fetal month (19½ weeks, 160 mm) already displays distinguishing features in the cochlear and canalicular divisions in the cochlear portion, ossification has been initiated, in the canalicular part, cartilage is not yet being replaced by bone, rather, it is being destroyed, rendered spongious to permit terminal increase in the arcs of the semicircular ducts

The buds of vascular tissue that destroy the cartilage enter through the subarcuate fossa, which at this stage is a relatively ample excavation

The first ossification center appears in the otic capsule at the age of about 16 weeks (115 to 120 mm), the last (14th) at the end of the fifth month

As soon as an ossification center is definitive, it is found to consist of three layers, each of which has its own rate of increment and maturation, and time of appearance in the cochlear and canalicular divisions of the capsule

The inner periosteal (or endosteal) layer already forms a thin parietal shell for the turns of the cochlea, it is completed *quickly but remains virtually unaltered throughout life*

An outer periosteal layer appears at the same time Immediately other laminae are added externally—in steady acquisition, and after the regular pattern existing in the cambium layer of the periosteum in a typical long bone, however, the structure differs therefrom in that, despite growth, the simple laminated bone is never replaced by bone of Haversian type

The middle layer, unlike the other two, is compound it consists of a *calcified cartilage matrix in* whose lacunae invading osteoblasts have surrounded themselves with bone which, while *formed in membrane,* is deposited upon the framework offered by the calcified cartilage This combination is intrachondrial bone The intrachondrial tissue is formed concurrently with the outer layers of the ossification center, but production of the endochondral bone is delayed until the early weeks of postnatal life, at which stage it is produced with sweeping rapidity

The layers of the capsule are especially distinct in the fetus at midterm, *i e ,* in a specimen of 21 weeks (183 mm) in the

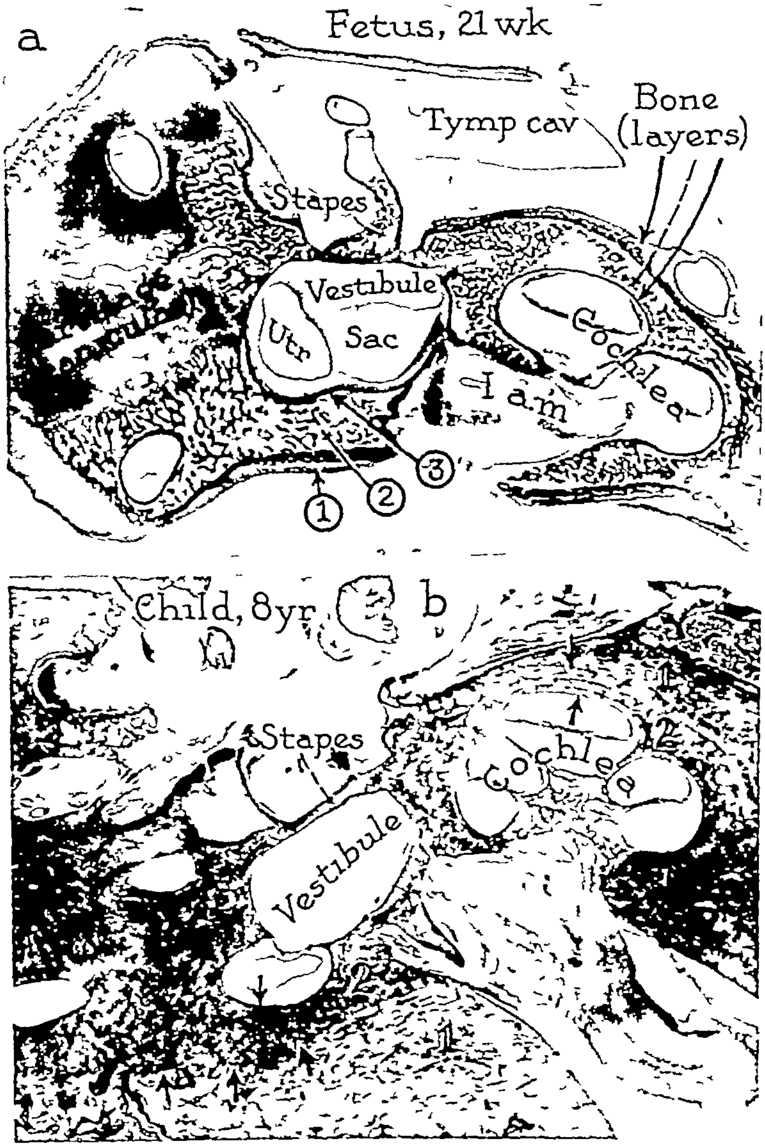

Fig 1 Stages in the development of the otic capsule Wisconsin series 21 and P37 a.—Fetus of 21 weeks (183 mm) b—Child 8 years old

Abbreviations I a.m internal acoustic meatus Sac saccule Tymp cav tympanic cavity Utr utricle

Numerals indicate the layers of capsular bone In the cochlear part of Fig 1-a (to the reader s right) the downward-directed arrow points to the external limit of the middle layer the upward-directed arrow to the internal (free) margin of the inner layer of bone In the vestibular and canalicular divisions of the same figure (to the reader s left) the single arrow touches the internal margin of the inner layer the three arrows point to the line of meeting of the outer and middle strata of bone cochlear, vestibular and canalicular portions of the capsule (see Fig 1-a)

These layers retain their fetal appearance, even in areas where the capsule is being rebuilt The tympanic wall of the lateral semicircular canal (the site of fenestration surgery) is one such area, and the external aperture of the vestibular aqueduct is another

In a 38-week (350-mm) fetus, cartilage persists in only two locations, *i e*, in the wall of the fissula ante fenestram and, continuous therewith, as a rim for the vestibular (oval) window The outer (periosteal) layer has undergone considerable thickening, like the bone of the other two layers, it is non-Haversian and permanent In the middle layer, the cartilage islands are covered by endochondral bone—marrow spaces being correspondingly reduced in bulk In portions of the cochlear capsule, space is still a prominent feature, its existence serves to set off the outer from the inner layer The inner layer is unchanged

In the newborn infant the otic capsule is still cancellous in texture This appearance is due to the histological structure of the middle layer, which is still composed mainly of intrachondrial bone Because of its open texture, the layer is clearly distinguishable from the other two, the inner being relatively thin and smooth-surfaced The outer layer will undergo steady increment until the temporal bone has attained adult form and dimensions The middle layer will assume a petrous consistency as a result of the production of new bone (deposited upon the intrachondrial spicules) The inner layer will remain virtually unchanged throughout life

In the ear of a child eight years of age, the three fundamental layers of the otic capsule are still distinguishable (see Fig 1-b) The chief postnatal changes are two in number increase in thickness of the outer layer , attainment of compact character by the middle layer Frequently a large part of the middle layer will have been destroyed to make way for air cells It has been established that pneumatization may be complete in the young child, and that in some individuals the process is under way in the late fetus

2 *Auditory Ossicles*

The structure of the stapes calls for special discussion in relation to problems presented to the surgeon in the operation for mobilization Developmental history fully accounts for its architectural weakness

In the fetus of 20 weeks (167 mm) the single ossification center has made its appearance on the obturator wall in the area of continuity of the crus with the base

At a slightly later stage (21 weeks, 190 mm), an osseous shell is circumferential for the crus, otherwise, the ossicle remains cartilaginous In the crural portion of the stapes, marrow has replaced cartilage

In the 23-week (202-mm) fetus, ossification has advanced to include the neck of the stapes, and to spread along the crura toward the head of the ossicle Cartilage remains at the basal extremity, but is eroded internally, on the internal surface, endochondral bone is forming

The stapes in the fetus of 24 weeks (215 mm) is composed of bone, except at the extremities Medially, cartilage covers the vestibular surface and the fenestral margin, whereas laterally the primordial cartilage of the capital end persists as an articular plate (at the incudostapedial joint)

The stapes of the 32-week (290-mm) fetus has attained adult form and structure It is completely invested by mucous membrane, both the basal and capital extremities are bilaminar (each of the layers being thin but complete)

All of the structural features which characterized the stapes in the late fetus and in the newborn infant are retained in virtually unaltered form in the adult the ossicle is excessively thin, its base, like the head, is two-layered (the cartilaginous lamina of the vestibular surface investing the endochondral lamina of the tympanic aspect) , mucous membrane not only covers the outer surface of the periosteal bone of the crura and head, but also coats the inner surface of the same layer where, as a result of removal of the obturator wall of the ossicle, the mucosal tunic comes to replace marrow

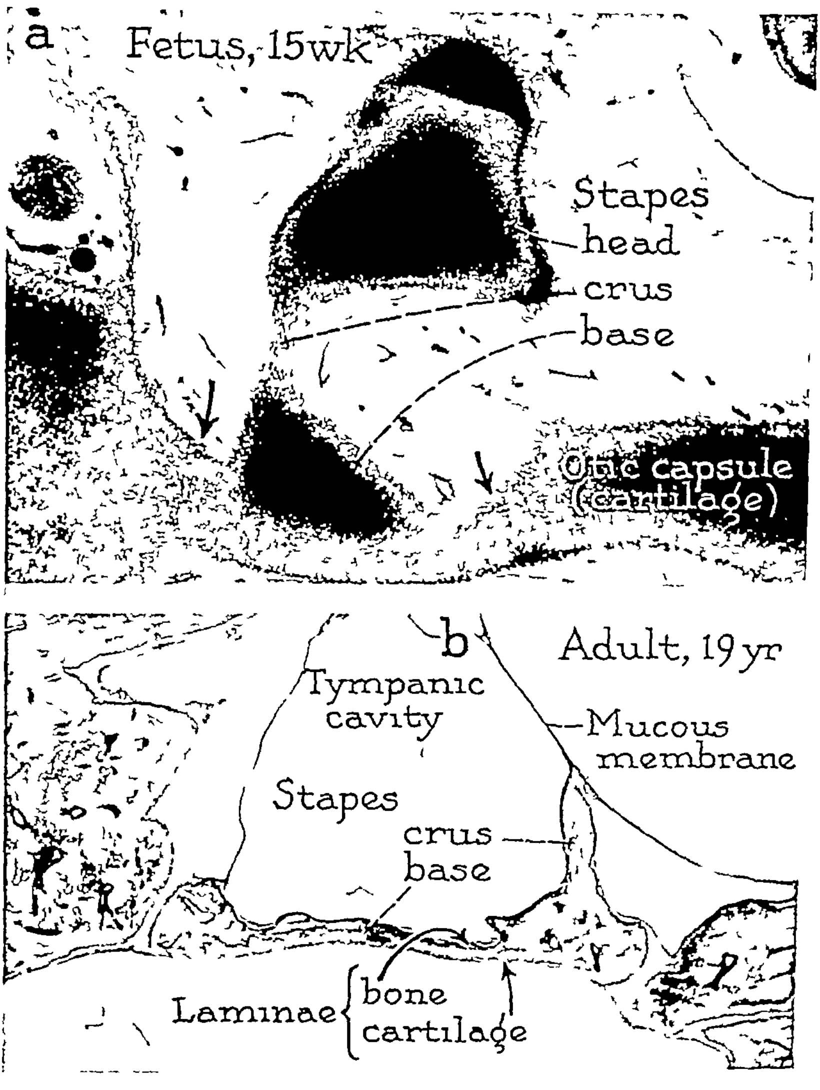

Fig 2 Stages in the development of the stapes Wis 50 and P29
a —Fetus of 15 weeks (111 mm) b —Adult 19 years old

and endochondral spicules The mucous membrane on the base of the stapes lies in contact with the endochondral lamina, which in a process of secondary growth, formed a covering for the persistent cartilage

When once the stapes has been reduced in bulk and strength, it subsequently undergoes negligible alteration The ossicle remains infantile—or, rather, it is already an adult bone in the newborn

By way of contrast, the histological structure of the incus is subject to remodelling at any age in a person's life span (see Figs 3-a and 3-b) , however, in some infantile specimens, excavation of both perichondrial and endochondrial bone may be under way, and in others, destruction is marked, but new bone is being applied to the walls of the recently formed spaces In some adults, erosion may affect chiefly the perichondral layer, in others, secondary excavations appear, as does concurrent formation of tertiary lamination

CONCLUSIONS

The otic capsule is already precartilaginous in the six-week embryo, whereupon the tissue begins to deorganize around the otic labyrinth, predicting periotic vacuolization (for semicircular canals, vestibule and cochlear scalae)

Although bone formation is under way in the cochlear region at 20 weeks, the canalicular division not only remains cartilaginous for a four-week period, but is rendered spongious, permitting expansion of the semicircular ducts Even when capsular ossification is virtually complete, the middle layer still consists mostly of intrachondrial bone Soon after birth, rapid deposition of endochondral bone contributes petrous character to the entire capsule The inner layer never changes, the outer thickens to imbed the capsule

The capsule undergoes late remodelling at the external aperture of the vestibular aqueduct and along the tympanic wall of the lateral semicircular canal, while bone in the canalicular region is being pneumatized

The ossicles, although derived from the branchial skeleton of the embryo, and ossified from a single center each, follow different courses of morphogenesis and at different rates of speed The stapes of the midterm fetus has already attained adult dimensions, but is destined to undergo profound reduction in bulk before birth, after which it remains structurally quiescent Like the otic capsule, the stapes never attains the Haversian stage of typical bone, in that respect it retains lifelong fetal structure The incus, on the contrary, experiences remodelling of both its periosteal and endosteal layers throughout life, yet suffers no grossly discernible loss in bulk

Difficulties which confront the surgeon in employing any one of the several techniques calculated to mobilize an ankylosed stapes are the result of the following circumstances the anatomic position and relations of the stapes, its extreme fragility and its inability to heal, once it has been fractured, the power of the otic capsule to produce rapidly-growing bone in the territory of the vestibular (oval) window All portions of the stapes are fragile, they are already frail in the infant, and will remain so throughout life The crura and base are always thin, the head is pitted or deeply excavated, or both The base (footplate) is usually the weakest part of the ossicle In many cases, bone is a thin lamina on the tympanic aspect, *i e*, toward the middle ear, cartilage, persisting from the fetal stage, completes the base on the vestibular surface

CONGENITAL STAPES FOOTPLATE FIXATION

A Preliminary Report of Twenty-Three Operated Cases [*][†][‡]

INTRODUCTION

Otosclerosis has long been recognized as a cause of fixation of the footplate We now realize there is a second cause, namely, congenital fixation of the stapes footplate This entity does exist, can be diagnosed by clinical means, and can be recognized at the time of surgery [**]

Shambaugh[1] has described five such cases, and Holmgren[2] reported a case of incomplete development of the oval window Altmann[3] has described the histological findings of a case of atresia with congenital footplate fixation Wolff[4] has observed abnormalities in the annular ligament of the new-born

EMBRYOLOGY

Embryologically, the malleus and incus are differentiated from the first branchial arch, or Meckel's cartilage The stapes is derived from the second branchial arch, or Reichert's cartilage Failure to differentiate results in a congenital abnormality of the structures involved, consequently, the stapes and stapes footplate may be involved without involvement of any of the other middle ear structures

DIAGNOSTIC FEATURES OF OTOSCLEROSIS IN THE ADULT

The differential diagnosis between otosclerosis and congenital footplate fixation may at times be rather difficult The key to the diagnosis of otosclerosis in the adult is *progression* of the hearing loss If a patient has a slowly *progressive* conductive or mixed type of loss with essentially normal otologic findings, the diagnosis is usually clinical otosclerosis (see Fig 1)

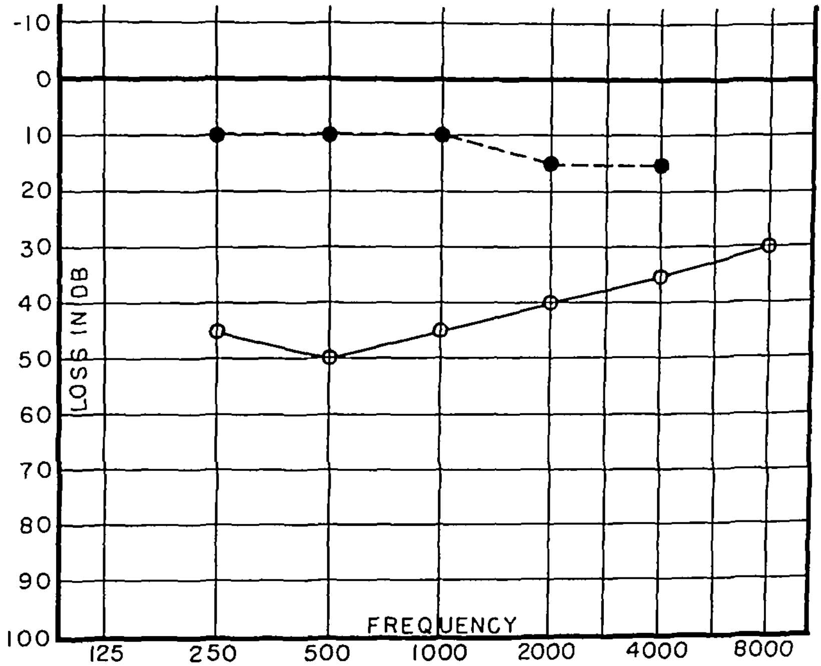

Fig 1 Otosclerosis

The amount of conductive impairment varies with the degree of otosclerotic footplate fixation The air conduction curve usually shows the greatest loss in the lower frequencies Cochlear involvement is quite common and usually involves the higher frequencies

DIAGNOSTIC FEATURES OF CONGENITAL FOOTPLATE FIXATION IN THE ADULT

The key to the diagnosis of congenital footplate fixation in the adult is the *absence of progression* of the hearing loss A patient with a history of a purely conductive *non-progressive* hearing impairment, who has essentially normal otologic findings, may be diagnosed as ossicular discontinuity, or congenital ossicular fixation, occurring usually at the stapes footplate

To determine accurately the *lack of progression* may be very difficult These patients give a history of accidental discovery of the hearing impairment, either by school tests, or as the result of a certain incident that called attention to their hearing deficiency The average age of such discovery in this series of cases was ten years After discovery the patient, and parents, become suddenly aware of the impairment and proceed to test the hearing acuity in various ways As the result one may feel that the hearing is getting worse, when actually the patient is only becoming more aware of the pre-existing deficiency Because of the increased demands made on his hearing, one may feel the hearing loss is becoming greater as he gets older because of his more adult activities

Patients with a congenital fixation of the stapes footplate have grown up with their impairment They automatically compensate for their deficiency, and become excellent lip-readers long before their hearing loss is discovered They frequently give a history of being slow in learning to talk, but all seem to have an excellent speech pattern (see Fig 2)

Audiometric findings in congenital footplate fixation are remarkably constant The air conduction curve is flat and averages 50 db in the three speech frequencies The bone conduction curve also is flat and remains within 10 db of the zero threshold throughout the audiometric frequency range

CONDUCTIVE LOSSES IN CHILDREN

We recently reviewed our patients under 12 years of age who had a conductive loss with essentially normal otologic findings, and who were examined in our office ten or more years ago We found these cases could be classified into four groups

GROUP NO 1

This group consisted of conductive losses of 15 to 35 db in the three speech frequencies, which responded to therapy and had no further difficulty in adulthood

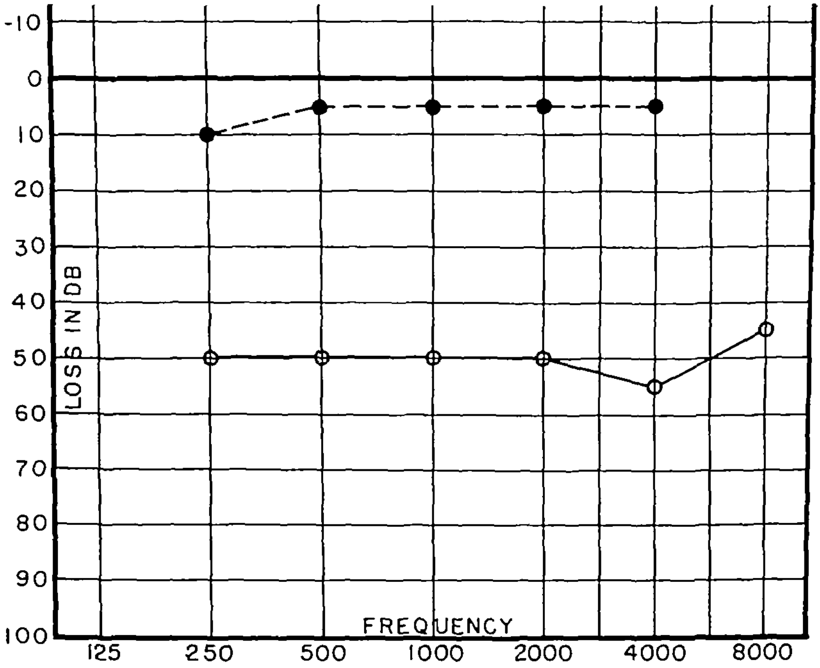

Fig 2 Congenital Footplate Fixation

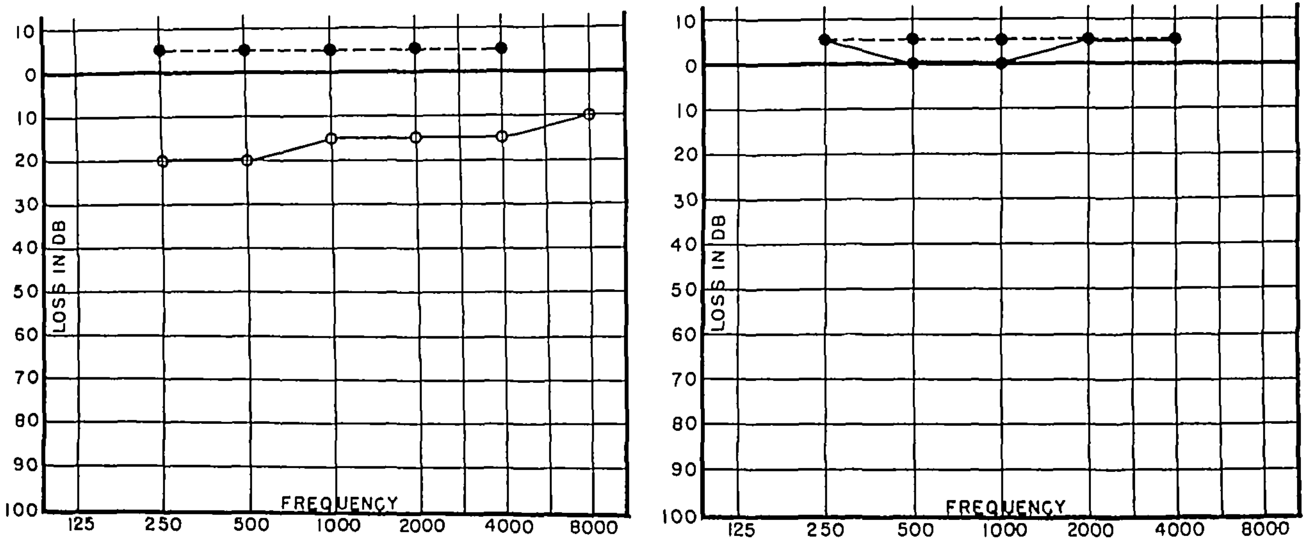
CASE REPORT

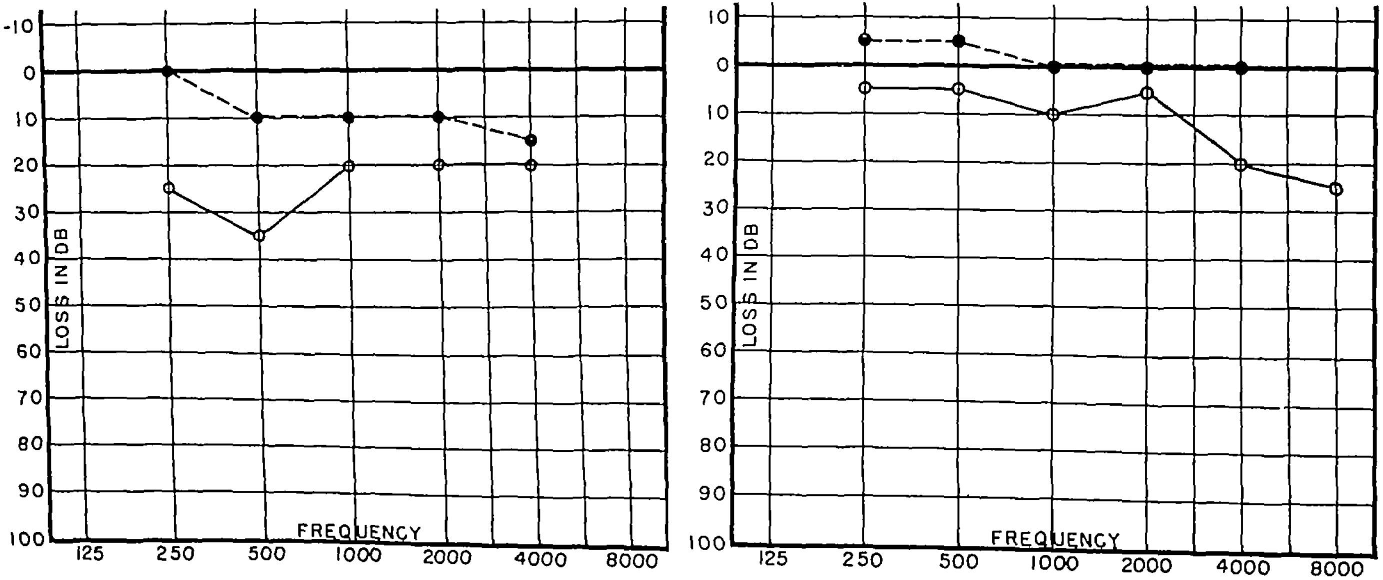
T E age five was first examined in 1945 concerning a hearing impairment which was discovered by routine school audiometry There was no history of middle ear disease and the otologic examination was essentially normal *A tonsillectomy and adenoidectomy was performed* followed by X ray therapy to the nasopharynx The hearing improved following this therapy and has maintained the improvement to date as per the following audiograms (see Figs 3 A, 3 B)



A.

B

Fig 3 A—Age 5 1945 B—Age 17 1957



A

B

Fig 4 A—Age 5 1946 B—Age 16 1957 Spontaneous hearing improvement

GROUP NO 2

This group consisted of children with mild conductive losses of 15 to 35 dbs in the three speech frequencies, who did not respond satisfactorily to therapy in childhood, but later regained their hearing after adolescence This gain was apparently due to spontaneous regression of tubal lymphoid tissue

CASE REPORT

E K age five was first examined in 1946 with a history of repeated upper respiratory infections and recurrent attacks of bilateral acute otitis media with drainage The parents had been aware of a hearing loss for several years

Examination revealed enlarged adenoids and tonsils and their removal was recommended The parents did not desire to have surgery performed, and no therapy was carried out either at that time or subsequently (see Figs 4 A, 4 B)

GROUP NO 3

This group consisted of children with mild conductive losses that increased to loss of serviceable hearing in adulthood, apparently due to otosclerosis Subsequent surgery now being performed on this group is proving the diagnosis of otosclerosis to be correct

CASE REPORT

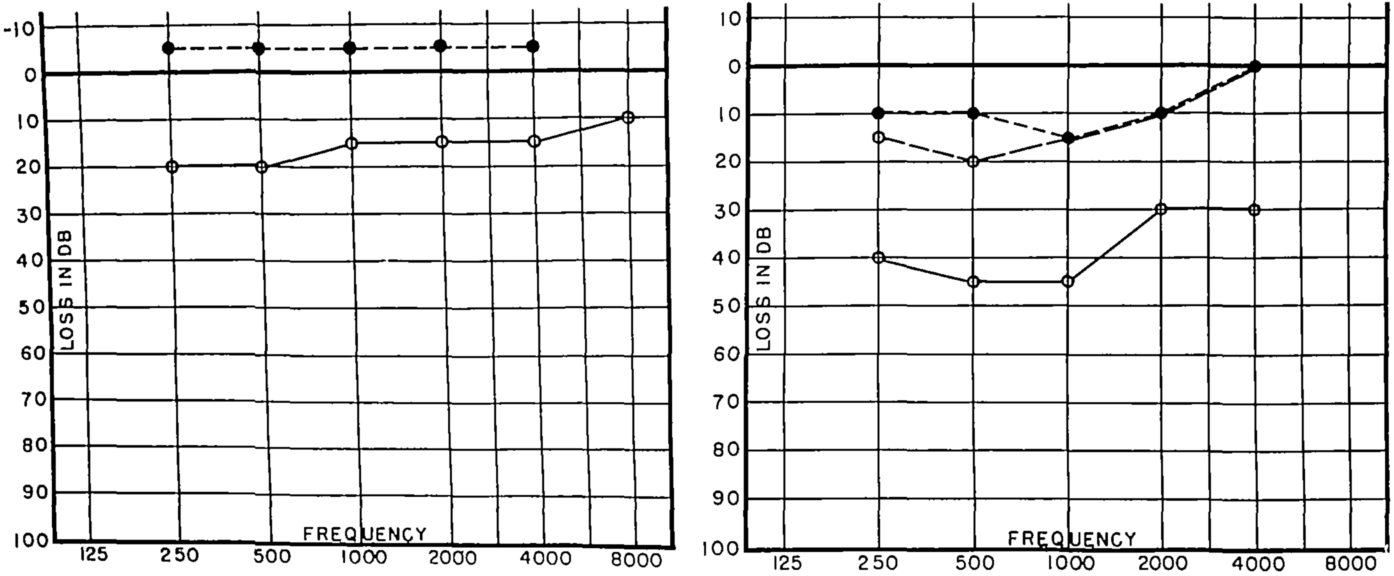
R K age 15 was first examined in 1954 She had noted a bilateral hearing loss for six months which was discovered accidentally and which she stated was not progressive She complained of some tinnitus and stated that she heard better in noisy places There was a positive family history of otosclerosis

Examination revealed essentially normal otologic findings The tonsils and adenoids had been removed at an earlier age and the nasopharynx was free of lymphoid tissue

Two years later another hearing examination was carried out and the hearing loss had progressed considerably during adolescence A mobilization operation was performed at that time with restoration of serviceable hearing as per the following audiograms The findings at surgery were characteristic of otosclerotic fixation (see Figs 5-A 5-B)

GROUP NO 4

This group consisted of children with a marked conductive loss in childhood, of 45 to 55 dbs, who showed the same degree of loss in adulthood ten or more years later, apparently



A.

B

due to congenital footplate fixation Subsequent surgery now being performed on this group is proving the diagnosis of congenital footplate fixation to be correct

CASE REPORT

V M, age ten years, was first seen in 1945 The parents stated the hearing impairment was first noted at three years of age, and that the child was rather slow in learning to talk The parents did not notice any progression in the loss and there was no history of ear disease The child was unaware of tinnitus and the family history was negative

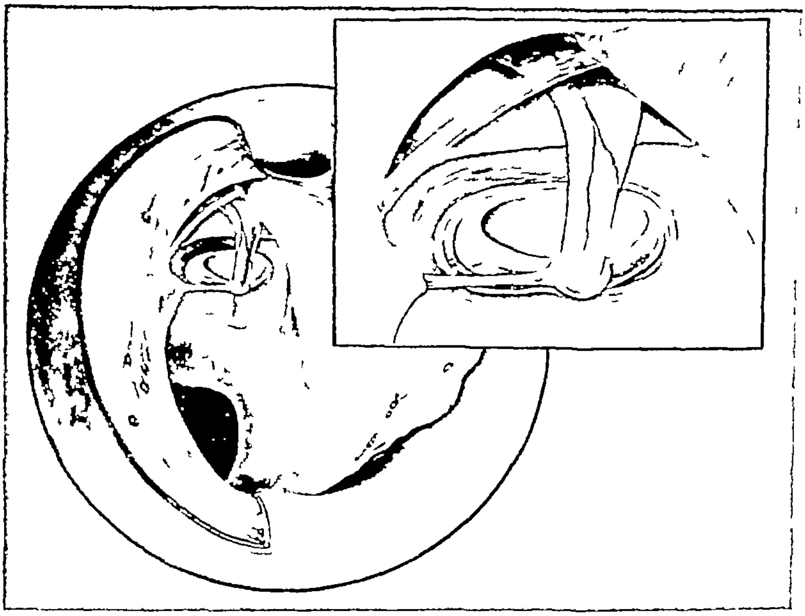

Fig 7 Normal Footplate

Examination was essentially normal except for the audiometric findings which revealed these characteristic audiograms (see Figs 6 A 6 B)

In a child under 15 years of age the diagnosis of otosclerosis is difficult, because the key factor of progression cannot be definitely established The degree of conductive loss at the time of discovery may vary from an average of 15 dbs to 35 dbs in the three speech frequencies, depending upon the degree of otoscelerotic footplate fixation During adolescence progression of hearing loss due to otosclerosis is frequently accelerated rapidly

If a child has normal physical findings, has a conductive loss not to exceed 35 dbs in the three speech frequencies and does not respond to routine therapy, the diagnosis may be clinical otosclerosis Confirmation of this tentative diagnosis can be achieved only by noting further progression of the hearing loss over a period of time, or by surgical exploration and examination of the stapes footplate

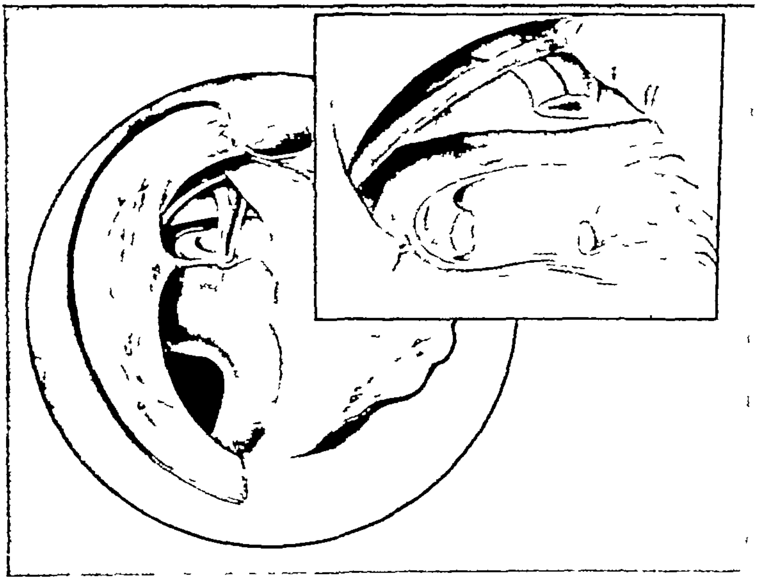

Fig 8 Otosclerotic Footplate

The diagnosis of congenital footplate fixation in the child may also be difficult, due to the lack of a history of progression of the hearing impairment, therefore, the diagnosis of congenital footplate fixation in children is based on normal physical findings and the characteristic flat 50 db pure conductive loss on the audiogram

In view of our long term studies of conductive impairment in children, it seems logical that any child under 15 years of age with a purely conductive hearing impairment approximating 50 dbs has congenital footplate fixation rather than clinical otosclerosis An analysis of our operated cases of congenital footplate fixation in children confirms this hypothesis

OBSERVATIONS AT SURGERY

Surgical exploration by the stapes mobilization approach reveals rather characteristic findings in cases of congenital footplate fixation (see Fig 7)

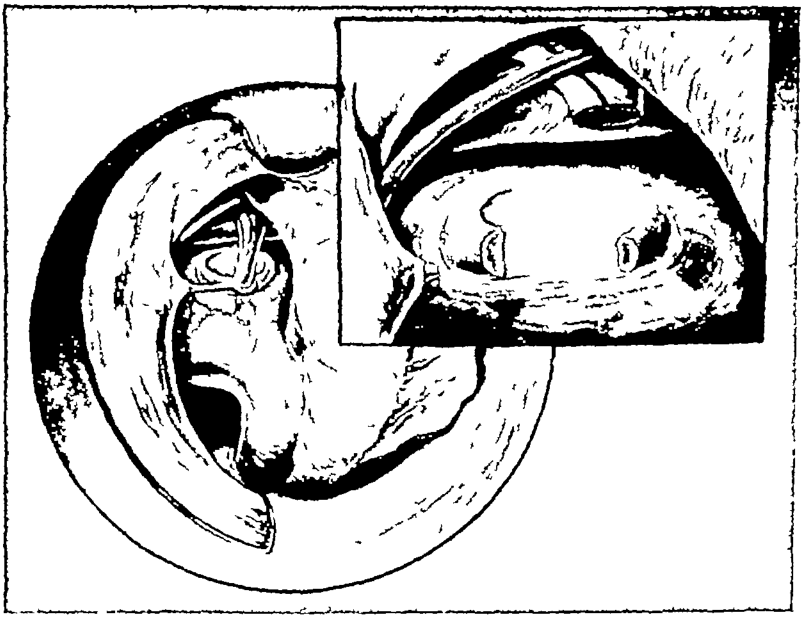

Fig 9 Congenital Footplate Fixation

The normal stapes footplate has a characteristic appearance *There is no increase in vascularity, and the margins* of the footplate and the annular ligament are distinct The central portion of the footplate is thin and usually has a bluish appearance Gentle palpation reveals uniform mobility (see Fig 8)

The otosclerotic footplate has an increased vascularity, usually in the anterior area The margins of the footplate and the annular ligament are difficult to visualize anteriorly, but usually are readily visualized posteriorly The central footplate area is often thin with a bluish discoloration Otosclerotic bone frequently engulfs the anterior crus at its footplate attachment Whitish otosclerotic plaques are often seen spreading over the surrounding bone of the otic capsule Palpation reveals fixation of the footplate, more often in the anterior region (see Fig 9)

In congenital footplate fixation there is no increase in vascularity The central portion of the footplate is not thin, and the bluish discoloration is usually not present The margins of the footplate and the annular ligament are difficult to visualize, since the footplate bone blends into the bone of the surrounding otic capsule This diffuse uniform bony fusion may be thin or thick If thin, the footplate can be readily mobilized, if thick, mobilization cannot be attained by manual pressures Gentle palpation reveals uniform and total fixation of the entire footplate

TABLE I

A Preliminary Report of Twenty Three Operated Cases of Congenital Footplate Fixation

Age of Discovery of Hearing Loss		
Average age	10 years	
Youngest age	2 years	
Oldest age	33 years	
(87% noted hearing loss before 14 years of age)		
Age at the Time of Surgery		
Average age	33 years	
Youngest age	6 years	
Oldest age	60 years	
(Five cases were over 50 years of age)		
Preoperative Air Conduction		
Average loss	50 dbs	Average in the three speech frequencies
Minimum loss	40 dbs	
Maximum loss	65 dbs	

SURGICAL RESULTS

All twenty-three cases were explored by the stapes mobilization approach Mobilization of the stapes footplate was attempted by needle and chisel techniques clinical otosclerosis An analysis of our operated cases of congenital footplate fixation in children confirms this hypothesis

OBSERVATIONS AT SURGERY

Surgical exploration by the stapes mobilization approach reveals rather characteristic findings in cases of congenital footplate fixation (see Fig 7)

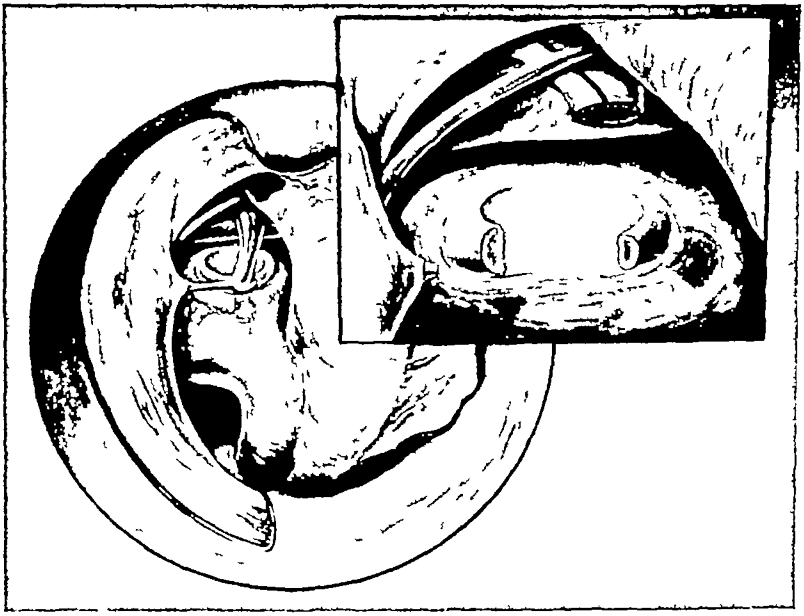

Fig 9 Congenital Footplate Fixation

The normal stapes footplate has a characteristic appearance There is no increase in vascularity, and the margins of the footplate and the annular ligament are distinct The central portion of the footplate is thin and usually has a bluish appearance Gentle palpation reveals uniform mobility (see Fig 8)

The otosclerotic footplate has an increased vascularity, usually in the anterior area The margins of the footplate and the annular ligament are difficult to visualize anteriorly,

Twelve cases (52 per cent) had a significant gain of 11 decibels or more in the three speech frequencies Eleven of these twelve cases reached the 30 decibel level or better three weeks following mobilization Eleven cases (47 per cent) remained essentially unchanged (within 10 decibels of the preoperative level in the three speech frequencies) In five cases (22 per cent) the stapes footplate could not be mobilized by manual means Of these five cases three were subsequently fenestrated and all three reached the serviceable level of 30 dbs or better

This series of cases of congenital footplate fixation is too small, and the time factor too short, to establish conclusions in regard to permanency Cases operated successfully one year ago, however, seem to be maintaining their post-surgical hearing improvement

CONCLUSIONS

1 The diagnosis of congenital footplate fixation is established by observing the characteristic flat audiometric curve by air conduction approximating 50 dbs in the three speech frequencies The hearing loss in these cases is non-progressive

2 Congenital footplate fixation is a definite entity which can be diagnosed clinically and confirmed at surgery

3 Mobilization in cases of congenital footplate fixation is usually more difficult than in cases with otosclerotic fixation If the footplate cannot be mobilized the patient is an ideal candidate for subsequent fenestration surgery

cause them to vibrate The round window membrane acts as a relief point so the in-and-out vibration of the ossicles can be transmitted through the scala to the round window, which then bulges in and out

There are several things that can happen to prevent this process first, the ossicular chain can be disrupted through the removal of the incus or the disarticulation of the incudostapedial joint A measurement of hearing in this case, an experiment which has been done many times on animals, shows that such a disarticulation gives a loss of around 60 db The reason for this is that we now have a useless drum membrane that is impeding the sound vibration from getting into the inner ear, also, the two windows are in the path of the vibrations that do get through Sound hitting the two windows in phase and with equal intensity will be cancelled out at the sensory cells which lie in the internal path between the windows

If the drum membrane is removed, as has been done both clinically and experimentally, the hearing will improve by about 15 db This leaves a loss of around 45 db, part of which can be accounted for by the cancellation effect of the sound hitting the two windows If, by some means, it were possible to get sound to one window alone, thus preventing the cancelling effect, hearing could be brought up to a 25 to 30 db level This, of course, is quite important because this is in the range of practical hearing—without an ossicular chain

Now let us suppose there is a stapes fixation This may produce a loss of 60 db or more Disarticulating the ossicular chain in this case will not produce more loss because the stapes is immobile and useless Although there is sound going in only one window the fluid can not respond to the vibration because it is blocked off at the other end by the fixed footplate of the stapes

In this case the first thing to try is, of course, breaking these adhesions to re-establish a normally moving chain If successful this is ideal, because the normal situation is restored, but, if this cannot be done, there are several pro-

Moderator Howard P House, M D Two years ago in Montreal, this panel analyzed its combined knowledge and efforts regarding stapes mobilization Today this same panel will bring to you newer thoughts and concepts in our thinking regarding stapes surgery during the past two years

In the interests of time conservation your Moderator today will ask each member one or two critical questions This will allow more time for audience participation and discussion at the conclusion of the panel presentation

First, I would like to call on the new member of our panel—Dr Merle Lawrence, will you discuss the function of the middle ear as related to stapes mobilization surgery?

Merle Lawrence, Ph D , (Ann Arbor, Mich) In order to speed the discussion along I shall use the blackboard to draw a schematic diagram of the ear, so that we can see what happens when we change parts of it We have the malleus (drawing on board), incus, stapes and inner ear, which I draw diagrammatically to show the endolymphatic system surrounded by the perilymphatic This gives us a picture of the normal ossicular chain, the drum membrane, malleus, incus, stapes and the scala media

The first essential for the production of hearing is the presence of the sensory cells, they must be present in the scala media and available for vibration The second item of importance is the relay of vibratory energy to these cells The primary purpose of the ossicular chain is to provide a match between the air and inner-ear liquids so the vibration can get into the fluids surrounding the sensory cells and again produces a drop in the response Removal of this plug brings the response back to the both-windows-open condition Obviously, in the presence of a normal inner ear the worst condition, aside from having both windows blocked, is to have one window closed and the other opened In the presence of a fixed stapes the situation can be improved by mobilization or temporarily by the drastic procedure of pulling the stapes out of the oval window

In the above experimental procedures the incus had been removed, so the drum membrane and its attached malleus were useless, having no direct connection with the mobile stapes or open window By removing this barrier to the sound, the response improves even further

The second slide shows the audiometric results for several frequencies The one curve shows the loss produced by the fixed stapes and the second shows the loss, a considerable improvement over the original condition, of mobilizing the stapes (and removing it) plus elimination of the drum membrane, malleus and incus It shows that through these procedures a marked improvement in hearing can be produced temporarily in the laboratory It does not indicate what the permanent results would be or what surgical complications would be encountered in the human

Despite the demonstrated improvement the average theoretical results would still show a hearing loss of about 45 db This is not enough of an improvement To be practical 15 more db must somehow be restored There is another mechanical property which can be considered in attaining this additional 15 db

We have mentioned that this 15 db loss is produced by sound hitting both windows in phase and with equal intensity This can be prevented by creating a situation that leaves one window open to the sound and protects the other without blocking it, that is, leaving it free to act as a relief point for the in-and-out motions of the other window

There are two ways by which such a situation can be accomplished one is by means of a skin flap over the open oval window or over a fenestra in the horizontal canal (as in the cedures that can be carried out which, if successful, can return hearing to the 45 db level

One of these procedures is to pull or break the stapes out of the oval window I would like to present two slides which show the results of such an operation on an experimental animal It is remarkable that the stapes can be pulled out without greatly changing the cochlear response from that produced with a mobile stapes with no ossicular chain

I would like to emphasize one thing at this point I am not advocating surgical procedures, I am talking about the mechanical properties of the ear under various conditions of surgical rearrangement in experimental conditions

In the first slide is shown a running-time record of the electrical response from a cat's cochlea when presented with a continuous 2000 c p s tone Such recordings are made possible by an electronic system which I shall not describe At the beginning of the record the stapes is fixed This is accomplished in the anesthetized cat by inserting a needle deeply into the cartilagenous portion of the Eustachian tube, a procedure which directs the remainder of the needle in a posterior direction directly past the stapes, wedging it against the promontory

The incus is removed, a procedure which, as long as the stapes is fixed, produces no change in the response Mobilization of the stapes by removing the needle, under these conditions, gives an improvement of about 12 to 13 db

As seen in the slide the next step is to pull out the stapes completely and, momentarily there is no change in response from that of a mobile stapes Such operations were separately reported as a surgical procedure on humans in 1892 by Blake and Jack, however, they soon abandoned it

Our next step, referring again to the slide, was to investigate the nature of sound transmission under the above conditions First, the now-open oval window was plugged solidly by pushing wax down into the niche There is an obvious drop in the response The response returns upon removal of the plug Plugging the round window in the same way we see an almost exact duplication and progression of techniques tried and abandoned years ago At first, in the final decade of the last century, there was mobilization which was followed by stapes extirpation and holes drilled in various regions Holes were drilled through the stapes, through the promontory, into the posterior canal and finally the horizontal canal I predict that in about 1980 somebody is going to rediscover fenestration of the horizontal canal

MODERATOR HOUSE Dr Lindsay, would you please discuss the pathology of extensive otosclerosis that might require footplate techniques for successful stapes mobilization?

JOHN R LINDSAY M D (Chicago, Ill) The histopathology is the one factor of stapes ankylosis which does not change, but as years go on we are more aware of the many variations which exist I thought it would be most informative to show a few of the really extensive cases of otosclerosis which would need some procedure directed at the footplate in order to be mobilized successfully

I am indebted to Dr Hilding of Duluth and to Dr Keeler of Oakland for the four specimens that will be shown

The first two slides are from Dr Hilding's case The first slide shows four sections through the same stapes to show how the condition varies Near the upper border the footplate is free at one side but extensively involved in otosclerosis and fixed at the other edge The section further down shows the fixation and greater extension of the otosclerosis Further down it extends well over the footplate, but still the posterior border is free in its upper part Lower down there is still a part of the footplate free where it is connected with the posterior crus The anterior crus is hopelessly involved in the otosclerotic mass This, as you see, suggests that the procedure first suggested by Fowler might be adaptable, that is, an anterior crurotomy and mobilization of the remainder of the footplate by creation of a fracture, leaving a mobile part of the footplate connected through the posterior crus to the remainder of the chain

The second slide shows a more difficult problem The situation is essentially the same in that part of the footplate is

Lempert operation) which then is so attached that an air space is left around the round window but at the same time acting as a barrier between the sound and this window Any opening in this barrier will, of course, not bring about the desired improvement

Another procedure is theoretically possible in the case of a firmly anchored stapes This consists of opening up the middle ear cavity by removing the drum membrane, malleus, and incus, which are useless in the face of an immobile stapes, and making a *minute* hole into the vestibule of the inner ear This hole must be small, because it has to offer acoustic resistance to the entering sound Such resistance cuts down the intensity of sound entering on the vestibular side and thus reduces the cancelling effect Any larger hole, such as was produced in the experiment shown on the slide by pulling out the stapes, offers no resistance at all to the incoming vibrations The tiny hole reduces the inner-ear cancelling effect and acts as a mechanical relief point for the unimpeded sound entering through the round window, so it is possible to obtain, by this method, an improvement up to the average theoretical level of 25-30 db as in the fenestration operation, and depending upon the natural acuity of the operated ear the results may be even better in some cases

I would stress that aside from the mechanical considerations mentioned here there are many physiological and medical problems involved Making a small hole in this manner may be fraught with dangers because it involves sticking into the vestibule a sharp instrument which could puncture the utricle and so injure permanently the endolymphatic system, also, the hearing results following such a pin-point perforation would more than likely fail to be permanent

If the initial attempts to restore a normally-operating ossicular chain through mobilization of the ossicular chain fail, it appears, when all factors are considered, that one should, for the patient's sake, resort to the now-proven fenestration operation despite the various other mechanical possibilities

Something should be learned from past experience, but quencies and the demonstration of a negative Rinne with the 500 and 1000 cycle tuning forks

2 A bone conduction threshold not lower than 40 db in the speech frequencies

3 A speech discrimination score with PB words not lower than 75 per cent.

4 Unilateral cases, if carefully confirmed by Weber lateralization, by quantitative masking and by Barany noise machine masking, providing that there is an expectation to reach the 30 db level, thus giving that patient the possibility of restoration of binaural hearing

5 It is pretty much our unanimous feeling that the poor ear should be done first

6 In general we do not urge or recommend simultaneous bilateral surgery

7 The choice of time for the second ear should be several months, about four months later at least

These represent our feelings about minimal requirements for primary surgery

Now as to revisions in general, chances for improvement are best with the first operation and become considerably less with successive reoperations

The surgical observations of the surgeon at the time of the first operation are often crucial in a decision regarding revision (From here on there appeared quite a diversity of opinion about revisions, and I am going to give them to you as we discussed them)

a Some on the panel felt that disruption of the ossicular continuity at the initial operation would be a contraindication to further surgery

b Others felt that such disruption would not contraindicate revision attempts by the use of newer techniques

c Some advise revision if there was no improvement at the first operation, if the surgeon feels that a newer tech-free, and one border is free from fixation but the anterior crus is hopelessly involved in the otosclerosis and the posterior crus is also slightly involved At one point it is touching on the otosclerotic mass and is slightly fixed Here the problem would be to get this free part of the footplate mobilized and also to get the posterior crus free without causing a fracture where it is involved by the otosclerosis It is questionable whether this could be done successfully

The third slide, from Dr Keeler's case shows a different situation This footplate is completely fixed all the way around the circumference The otosclerotic mass involves the footplate so that to mobilize this footplate it would be necessary to go through fairly active areas of otosclerosis This would require some method of mobilizing the footplate, whether by chisels or by whatever method the operator might prefer

The next slide from the opposite ear of Dr Keeler's case is somewhat similar This is also completely fixed all around the circumference, and the otosclerosis extends into the footplate The crura are not too bad, although one crus is extensively involved by otosclerosis This would certainly require some method of attack on the footplate in order to have any chance of success The method of attack might vary with the particular operator

MODERATOR HOUSE Dr Victor Goodhill, will you discuss the selection of cases for mobilization? Have our thoughts regarding selection changed any in the last few years? Please discuss this problem from two standpoints First, the indications and selection for the initial operation, second, the indication for revision of the initial operation

VICTOR GOODHILL, M D, (Los Angeles, Calif) These recommendations represent the composite views of the panel There are occasional exceptions to all of these statements, depending upon the judgment and experience of the individual surgeon

Minimal requirements for selection of candidates

1 An air bone gap of at least 25 db in the speech frethe event that mobilization attempts transcrurally are not successful and before fracture of the crura has occurred The other half of the panel proceeds directly to the footplate using picks, chisels or other instruments applied to the margins to loosen it and obtain mobility All members of the panel agree that in working on the footplate any perforation that opens into the vestibule definitely increases the danger to the labyrinth Deliberate anterior crurotomy, as described by Fowler, is utilized in occasional cases by members of the panel, but in the majority of cases an attempt is made to mobilize the entire footplate

In concluding on the technique of this operation I would like to make a little statement, which was suggested to me by Jim McLaurin, that there are two operations for otosclerosis

MODERATOR HOUSE May I interject just a moment before you get to this second part, by asking you your second question?

DR. SHAMBAUGH Yes, indeed

MODERATOR HOUSE What are the thoughts of the panel on fenestration of the footplate as described by Dr Rosen?

DR SHAMBAUGH At this time the majority of the panel members believe that a deliberate fenestra in the footplate without communicated mobility from the tympanic membrane to the mobilized footplate, or fragment of footplate, in all probability will not produce a lasting satisfactory level of hearing improvement

Now may I make that last statement, that there are two operations available for otosclerosis? One is the fenestration operation and the other is the "frustration" operation, frustrating because of the unpredictability of its results

MODERATOR HOUSE Thank you, Dr Shambaugh Now I will call on Dr Kos (There is another place you might use the word "frustration" That has to do with attempting to arrive at statistical evaluation of results in mobilization surgery) nique in his hands offers hope for mobilization, which did not exist at the first operation

d Some advise revision in any case if an initial improvement regresses at any time Others feel that such revision should be done only if the initial gain persisted at least nine months Some felt that revision should be done only once, others, many times In conclusion there was no true unanimity of opinion on all of these aspects of revision

MODERATOR HOUSE Thank you, Dr Goodhill I believe we conclude from this that we all agree on the indications for the initial procedure, but again you can see apparently there is no unanimity of thought pertaining to true indication for revision or on how many times the revision should be carried out

Dr Shambaugh is going to answer two questions that I will pose to him First, what major technique changes have occurred during the past two years in stapes mobilization surgery?

GEORGE E SHAMBAUGH, M D , (Chicago, Ill) Three major developments in technique have occurred since we first assembled this panel One is the utilization of audiometric testing during the operation in the operating room This was employed by several members of the panel two years ago and is now employed by all members

The second is the utilization routinely of the operating microscope to give a magnification of 10 to 16 times for visualization of the footplate Two years ago the majority of the panel relied upon two to two and one-half times magnification, and today all members of the panel agree that the operating microscope is essential for this surgery regardless of technique

The third development, which is largely dependent upon the increased magnification of the operating microscope, is the direct attack upon the footplate At the present time approximately half of this panel start with the transcrural attempt at mobilization, either on the incus, on the neck or on the head of the stapes and then proceed to the footplate, in of 30 db or better in the three essential speech frequencies the spread between us is reduced somewhat—the range being 25 per cent to 65 per cent The average of the group in this category is 42 per cent Two years ago this figure was 35 per cent Four of the participants achieved 42 per cent or better All of the rest, but one, stand very close by Two of the panelists hit this target with a closure of the air-bone gap in every one of their cases The others ranged from 13 per cent to 70 per cent The highest figure in this category two years ago was 59 per cent

It is notable that those who have performed the most operations have in general presented the more modest statistics It may be that these panelists are stuck with less desirable statistics because they led the way through the maze of uncertainties, and now having passed on their experiences have saved the others from falling into the inevitable traps of exploration I know that some of us have been experimenting in many ways with surgical techniques, and this is not always without its indebtedness to failure

Regression of hearing following a successful surgical result is always an unpredictable barrier to permanent improvement There are at least 12 recorded concepts of regression from this group There may be more It is difficult to reconcile the wide spread among us of the incidence of regressions These range from 4 per cent to 32 per cent The average is 15 per cent, however, when one considers that some of these participants are following patients whose operations took place three to five years ago and others are following those whose operations are of less duration, one possible explanation may be derived Time takes its toll of regressions even though it be in decreasing numbers

Operations resulting in worse hearing range from 0 per cent to 8 per cent in this group, depending on at least seven definitions of what constitutes "hearing made worse" The average is slightly over 3 per cent (about the same as it was two years ago) This percentage in 7,420 operations is probably acceptable if no other complications are involved, and according to the statistics of this group it is not so severe as it was once anticipated

I will ask Dr Kos to describe to you some of these complexities of analysis, and then he will present to you our results during the past two years

Dr Kos, do these results look as though we are gaining or losing in our attempt to restore hearing through mobilization surgery?

C M KOS, M D (Iowa City, Iowa) I take this opportunity to thank each of the members of this symposium for cooperating so generously in providing me with these data Since each has his own method of keeping records it was not easy for him to extract the precise information requested, but all of them made a valiant effort to comply Some irritations were aroused One began every reply to my inquiries with "Damn all questionnaires" Another when he reached the limit of his patience suggested sarcastically that if necessary he would write my paper for me I wanted to accept his invitation Others stuck to the point in spite of having some reason to rebel and delivered without protest

I must give to Dr Jim Shapley, our Director of Audiology, and to Mrs Iles, his able assistant, the entire credit for handling the information received Had I followed their original recommendations for the questionnaire, the entire job would have been easier, but my efforts to simplify a complicated task only compounded the difficulties, so Dr Shapley and Mrs Iles did the best they could to straighten things out We have lots of figures, but to give them in detail would require more explanatory notes than there is time and space available, therefore a contraction will be presented

The ten otologists on this panel, whose experiences range from 105 to more than 2,000 stapes operations, have produced an equally varied spread of results Together this group has performed 7,420 surgical procedures to mobilize the stapes as of January 1, 1958 Two years ago the panel reported on 1,091 operations Our total successes, of at least two months' duration, range from 25 per cent to 74 per cent, depending on each individual's criterion for success Our average success according to these various standards is 49 per cent When success is precisely defined as an average pure tone threshold worse" we have agreed we mean more than 20 db worse loss than the patients had before the operation Throughout the panel there were only three dead labyrinths, and one of those occurred about a month after operation, suddenly and inexplicably There is a question whether this dead labyrinth had anything whatsoever to do with the operation There was 1 per cent of persistent perforations There was a good deal of question in the minds of the panel whether this should be listed as a serious complication

There was no facial paralysis that was permanent There were three or four that developed a transient facial paralysis after the operation They recovered, and this was annoying but not serious

There was annoying persistent vertigo in three-tenths of one per cent There was a great deal of question about the chorda tympani in the letters written to me I could summarize the ideas of the panel as follows In general it was felt that stretching the chorda tympani hard was worse than cutting the chorda tympani Some of the panel felt that any injury to the chorda tympani was a serious matter, and all thought it should be avoided if possible

I have just discussed with you the complications that were suffered by those on this panel Throughout the country the story is quite different There are several cases of permanent facial paralysis There are several dead labyrinths There are a few very annoying chronic otitis medias One case developed mastoiditis, which could not be controlled and which eventually developed a base of the skull syndrome He is still alive but has a paralysis of the nerves that go through the jugular foramen, the VIth nerve and I think the Vth At any rate he had an extradural abscess at the base of the skull, and the patient is alive, I am sure, only because of hard work and chemotherapy

Finally, I would like to mention that there have been *two deaths,* one from staphylococcus labyrinthitis followed by meningitis, which was not controlled with the most heroic therapy and operation The other—this case thought to be a hospital staphylococcus that was resistant to all chemo-

Our experiences of the past two years indicate that significant progress has been made in stapes mobilization We are now aware that regressions continue to rob us of some of this progress and these are likely to become our prime target for investigation in the years to come

The experiences acquired during the hectic period of assembling these data point out the very important requirement for developing and establishing a common language to bridge the conceptual differences between us and others reporting in this field Several of my colleagues have also made this plea Fifteen different criteria for success, 12 concepts of regressions, and seven definitions of what is "hearing made worse" call for conferences designed and conducted to resolve these discrepancies

MODERATOR HOUSE Thank you, very much, Dr Kos

You have my sympathy and I am sure the sympathy of Dr Goodhill, because the two of us, in Los Angeles, got together before the Montreal meeting and attempted to go through this maze of information in an attempt to determine the results at that time, and you can see we were successful in convincing Dr Kos that he should fulfill his term of duty on this occasion

Now I will call on Dr Fowler, are any significant complications very frequently found in stapes mobilization surgery?

EDMUND P FOWLER, JR., M D (New York, N Y) I am sorry to report that this panel is no better sending statistical material to *me* than they were with Dr Kos, as a matter of fact, I think they were worse Perhaps I did not work as hard at it as Dr Kos did, but there was no way in which I could put figures together, that would give you any idea of the complications of mobilization surgery in a statistical fashion I believe it is most important to emphasize that the panel had about 3 per cent of cases that were made worse, as just reported by Dr Kos

You also notice that he mentioned that this ran between 0 and 8 per cent He did not point out that of the 3 per cent only a half of one per cent were severely worse By "severely so confined, in which instrumentation is so extremely limited, in which the structures must remain *in situ,* in which the surgical efforts involve a diseased area, and in which nothing is removed, so that the diseased focus remains? When bone, whether otosclerotic or not, is broken or cut through, I would assume that Nature's reparative process would sooner or later take place, and it does in many cases On the other hand, the fact remains that repair does not *always* occur, and thereby seems to refute my negative assumptions Since my topic is concerned with the prospects of stapes surgery, I must at this point declare that just as the problems of fenestration surgery were solved, these stapes problems will also be solved

A notable observation has been that many patients have reached a level of hearing to a degree that is attained less often by fenestration The joy of both doctor and patient following a brilliant result with stapes mobilization is not infrequently tempered by the disillusionment of ultimate failure, or if not in failure, in at least a recession of the hearing from the high degree of initial improvement The recession may occur not only in several weeks but as late as 20 months afterward

To my recollection, never in the history of otology has there been the development of so many techniques as in stapes mobilization The early enthusiasm for this operation stimulated the dormant inventiveness of many otologists throughout the world, and the most intricately designed instruments have appeared and disappeared For the present I do not favor mobilizing the stapes by mechanical means I believe, as Rosen does, that the mobilization is best accomplished by the sensitiveness of touch and the control of pressure in the surgeon's fingertips, and for this reason, in my opinion, no mechanical instrument, at present, can be substituted

The prospects of stapes mobilization are threatened when any otologist declares that a *promise* may be made to the patient that the hearing *will not* be worsened, and that if the attempt to mobilize the stapes should fail, the otologist *can always* resort to the fenestration procedure This statement would be true more often if the otologist knew *when* to stop therapy—is even more disturbing because of pneumococcus meningitis This patient seemed perfectly all right for 10-15 days, except for a little suppuration, which is not too uncommon in the early cases, (even for this panel) but suddenly a few days after his last visit to his otologist he developed a coma with a pneumococcus meningitis which was not controlled by chemotherapy and he died

MODERATOR HOUSE Now I should like to call on Dr Philip Meltzer, who will give us some of his views pertaining to the past, the present and the future of stapes mobilization surgery

PHILIP E MELTZER, M D (Boston, Mass) It is my intention to offer a word of warning that the procedure of stapes mobilization should be undertaken with a complete awareness of its pitfalls

This operation has fired the imagination of otologists throughout the world, and aroused in the mind of the layman a reaction brimming with hope for the alleviation of deafness So many procedures for stapes mobilization have been devised that the time has come for a discussion of their rationale It has never been denied that the restoration of the ossicular chain as a mobile unit for sound transmission is not valid, therefore, this operation stands on firm ground Whether or not a stapes once liberated will continue to remain so, and which of the many procedures will accomplish this most often and permanently, are questions to be discussed at symposia of this kind

I have observed the technique of some of the most practiced surgeons of this country, and my critical evaluation of this operation and my queries for the future are based on what I have witnessed, and my own experience

In fenestration surgery we are confronted with several problems Serous labyrinthitis and regeneration of bone in the fenestra are chief causes of failure Surgical access to the critical area for making the fenestra was not too difficult, and, as you are well aware, the continued advance in technique practically insures the success of this operation in well selected cases, but what can we look forward to, anatomically and surgically speaking, in the region of the stapes—a region to how it feels to have started all this stapes surgery On April 2, 1952, while I was testing a patient to see whether his stapes was rigid enough to have the Lempert operation I mobilized the rigid footplate of the stapes by pressure on the neck and the hearing improved immediately That patient still has normal hearing I think that had I or anyone else like Rip Van Winkle, gone to sleep on April 3, 1952, and awakened today to hear this panel and see the beautiful demonstration of middle ear structures by Dr Hough, he would feel that a very pleasant dream had indeed come true

It is very impressive to hear Dr Merle Lawrence give us some understanding of the mechanism by which hearing is restored by my fenestra ovalis procedure

I would like to show one slide to demonstrate whether it is possible to have lasting improvement following fenestration of the oval window Of 141 successful cases, eight or 5 7 per cent, have regressed partially 5 per cent have regressed completely and the number that have maintained the hearing improvement is 89 3 per cent of these 141 cases We have data on 72 of these successful cases for periods of three months to a year, on 57 cases for periods of one to two years and in 12 cases the hearing has been maintained for periods of two to three years

I should like to say to this entire Society that I was wrong when I said that this was a simple operation I would like to erase that from the minds of all of you It is not simple, and as time goes on it becomes more exacting

Moderator House We will now call upon our official discussors to give us three or four minutes of discussion of their experience, whether they agree or disagree with those on the panel, or give any newer thoughts they might have to offer at this time in their opinions of mobilization surgery during the past two years First, I will call on Dr Bellucci of New York

Richard J Bellucci M D (New York N Y) I am sure the official discussers are privileged on this occasion as they are not limited to discuss only Dr House s one question

I have two or three points I would like to make first in our experience in order to obtain a consistently satisfactory improvement in in his desire to free the stapes, and ceased to pursue traumatizing techniques that may preclude the fenestration operation

I now want to discuss the delicate and controversial issue of the otologist's qualifications for the performance of this type of surgery The stapes itself is so variable and fragile in structure, so loosely united with the incus, and so deeply placed in the fossa in such close relationship with the facial nerve, that this area is particularly vulnerable to accidental injuries and fracture, in the hands of even the most competent surgeons Just as the casualties of bad fenestration surgery have been observed over the years, we are now observing the casualties of bad stapes surgery The surgeon who is trained, but inexperienced, should not even consider attempting this procedure without first observing and learning in the most painstaking manner He must also be trained in clinical audiology as well as in all phases of temporal bone surgery, so he will be equipped to render a complete service to his patient

It is easy for me to stand before you and make these stipulations, but where is a man to get this kind of training? That is a problem that those persons in charge of residency training programs must solve by providing the training that will insure competence Perhaps another solution will be that the more experienced otologists will act as preceptors in their private practices, or that teaching institutions will provide courses for qualified men

Each one of us should examine his conscience to determine whether we are honestly equipped to perform the delicate maneuvers mandatory for the procedure of stapes mobilization Then and then only can we give to the patient the type of care that is so rightfully expected of us

MODERATOR HOUSE Now I will call on Dr Sam Rosen to tell us of any comments that he would like to make regarding this work Further, I would like to ask Dr Rosen this one question, how does it feel to have stimulated all of this interest in otosclerotic surgery?

SAMUEL ROSEN, M D, (New York, N Y) (Closing) I don't know quite how to answer Howard House's question as for the mobilization operation Here is one where the facial nerve and the promontory have reduced the oval window niche to a slit and the footplate is of course not visible This case is anatomically unfavorable for mobilization operation

(Slide) Where there is a large otosclerotic mass involving the whole footplate mobilization is a difficult procedure and I believe fenestration is the procedure of choice

(Slide) Here where both crura are affixed by the otosclerotic lesion even though the footplate is blue and does not show evidence of infiltration the final result is usually not satisfactory as the continuity of the ossicular chain cannot be preserved

MODERATOR HOUSE I would now like to call upon Dr Frank Sooy of San Francisco

FRANCIS A. SOOY M D (San Francisco Calif) I would like to show you very briefly four types of cases that can we feel be confused in the pre-operative diagnosis of clinical otosclerosis

Many otologists have been increasingly concerned with the number of patients seen in consultation who present ordinary office puretone audiograms which are typical of otosclerosis but who on further study or surgical exploration are found to have some other clinical condition.

The excellent paper presented by Dr Howard House at the American Otological Society calling our attention to 26 cases of congenital anomalies of the stapes footplate simulating otosclerosis is one such condition wherein confusion might arise particularly in children His finding on this syndrome in 1 per cent of his stapes mobilization cases is particularly significant as is the fact that in most instances this can be established clinically before surgery

We feel that the time has now come to evaluate critically our conductive hearing losses in order to catagorize these patients into favorable cases and unfavorable cases and we are now putting our first 500 cases on punch cards in which over 500 items are indexed in order to evaluate various pre-operative tests in the hope that a more accurate prognosis can be made by means of more complete preoperative testing

Four patients illustrating diagnostic problems are presented

I Congenital Stapes Anomalies

This seven year-old boy (see Fig 1) was recognized as an anomaly preoperatively by the presence of hand deformities and was successfully treated in the premobilization period by fenestration

II Unilateral Complete Hearing Loss with Inadequate Masking

Fig 2 shows the usual unmasked office audiogram in this condition while Fig 3 demonstrates the effect of masking at the usual maximum of 50 db with the ordinary audiometer Fig 4 reveals the true audiogram when masking is carried out at levels of 90 db under research conditions using white noise or sawtooth masking Since many audiometers provide only 50 to 60 db of masking this is a real problem

III Use of Psychogalvanic Skin Reflex Audiometry (PGSR)

Fig. 5 shows the audiogram of a five-year-old girl who was referred for stapes surgery on the basis of PGSR testing only Subsequent study by conventional methods using an audiologist trained in children s testing reveals a pure perceptive loss (see Fig 6) hearing the continuity of the ossicular chain must be maintained, therefore, techniques which depend upon the strength of the crura for mobilization have been discarded, and all forces are applied directly to the footplate at the point of maximal fixation With the microscope and with direct visualization of the point of the needle it is possible to obtain visual as well as tactile control

We have done considerable experimental work on animals, have fractured the footplate, have removed the stapes from the oval window and a variety of these operations We have found that considerable tissue reaction occurs following trauma to the oval window, and we have experimentally induced stapes fixation by these traumatic procedures We believe that mobilization of the stapes operation should be done with the least trauma to bone and mucosa This operation should be a gentle procedure done carefully and slowly, exploring the weaknesses in fixation which will permit mobilization by the simplest means A very careful pre-mobilization evaluation of the pathology, therefore, is required before mobilization is attempted By this pre-mobilization examination we are able to understand the pathology and to modify the technique of mobilization accordingly In using the simplest means of mobilizing, trauma to the stapes and footplate is reduced

If we can leave the joint and the stapes mobile and as normal as possible we believe we have achieved our goal I believe that excessive trauma will certainly induce refixation

I would like to show the classification we use as a guide for stapes mobilization

(Slide) We have devised a classification based on the anatomical and pathological findings, the degree and position of the otosclerosis at the footplate This is Class I the characteristics of this Class I can be summarized as follows Show no narrowing of the stapedial vestibular joint, the footplate is blue, palpation of the posterior end reveals motion, and palpation of the anterior end reveals that there is some degree of fixation, 36 per cent of the cases studied were found to have the characteristics of Class I It is obvious here that any technique will mobilize this type of fixation, however, we placed the needle point right at the junction of the crus and the footplate Slight pressure usually causes mobilization

(Slide) Class II the characteristics of Class II are narrowing of the stapedial vestibular joint but not involving the anterior crus or then it may be the posterior crus The footplate is blue, due to the flexibility of the stapes slight motion can be seen on palpation at one end of the footplate In this slide at the anterior end there is definite fixation Sometimes the footplate is involved as shown In this group we find the most difficulty as it requires the application of the mobilizing forces directly to the point of the otosclerotic fixation having to go through the lesion and causing some degree of trauma We therefore have the highest *rate of refixation in this type of case There were 41 per cent of these* cases in our study, which means that the largest group belongs to this Class II

(Slide) Class III is advanced otosclerosis involving the anterior crus, the footplate and the vestibular wall Only 14 per cent of the cases were found to be in this group Mobilization in this group of cases is done by means of the anterior crurotomy of Fowler where the lesion is circumvented Part of the footplate and one crus operate together for the transmission of sound to the oval window The anterior crus is divided above the otosclerotic lesion at this point

(Slide) In Group IV we have the group of cases which are unfavorable

immediate postoperative level of hearing and No 3 the red line the postoperative level of hearing after two months showing an improvement in the conversational range but a sharp drop in high tones this suggested possible damage to the inner ear by the footplate manipulation When I returned home from this meeting about a month later I received a call from this man in which he stated that his hearing had completely disappeared in the operated ear Audiograms were done and confirmed that there was a complete loss of hearing (slide)

Now in this case a hole was inadvertently made in the center of the footplate What then might happen if one uses the technique as demonstrated by Dr Shea in his motion picture in which it appears that a hole is intentionally made in the center of the footplate? An occasional dead" ear is bound to result furthermore alterations in the membranous labyrinth, as illustrated in the following cases, may occur

In two patients additional complications of direct stapes footplate manipulation were revealed in subsequent labyrinthine fenestration operations In one case (slide) when the cupola was removed the membranous canal was shriveled into a brownish flat thread hugging the upper margin of the bony canal in the other (slide), a thin brown membrane suspended from the margins of the fenestra like a hammock dipping into the cavern of the bony canal was present The status of the membranous canal below this was not determined as this thin coagulum was not disturbed Fortunately both of these patients had a good hearing result fortuitous no doubt when one considers what was found in each instance As Dr Meltzer has stated the patient usually is told that if his stapes operation fails he still has the opportunity of gaining hearing by a subsequent fenestration procedure In the light of the experiences of these two cases one must be conservative in footplate manipulation to permit the maximum chance of success for a possible fenestration operation This should be a cautious circumferential manipulation of the footplate instead of a hole-punching type of procedure

Two years ago I stated that it was unwise to proceed with a labyrinthine fenestration at the same operation if it appeared that the stapes mobilization was a failure Nothing has occurred in the past two years to cause me to change this opinion

MODERATOR HOUSE I would now like to call on Dr Schuknecht

HAROLD F SCHUKNECHT MD, (Detroit Mich) I will limit my discussion to a brief description of my present technique and to an explanation of why I believe it is a rational approach It should be evident to everyone by now that it is not an easy surgical procedure and that it is not free of complications In about 400 operations I have three patients with near total deafness in the operated ear One of these resulted from simple trans incudal mobilization one from chisel mobilization and one following the use of the metallic stapes prosthesis

I agree that patients must be told that there is a danger that the hearing can get worse The results are good enough nonetheless to justify recommending the operation after properly informing the patient of possible complications and the chances for success

I use the direct footplate approach using the Heermann chisels In my opinion these chisels are best used by holding them in the fingers Light to heavy hammer blows are given as necessary to go through the otosclerotic focus when possible If that fails an incomplete footplate mobilization is accomplished

IV Collapse of Ear Canal Due to Headset Pressure

Fig 7 shows consistent puretone and speech tests in a 26 year old girl whose response to spoken voice was somewhat better than her audiogram PGSR testing (see Fig 8) suggested usable hearing in her left ear

Stapes mobilization revealed otosclerosis in the right ear with a gain of 32 db in this ear *after* she was tested by holding the headset a fraction of an inch *away* from her ear (see Fig 9) A similar test on her un operated ear revealed a gain from 51 to 29 db This phenomena, which has been described by Scott Reger is now called the Viehweg syndrome in our laboratory after the audiologist who discovered two such cases in recent months

MODERATOR HOUSE Dr Scheer was not able to attend the meeting I will now call upon Dr Shirley Baron

SHIRLEY H BARON, M D, (San Francisco Calif) Two years ago in the discussion following the symposium, I presented two cases one demonstrating the advantages, and one representing one of the possible disadvantages of direct footplate mobilization

(Slide) This was the case I presented as the one showing the dis advantages of footplate mobilization This patient had violent vertigo immediately following surgery The vertigo persisted for four days There was some loss of balance or dizziness for about six weeks after surgery I presented this same slide showing No 1, the black line which was the pre-operative level of hearing No 2 the green line the

3 Deep focus Fixation of the stapes may be due to a deep focus which has grown onto the under surface of the footplate No visible evidence of the otosclerotic focus may be present with any magnification when viewed from our surgical approach yet the stapes may be fixed to varying degrees of slight to marked as judged by the application of pressure to the head or footplate of the stapes

4 Combined foci Any or all of the above types of foci may be combined depending upon the extent of the otosclerotic involvement The combined type is usually massive in character and usually results in firm fixation which does not yield to mobilization with our present technique

It is our belief that appropriate attempts should be made to mobilize all fixed stapes in acceptable candidates regardless of the appearance of the otosclerotic focus If mobilization techniques fail or if refixation occurs acceptable candidates are then encouraged to have fenestration surgery

MODERATOR HOUSE Now, Dr Sullivan

JOSEPH SULLIVAN M D (Toronto Can) We have been stampeded and somewhat mesmerized however I congratulate the panel on its frankness and honesty particularly the summation of the remarks of the panel by Dr Meltzer I think that the remark of Merle Lawrence will be validated in the future Coupling that remark with the excellent contribution of Dr Hough and to which Dr Sooy referred today this procedure may resolve itself into an approach of congenital malformations of the middle ear rather than the moderately severe otosclerotic

From the Epistle of St. James the 1st Chapter Verses 19 20 21 Let every man be swift to hear slow to speak and slow to write

I believe I must emphasize that latter phrase briefly I make a plea for a uniformity in terminology correct in basic English namely stapes mobilization with a mental reservation that this term may not be entirely accurate

Three surgeons Dr McAskile Dr Smith and myself have evolved a technique and this was written before the panel remarks came for stapes mobilization which in a series of about 500 cases is yielding a 30 db or better level of hearing in about 40 per cent of the cases for one to four months following operation for cases suitable for fenestration There are exceptions they are few in number Roughly half of all our mobilization cases fail to achieve a hearing improvement comparable to fenestration while about 3 5 per cent of all mobilizations end up with a further hearing loss of significant degree

We believe four factors should be emphasized in this procedure

1 The use of the operating microscope is essential for the best constant result and there the most important question has been answered which I had intended to interject to the panel can a fenestration always follow a non successful stapes mobilization?

2 Direct visualization of the footplate is necessary and I hereby insert a word of caution In spite of what has been said after nearly 30 years experience in temporal bone surgery that footplate perforation is not a fenestration it is a primary procedure It is frequently followed by failure and early closure and is not without danger Would someone on the panel venture an opinion pertaining to the question about the persisting vertigo and is labyrinthitis in such a patient a condition where revision of the patient may be attempted?

The use of pressure directly inwards towards the vestibule should be the principal attack in attempting mobilization and it is used only on

In about 3 per cent of cases, the oval window is filled with a plaque of hard otosclerotic bone, and a successful mobilization cannot be accomplished. With the direct footplate techniques the footplate is sometimes comminuted, the bluish thin portion is in pieces, and the crura make contact either with these fragments or sit in a pool of perilymph. The columella effect remains and a good result is possible.

Eighteen months ago, I performed a repeat operation on an unsuccessfully mobilized ear and replaced the previously fractured stapes with a tantalum wire prosthesis. This patient was not a candidate for fenestration surgery because of poor bone conduction thresholds. The tantalum wire was looped and tightened onto the lenticular process with the other end protruding through the remaining pieces of footplate into the vestibule. The patient acquired a good hearing improvement which has been maintained to the present time. Since then, I have used this technique on about fifty patients.

Whenever the direct footplate approach fails to result in a satisfactory columella effect because of crural injury, the tantalum or stainless steel "pin" can be used to reestablish the "columella." Often I remove the head, neck and crura of the stapes. The pins are made of .005 inch suture wire shaped into a small "question mark" of suitable size with or without a small "ring" at the bottom. The length of the "pin" is such that when the loop is tightened on the lenticular process, the distal "ring" is in contact with the fragments of footplate.

I now use the pin in over half of all mobilizations and am convinced of its efficacy.

MODERATOR HOUSE: Now I should like to call upon Dr. Fred Guilford.

FREDERICK R. GUILFORD, M.D. (Houston, Texas): We do not believe it is possible with our present knowledge to classify a stapes as to its possibility for mobilization by the appearance of the otosclerotic focus present. It has been our experience that the examination of the otosclerotic focus alone during the stapes mobilization operation, with our present methods using magnification of from 6 to 25 power, does not give us adequate information concerning the possibility of its mobilization.

The relationship of the plane of the otosclerotic focus to the plane of the footplate as well as the extent of the otosclerotic involvement are important factors which may govern the possibilities of surgical mobilization of the stapes.

The relationships of the otosclerotic focus to the level of the footplate may be given a surgical working classifcation as follows:

1. *Superficial focus.* The main body of the focus is above the level of the footplate. Impingement of the focus on the anterior crus or onto the superior surface of the footplate may be the cause for the fixation. A focus of this type may be quite large and yet the stapes can be readily mobilized. At times the whole superficial focus mobilizes with the stapes.

2. *Interstitial focus.* In this type of involvement the fixation is due to a focus which apparently grows into the substance of the footplate without marked overgrowth of bone above the level of the footplate. In this type the white otosclerotic bone can be seen extending from the periphery into the blue-gray footplate often giving the appearance of the gray white arcus senilis seen in the cornea. This type of fixation is often strong and rigid. Mobilization effected in the presence of this type of involvement may be associated with a linear fracture of the footplate parallel to the margin otosclerotic focus in the footplate.

those that are obtained from fenestration, and the percentages of success from fenestration are infinitely higher

Moderator House I would now like to call on Dr Moses Lurie of Boston

Moses H Lurie, M.D (Boston Mass) I think this is the most stimulating discussion that I have heard on mobilization of the stapes but as I listened I suddenly became aware of the fact that it was not mobilization of the stapes they were talking about. They were talking about various operations on the vestibular part of the membranous labyrinth Each man seems to have had his own idea how to approach and how to play with it Until we get a standard method upon which we can all agree we are never going to get any statistics We must know exactly what each man does and we must give each man s variation of the operation a definite place in this work There is no question in my mind that mobilization will find its place It is just like the arguments that came up with fenestration I know all the vicissitudes and variations which we went through and now are going through again

I heard some statements which upset me a little bit One was, if you are going to do bilateral mobilizations of the stapes wait four months I would wait a much longer time I would wait over a year, because you still have the possibility that you may give this patient bilateral deafness and one must always respect the sensitivity of the membranous labyrinth

I do not think the criteria of success are definite enough One talks about four months two months three months No case is a success in my mind even in the fenestration cases that does not have good hearing at the end of one year After a year—then you can start talking about success for mobilization The one thing I would like a good many of you to carry away with you today is as Dr Meltzer said that you must practice this type of operation I started to work with it and gave it up because I found that I could not accomodate my eyes to this type of work but there is no reason why the younger men cannot do it and carry on

The other thing I would stress is the demonstration that Dr Lawrence has given you about what the drum and the ossicles do in regard to transmission of sound Remember, cracks in the footplate may give you good hearing for a short time, but you are playing with a pathological process which you have not stopped and which may destroy all your effort in one or two years Then the patient will be back to where he was originally

Moderator House Thank you, Dr Lurie I should like to now call on Dr Tonndorf

Juergen Tonndorf M D (Iowa City Iowa) When Dr Rosen asked me whether I would like to discuss the principles involved in footplate fenestration I did not know what my good friend Merle Lawrence had to say on this subject Now I feel a little embarrassed All that remains for me after his lucid presentation is to amplify some of the points

In trying to bring the acoustic task of the middle ear upon a simple denominator one might say that this task is twofold first impedance matching second preservation of the phase difference between the two cochlear windows The latter for reasons of cochlear mechanics has a value of 180°, however I would like to point out in this connection that the way nature has solved these two tasks is by no means the only the footplate or crura at the very beginning and the end We test the mobility of the stapes by the lightest pressure on the incus and that sense of touch can be very well developed in animal experimentation on nerves Working on either side of the anterior crus, if possible is preferable not through the otosclerotic focus, because this region has a tendency to fracture

Finally a few words of caution concerning the facial nerve There may be a dehiscence in the facial canal as it runs along the upper margin of the oval window so that the unprotected nerve sheath bulges in the oval window To quote Cawthorne, there is plenty more to do, and whether to push it or rock it, or pull it, or perforate it, or remove it and bypass it, the stapes deserves all the critical attention we are able to devote to it

In conclusion, there are many arts among men, the knowledge of which is acquired by experience For it is experience that causes our lives to move forward by the skill we acquire while the want of experience subjects us to the effects of chance

MODERATOR HOUSE I am sure that these thoughts are likewise those of the panel Now we have had several who have indicated their desire to discuss this We have in mind also to call on a few more who are not sure at the moment that they are going to discuss it, who have not turned in their cards First of all I will call on Dr Theodore Walsh

THEODORE E WALSH, M D (St Louis, Mo) There are just one or two remarks I would like to make I agree with Dr Meltzer emphatically when he remarks about being honest with the patient and in telling the patient that he can not always have a fenestration if a mobilization fails I agree that usually one can do a fenestration when a mobilization fails but not always

I had a case which illustrated this to my great sorrow A girl who was an ideal candidate for fenestration, a nurse, who needed her hearing, consulted me some three years ago She refused fenestration at that time and recently came back demanding the stapes mobilization She asked me, 'Suppose this fails, can I have a fenestration?' and I said, 'As a rule, yes, but accidents can always happen, and we might not be able to do it I still advise a fenestration'

She insisted on the mobilization, and we did it with the very greatest of ease This was an extremely easy case, and the hearing on the table came up to the 15 decibel level, however, when I removed the drapes feeling very pleased with myself for having mobilized her stapes, she remarked that she was very dizzy

She had no nystagmus but did remain extremely dizzy, vomiting and unsteady on her feet, and three weeks later had a completely dead ear She has not forgiven me

I believe one should be very careful in all the work one does around the footplate It is very nice if one can mobilize a stapes easily, but if there is any chance of damaging the hearing by excessive efforts at mobilization I believe one should quit and do a fenestration later Incidentally I agree with Dr Sullivan when he says that the hearing results from mobilization are no better than they are from fenestration In reviewing all our cases of both fenestration and mobilization there are very few mobilizations that have a residual hearing level better than

Dr Kenneth M Day I would comment on the comparison of the hearing following fenestration and mobilization There must be a dozen patients upon whom I performed a fenestration some years ago and have recently mobilized the stapes of the other ear In half of these cases the hearing level in the fenestrated ear and in the mobilized ear is almost the same

One of the patients happened to be a young musician He has music in his fingers Discrimination scorers are the same but he said 'I like the first ear for music" There is a little distortion in his mobilized ear Most of the patients upon whom I have done a mobilization on the second ear say I may hear as well in the mobilized ear but I seem to hear more clearly in the fenestrated ear"

Is that due to traumatic labyrinthine reaction from working around the footplate? We are always worried about trauma when we make a fenestra in the horizontal canal I wonder if this is not a case of more traumatic reaction in the cochlea by working on the footplate than back in the horizontal canal

Moderator House Now we will hear from Dr Hoople

Gordon D Hoople, M D (Syracuse N Y) This has been most interesting There are many things that one could say but I want to confine my remarks to one aspect of the whole subject and that is none of us should go away from here thinking that we have the final answer on the chances of percentage of success Dr Kos has told us the reasons why There is a figure projected which shows 42 per cent as the overall results of all the panelists If I interpret the presentation correctly this is the result of all their cases to the present time It includes some of the cases that were not successful in the very beginning of mobilization surgery I am afraid that it also includes some cases which the panelists have done by footplate manipulation which in three months six months a year or more from now may not have as good hearing as they have reported at the present time

I have some evidence which is not ready for presentation now that footplate work is spoiling some of the results of men who did not formerly attack the footplate One member of the Society who has spoken this morning stated at Philadelphia at the Midwinter Meeting that he had 72 per cent successes in doing mobilization surgery but in four months 17 per cent of these had regressed to the former hearing level (These are his own figures Maybe I have missed out by one or two per cent but that is not the point) I am not belittling him at all but this is success of an operation but not success in producing better hearing as far as the patient is concerned So we will have to wait a long time before we know what the results are and we must take into consideration the present rash of footplate manipulations I use that word advisedly

Finally I would like to say one thing which I think most of us have forgotten The last word that was said in the panel two years ago in Montreal was said by the man who today would be the President of this Society had he lived He himself was not a fenestrator but he said this 'I believe that this work should be done by men who know fenestration surgery I leave you to put whatever interpretation you wish on his words but I want to remind you that he said them

Moderator House Now with the passage of time I take this opportunity to return to the panel for any closing comments they might like to make way this can be accomplished I would illustrate this point with the aid of three slides

(Slide) This first slide shows a schematic diagram of the normal middle ear Impedance matching is accomplished by application of the transformer principle the large ear drum is coupled to the small footplate via the ossicular chain In the lower drawing a different approach is used, one which is widely applied in engineering, the so called acoustic horn This horn accomplishes essentially the same that the ossicular chain does in the upper drawing I admit that within the limited space between the pinna and the window, a horn would be somewhat unsatisfactory at low frequencies that is below 500 cycles

(Slide) Now we come to the second task the preservation of phase differences In this slide I made up two theoretical cases which represent two extreme solutions of the problem The first of these solutions consists in doubling the ossicular chain Normally (the upper chain of this drawing), the eardrum and the oval window move in phase In the lower (hypothetical) chain the incus is assumed to pivot about its center so that the eardrum and the round window, to which this second chain is connected move in opposite phases This way one would obtain a drive mechanism which engineers by a very descriptive term, call a pushpull drive mechanism

The other extreme solution would consist of shielding the round window completely so as to produce an infinite impedance mismatch between the eardrum and the round window From the third drawing on this slide it is obvious that Nature does not use either one of these extreme solutions but makes somewhat of a compromise First, there is a certain amount of phase shift through the ear drum This shift is maximal namely 90°, at 1500 c p s and smaller for all other frequencies being positive at lower and negative at higher frequencies, thus the phase shift principle is operative to a certain extent The second principle is the impedance mismatch The ossicular chain represents a solid coupling system which has a high degree of energy transfer The other pathway eardrum to round window, has a lower degree of energy transfer furthermore the two windows are of different size the round window being the smaller of the two Third (not shown in this schematic drawing) the eardrum and the round window are not in an identical plane so that partial reflection might occur Of course this latter fact does not operate at low frequencies but it may become important however at frequencies above 2 000 cycles

(Slide) This last slide gives the reason why Dr Rosen s method of footplate fenestration is acoustically feasible Now both windows are coupled to the eardrum in a similar fashion, however because of the fact that the window in the footplate is so much smaller, we have a better impedance match from the ear drum to the round window and a lesser impedance match to the window in the footplate The assumption appears logical as Dr Lawrence has pointed out before that the relative sizes of these windows are very critical Without having done any measurements or experiments along this line I would venture to predict that a plot of amplitude of window motion vs size of the footplate window would first increase and after going through a maximum it would go down again At this time, I am in no position to say anything about the degree of gain one might achieve by this method and of course it is completely out of my province to say anything about the probability of postoperative changes *The only thing I would point out here is that* this method is acoustically feasible

Moderator House Dr Day, may we have your comments?

tion by one of my associates in which the crura were fractured at the same time the footplate was mobilized and you will notice the further loss of hearing by air and the increase in the air bone gap due to discontinuity of the ossicular chain despite a successful mobilization of the footplate Two years later the patient returned for revision At this revision a tantalum wire as Dr Schuknecht has described so nicely was placed between the incus and the center of the mobilized footplate and we see that the air bone gap now has been reduced to somewhat less than 50 per cent of the pre-operative level We have re-established the continuity of the ossicular chain and as Dr Lawrence has stated three times I think I would like to say for the fourth time for best results we must have a continuity between the tympanic membrane and the movable portion of the footplate

Moderator House Thank you, Dr Shambaugh Now may I call upon Dr Kos for any comments he might have in closing

C M Kos MD (Iowa City Iowa) (Closing) Well the figures speak for themselves though not very accurately for obvious reasons which have been mentioned here several times I should like to emphasize that regardless of any other concept in connection with this operation at the present time it is essentially an exploratory operation It is exploratory for two principal reasons—One is that there is no pre-operative or clinical clue on which one can hang enough confidence to predict what the outcome may be second there is no surgeon who can possibly accurately anticipate what he will find before he raises the tympanic membrane

Moderator House Now Dr Fowler, before closing I would like you also to answer the question of Dr Sullivan, namely to comment a little further on persistent vertigo following mobilization surgery as a complication

Edmund P Fowler Jr MD (New York N Y) (Closing) I think it is wise at this point to emphasize that the footplate can be mobilized in a number of ways This is my personal opinion and not held by some on the panel and that is why I left it to this time I believe that as a rule the stapes (Slide 1) is mobilized by fracture through the footplate as shown in I IV or V I also think that this is probably the best way to mobilize the stapes ankylosed by otosclerosis because if it is mobilized through the focus as in II it seems to be the ideal way to invite more closures

(Slide 2) To answer Dr Sullivan to a certain extent this is a section of the footplate of a patient in which an anterior crurotomy was done Inadvertently in testing the footplate a puncture of the footplate occurred (between the arrows) This patient died 15 months after the operation and you can see that there is tsill a spicule of bone in the labyrinth (above arrow on left) There was no infection in the labyrinth I think that if you push this spicule of bone a little further that it can be pushed into the utricle or it can rest on the utricle and produce vertigo by acting as an overgrown otolith Unfortunately we are not always as lucky as we were in this case when there is a hole in the footplate of this type If there is any infection present in the middle ear it could get into the labyrinth through such a hole

Finally I would say that the size of the hole in the footplate may make a great deal of difference as far as subsequent hearing is con

DR LAWRENCE I don't believe that there is any need for saying three times what I said, but I thank Dr Tonndorf for the amplification and would like to re-emphasize what the result will be, if one can re-establish the normal condition I leave the rest to the panel

MODERATOR HOUSE Dr Goodhill, I would like to ask you two questions one is in answer to Dr Sullivan Can cases of persistent, annoying vertigo be revised?

DR GOODHILL I have not revised any In answer to Dr Sullivan's question as to why they happen I am quite sure that they are due to permanent displacement of utricle, saccule, macula and fixation, by some kind of fixation in the vestibule

MODERATOR HOUSE Are there any other closing comments you would like to make?

DR GOODHILL I would like to make one comment in regard to Dr Hoople's statement I think he would be very happy to learn of the activities of the Committee of the Otosclerosis Study Group, which met here a day or two ago I don't believe I am going to disclose any confidences when I tell him that this committee, working up a report for the next meeting in October, has decided to eliminate three words in their recommendations for evaluation techniques for all types of conductive deafness surgery The first word is success, the second word is permanent, and the third word is total It will be our recommendation that neither of these three words be used in any reporting techniques

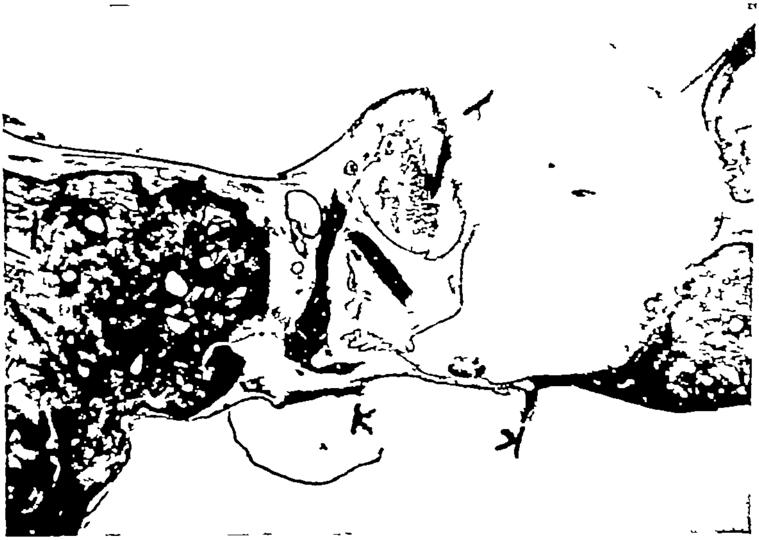
It will be our further recommendation that all evaluations be reported in two separate categories, each category being reported for Class A Class B and Class C cases The first category will be the 30 db level This is important from the psychosocial point of view This is one method The other method will be evaluation in terms of the degree of closure of the air bone gap, and the word which we probably will use will be per cent improvement, or per cent closure, of the air bone gap The word 'success" is out

MODERATOR HOUSE Thank you Dr Goodhill

I should now like to ask Dr Shambaugh for any closing remarks, but before doing so I would like to ask him in view of our techniques what are his thoughts pertaining to mobilization of a patient who has been previously unsuccessfully fenestrated on the same ear

GEO E SHAMBAUGH, JR, M D, (Chicago, Ill) (Closing) We have attempted to do this procedure in a number of cases and all of them were failures Theoretically such a procedure, if you can also perform a myringostapediopexy might be successful but in none of the cases that we have done it has there been any improvement So we feel that this procedure is not of any value

In closing I would like to show a single slide if I might This slide emphasizes some of the fundamental physiology of the ear which Dr Lawrence presented so beautifully In the upper left see the patient s air bone His is the type of case classified as Type C because of poor bone conduction but with a good air bone gap The patient had mobiliza cerned also the stiffness of the healing process Months later it can even be what the stiffness is later which produces the effects that were mentioned by Dr Lawrence and Dr Tonndorf Finally the position and overhang on the round window may also make a difference Until we understand these things we will not understand mobilization

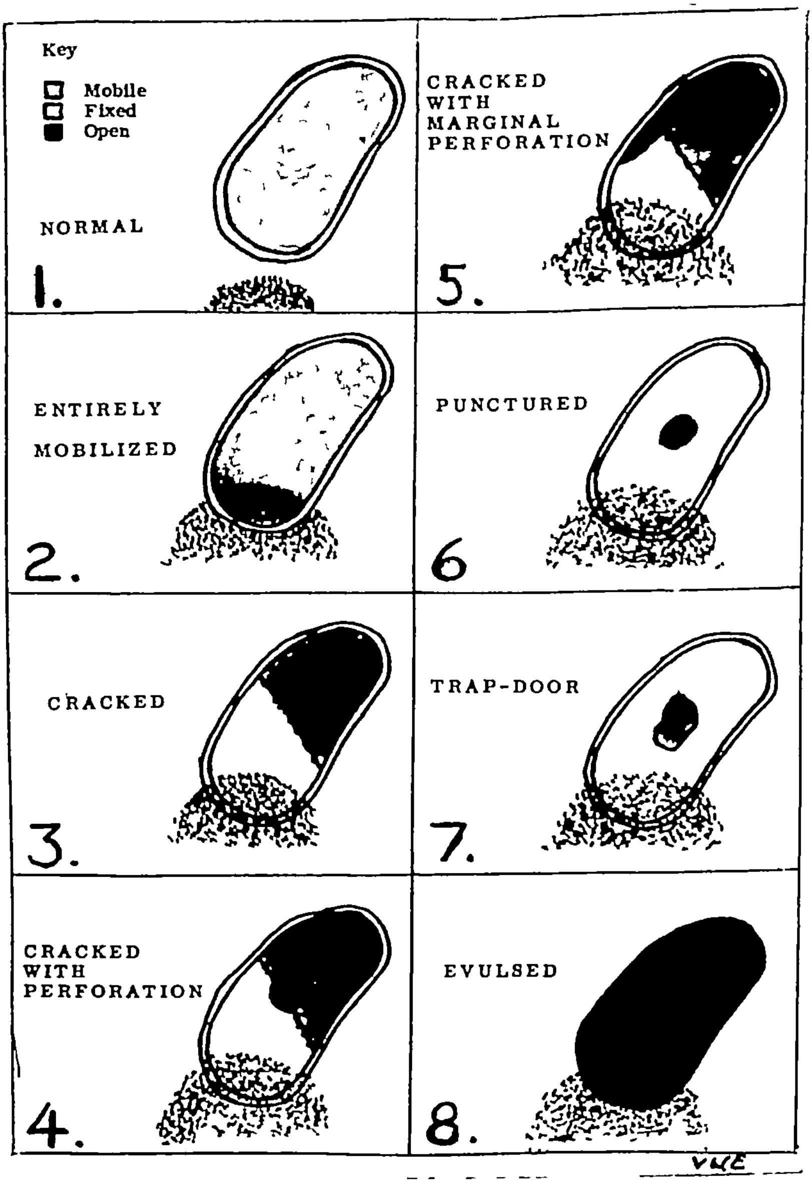


Slide 2 Histological preparation of a patient who had stapes mobilization (anterior crurotomy and footplate puncture) 15 months before his death Fractured anterior crus is shown just behind the classical otosclerosis on the left and the fibrous closure of the hole in the footplate is seen between the arrows Above the arrow on the right is a spicule of bone which has dropped downward into the vestibule and below the arrow on the left is a bit of floating endostium Note that there is no evidence of infection in the labyrinth

Moderator House It is now my pleasure to make a few closing remarks on the subject

First, Dr Lawrence has brought to this group his comments and description as to why these operations work He has also made the prediction that in the eighties we will return possibly to the fenestration operation in otosclerosis I would like to comment that the fenestration operation still offers the very best chance of restoration of hearing in suitable cases of surgical otosclerosis

Dr Lindsay pointed out by means of histopathological examination why footplate techniques are essential in some



Slide 1 Diagram of eight ways in which the perilymph might be mobilized in various types of mobilization procedures

The comments of Dr Meltzer are always highly valued for their conservatism and the prospectives of the future are well taken We grow with otology, with experience

To Dr Rosen we are grateful for his observations that have brought about this fine discussion today We are also grateful to him for having pointed out that this operation is not a simple procedure, but indeed a complex one and not without the possibility of significant and serious complications Dr Rosen stated his experience with fenestration of the footplate has been gratifying in obtaining immediate as well as lasting improvement in hearing This was not the opinion as expressed by Dr Shambaugh Only time will settle this difference of opinion

In conclusion I would say that we must continue with thoughts of conservatism and an open mind Great progress is being made in all phases of otology through laboratory and clinical research The progress being made in stapes mobilization surgery has been presented today

I thank the panel, the official discussers, the other discussers for their contributions today, and the audience for your kind attention

AMERICAN BOARD OF OTOLARYNGOLOGY

The American Board of Otolaryngology will conduct only one examination in 1958, and this will be October 6-9, 1958, in Chicago, Illinois, at the Palmer House

For further information address Dr Dean M Lierle, Secy-Treas , University Hospital, Iowa City, Iowa

extensive cases of otosclerosis I would like to make a plea for all of us to supply these gentlemen doing histological work with more and more specimens

Dr Goodhill confirmed our indications for the initial operation as presented two years ago There has been little change in these indications He stressed the necessity of unilateral masking to prevent the operation of stapes mobilization being done on unilateral perceptive deafness He pointed out the indications for revision He stated we are not in agreement regarding indications for revision The greatest help in this regard is to observe and make accurate detailed notes as to what was done at the initial operation Note at that time as to whether or not you feel a subsequent revision is indicated

Dr Shambaugh told us that the techniques have changed These changes include the use of the microscope, audiometry in the operating room, and more direct approaches to the footplate itself Both Lawrence and Shambaugh have stated that small perforations in the vestibule may improve hearing, but the lasting results of these procedures are questioned at this time He pointed out that the fenestration operation is predictive The frustration operation (stapes mobilization) is not predictive

Dr Kos told us that at Montreal this panel had operated approximately 1,100 cases Today this panel has operated 7,400 cases The results he reported average two months following surgery and he reported that 15 per cent of this group had subsequently regressed He mentioned that 49 per cent of our cases received improved hearing Of these 49 per cent who obtained improvement, 42 per cent reached the 30 db level or better It is the opinion of the panel that the incidence of regression is greater as we work more and more on the footplate

Dr Fowler stated that three per cent of the cases operated by this panel were worse, of which one-half of one per cent were severely worse Included in this series were three dead labyrinths that occurred following stapes mobilization He also mentioned that others have reported two deaths and one extradural abscess following this surgery had married the Democratic or Popular dictator, Marius, died, he said in the funeral oration

“On her mother’s side Julia descended from the ancient Kings, on her father’s from the Immortal Gods Themselves Her mother and my grandmother, Marcia, descended from Marcius the fourth King of Rome, while we of the Julian House trace back our origin to Venus herself In our family, therefore, we combine the Divine Right of Kings, who are the greatest among men, and the worship of the Gods, to Whose Power even Kings must bow”

Though obviously proud of his family and possibly not unmindful of his destiny, he was no idle boaster when it came to his own deeds as set out in his “War Commentaries” It could never be said, however, that he hid his light under a bushel, indeed, it would have been difficult so to do, as his great deeds would have shone out

In view of his noble origin, which included nearly all the Patricians, it might be thought that Julius Caesar would follow the Optimates, or Republican Party, which included nearly all the Patricians Instead he joined their opponents, the Populares, or Democratic party, to which the middle classes gave allegiance In this, no doubt, he was influenced by his uncle, Marius, who had been the leader of the Populares After the eclipse of Marius when Julius Caesar was a youth, Sulla, the champion of the Optimates, came to power and dealt very severely with his political opponents Fortunately for the Roman Empire, the young Julius was left alone, though he had to travel abroad for some time

Despite the great care taken to avoid any individual form of dictatorship in the Roman State it gradually came about that political power was concentrated into the hands of a comparatively small group of Patrician families who saw to it that they dominated the Senate Consequently, many of the laws which were passed favored the Patrician and land-owning classes Successful wars brought more slaves into Roman hands, and these slaves went to swell the estates of the landowners who were able to cultivate their land with cheap slave labor Thus the smaller farmers could not com-

JULIUS CAESAR AND THE FALLING SICKNESS*

TERENCE CAWTHORNE, F R C S ,

London, England

The idea for this paper came when, some years ago, I was re-reading Shakespeare's "Julius Caesar" at a time when I was preparing an article on Mènière's Disease In the very same scene, and separated by but a few lines, the following statements are made

Julius Caesar (who has been talking to Anthony about Cassius ends by saying) "Come on my right hand, for this ear is deaf"

Then shortly after, in a discussion about Caesar between Cassius, Casca and Brutus, the latter says

''Tis very like he hath the falling sickness"

Now it has always been assumed that Julius Caesar suffered from epilepsy, but unilateral deafness and the "falling sickness," I thought, could mean Mènière's Disease, so ever since then I have been inquiring into the life and times of Julius Caesar, with particular reference to his ailment

As the 2,000th anniversary of his death by assassination fell on March 15, of last year, it seems an appropriate time to discuss his disorder and to recall his remarkable career, which was brought to a brutal end by a determined band of his associates, many of whom he regarded as trusted friends Though he was the most powerful and the most popular man in the civilized world, and though it was freely admitted that he had done more for the glory of Rome than any other citizen, he had by his remarkable and versatile talents shown up the lack of ability in many others, earning the envy and malice of those around him whose ambitions were so much greater than their often meager abilities

A Patrician by birth, his was one of the oldest and noblest Roman families, the Julians, and when his aunt Julia, who

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication Feb 27 1958

reach this post, which has been described as a "carnival of illegality and mob law, which made a fitting close to the whole of his demagogic career "

Once his Consulship was over he took over the pro-Consulship of the Gallic Provinces, at the same time forming an uneasy alliance with the financier, Crassus, and the ex-soldier, Pompey This was known as the Triumvirate, and each was of equal Consular rank and power Caesar left for his Gallic Province, and it was 10 years before he returned to Rome, having in the meantime conquered the whole of Gaul, contained the Germanic hordes and invaded Britian twice

Despite his previously slight military experience, Julius Caesar soon proved to be an exceptional leader in war He was not only a great strategist and military tactician, but he was also a leader of men Many was the time that he, personally, led his men into battle, and he was often in the thickest of the fight As an orator and as a politician he was unequalled, and by sheer force of intellect he could persuade men to his way of thinking, equally well in committee, in the political arena and before a group of tired and even rebellious soldiers Even the eloquent though vacillating Cicero, the silver-tongued orator, was compelled to admit that he had met his master in Julius Caesar , but he never forgave Caesar for this, and I believe that it was he, Cicero, who was behind the plot to kill Caesar

At the end of the Gallic campaign Caesar fought his way back to Rome, from which his opponents, the Senate (headed by Pompey) had fled, and four more years of fighting in Spain, Greece, Africa and again Spain were needed before he finally returned triumphantly to Rome

During the year that was left to him he laid the foundation of a new autocracy headed by a Sovereign to rule the Roman Empire in the place of the Senate and the people His names have been immortalized in the month of July, and in the title of Caesar, Czar and Kaiser He forgave his political enemies, and this was his undoing, for they could not forgive him

As a young man he was undersized and delicate, but he grew up to be virile, tough and even licentious Though he pete with this cheap labor and sold their farms to seek their fortune in the Capital, adding to the number of the "hangers on" and unemployed

Successive political leaders vied with each other to gain popularity, and the increasing inefficiency and corruption of both parties were undermining the State, so that the time was ripe for a man with that rare combination of ambition and ability to rescue the Roman Republic from the slough of corruption and selfishness which was threatening to engulf it Though we know that Julius Caesar was the man to do this, it took him 50 years of pushing, bribing, intriguing and fighting to convince his contemporaries Even when he had succeeded, they could not forgive him, and despite all he had done for them and for the State, they murdered him, though they preferred to call it "tyrannicide"

This was a political blunder, for Caesar was the one man who could have built upon the old foundation, a solid and workable government His assassination involved the State in fresh struggles and civil wars, until in the end it fell under the supremacy of Caesar's heir and nephew, Augustus, who established a far more despotic rule than that which the so-called liberators had attempted to avert

Born in the year 102 B C, Caesar was, thanks to his uncle Marius' influence, given, of all things, a senior religious appointment as Flamen Dialis, at the age of 15 This gave him a seat in the Senate, but precluded him taking an active part in war or politics This did not last very long, and at 19 he went abroad, gaining experience in war as an aide-de-camp and as an orator and lawyer, from the leading teachers in the Grecian Islands This included an episode at the Court *of King Nicodemus, which later on was magnified by his* opponents into a homosexual scandal, however, his conduct in more mature years shows that if this incident ever occurred, it was but an adolescent prank, for Sir Charles Oman refers to him later as "the inevitable co-respondent in every fashionable divorce" Returning to public life in Rome at the age of 30, he achieved the coveted Consulship by the age of 42

He was not too particular about the means he employed to *are not perfect which have this disease of the falling evil, when standing on their feet they speak to the common people, but are soon troubled with a trembling of their body and a sudden dimness and giddiness*

It may be noted that in none of these three statements is there any reference to loss of consciousness, to foaming at the mouth, to twitching of the face or limbs, or indeed to any of the other manifestations of epilepsy

Plutarch, the Greek Philosopher and biographer, was born in the reign of Claudius half way through the first century, A D He wrote in Greek and his most famous work, his "Lives," compares and contrasts the Greek and Roman heroes His is the most contemporary and the fullest life of Caesar

There is another by Suetonius, the first in his series of "The Lives of the Caesars" This was written some 70 years after Plutarch Suetonius had the advantage of being Secretary to the Emperor Hadrian and in this position had access to Imperial Archives His "Life of Caesar," written in Latin, makes but one short reference to Julius Caesar's ailment "He was twice attacked by the *falling sickness* during his campaigns"

As might be expected, Caesar himself makes no reference to this sickness in any of his works, nor is it mentioned by Cicero, Lucan or Dio Cassius

Shakespeare's source of information about Julius Caesar came from Sir Thomas North's translation of "Plutarch's Lives", and it is Sir Thomas North who coined the term *"the falling sickness"* He did not translate direct from the Greek, but from the French of James Amyot, Bishop of Auxerre There is no mention in Plutarch, or in any other Greek or Roman author, of Caesar's being deaf, even in one ear

The only reference I can find of Julius Caesar's deafness comes from George Wherry, in "Notes and Queries (1909), Series 10, Vol XL, p 243

Julius Caesar's Deafness Shakespeare makes Julius Caesar deaf in the left ear To Mark Anthony, Caesar says "Come on my right hand for this ear is deaf," and his attacks of loved luxury and power, he never over-indulged in eating or drinking, and between the ages of 40 and 55 lived the hard life of a soldier on campaign Always in the public eye, any disorder, infirmity or even slight accident is sure to have been noted and even magnified We have heard of his baldness and of his amours, and even when he stumbled and fell when disembarking onto African soil during the Civil war this was noted by Plutarch I am sure that if he had been subject to real epileptic fits we would have heard much more about them than has come down to us from the writers of those times

Our main source of information about Caesar's "falling sickness" comes from "Plutarch's Lives," in which it is mentioned three times

The first was part of a general description of Caesar

He was lean, white and soft-skinned, and often subject to headache, and other while to the falling sickness, the which took him the first time, as is reported, in Cordoba

Now Caesar was three times in Spain The first time was before he was Consul, the second in the early stages of the Civil War before he defeated Pompey at Pharsalus, and finally after the African campaign, when he was dealing with Pompey's son and his followers This must refer to the second campaign in Spain, as Plutarch's next reference to the sickness is in the African campaign at the battle of Thapsacus against King Juba and Scipio When he did not take his usual place in the forefront of the battle Plutarch says

For as he did set his men in battle the falling sickness took him, whereunto he was given, and therefore feeling it coming, before he was overcome withal, he was carried into a castle not far from thence, where the battle was fought, and there took his rest till the extremity of his disease had left him

Plutarch's third reference is to the time when the populace offered Caesar the Emperor's crown and he refused it three times

Notwithstanding it is reported that afterwards, to excuse this folly, he imputed it to his disease, saying that their wits committee, ended the meeting Clearly such a description could include epilepsy, a stroke, a heart attack, and also an attack of Meniere's Disease

Now, as Caesar's mental and physical powers remained unimpaired between attacks, it seems unlikely that they were caused by heart disease or a cerebral catastrophe This leaves epilepsy and Meniere's Disease

When the "falling sickness" first overcame him, Caesar was in the early 50's, a common time for Meniere's Disease to start As the most famous man of the Ancient World, there was no shortage of writers and poets to publicize his failings as well as his strength Had he really suffered from epilepsy it is difficult to believe that it would have been passed over in the few words that have come down to us, nor can it be said that the Romans were unacquainted with epilepsy, for here is a description given by Lucretius of an epileptic fit

Oft times with violent fits a patient falls,
As if with thunder struck, and foams and bawls,
Talks madly, shakes, moves here and there, breathes short,
Extends and tires his limbs with antic sport,

* * * * * *

His weakness wears and he forgets his pain,
His strength, his life, his sense return again

Had Caesar suffered from major epileptic seizures, surely these sensational attacks would not have been passed over so slightly by the careful biographer Plutarch, or by the gossip Suetonius

Had these attacks been something more serious than a labyrinthine disturbance, they must have left a greater mark on the man who, for the last 15 years of his life extended and dominated the Roman State A man, moreover, who, at the end of 12 years' continuous fighting and political intrigue could take time off to share with Cleopatra one of the great love affairs of the world

That it could have been a minor form of epilepsy cannot be denied, though sufferers from "petit mal" so often are *epilepsy are also noted in the play "He hath the falling sickness" It is quite possible that attacks of giddiness, associated with Meniere's Disease of the ear, may have been mistaken for epilepsy The Romans were familiar enough with epilepsy, which they called "morbus comitialis," from the attacks witnessed in the Forum or Senate House, which broke up the Assembly, and it is unlikely that aural vertigo was understood at that time*

Where, then, did Shakespeare get his reference to Julius Caesar's being deaf in the left ear? It has been suggested that there might be some political significance in this, but it cannot be in the modern sense, for the term "Left Wing" and "Right Wing" became significant only in the Assembly of the French Revolution Again, could it be that Caesar was suggesting that he was going to forget what had just been said? But as he had just been doing all the talking and very little listening, there is little point in this suggestion As there does not appear to be any mention of Caesar's being deaf in any of the references available to Shakespeare, he may have put this in so as to add a touch of realism to the part We know that Shakespeare always made his great historical figures behave like ordinary human beings, and indeed, it is just that homely touch that makes his characters live It could well be that Shakespeare knew someone, or possibly more than one person, who was troubled with the "falling sickness" and deafness, and that he introduced the deafness in one ear in order to make Caesar like other men There is no reason to suppose that the deafness was brought in to help the stage business

Even if we deny Caesar's deafness on the grounds that we have only Shakespeare's word for it, we are still left with his "falling sickness" Plutarch, writing in Greek, refers to this as "Epileptikois," a term used in those days for any seizure that caused the sufferer to fall down and be helpless It is not surprising that many writers translated this as epilepsy, and so the term "falling sickness" and epilepsy have been loosely regarded as the same thing

Suetonius, writing in Latin, uses the term "morbus comitialis," the disease which, when it attacked a member of a

CASE OF TRACHEO-MALACIA FOLLOWING REMOVAL OF ADENOMA OF THYROID GLAND*

DEZSO KASSAY, M.D., (By Invitation),

Philadelphia, Pa.

A 50-year-old male, a dentist, had been complaining, for about six months, of a gradually increasing dyspnea and stridor. Bronchial asthma had been diagnosed in a hospital in Hungary.

On admission we found a well nourished man, 5'4" tall, and muscular; the patient's neck was extremely thick and short. On the left side of the neck a spherical resistance with a diameter of about 5 cm. could be palpated. This tumor moved up and down simultaneously with the swallowing action. The dyspnea appeared to be mild and the stridor audible only before the open mouth.

Planigraphy (see Fig. 2-A) showed the trachea displaced slightly to the right, and its lumen narrowed markedly from the left side by a protrusion 45 mm. in length. Tracheoscopy showed the tracheal lumen enormously stenosed by lateral compression. The mucosa appeared red and swollen, but no tumor tissue was noted. The biopsy and histologic study revealed only inflamed mucosal structure.

TRACHEAL STENOSIS DUE TO COMPRESSION BY ENLARGED THYROID GLAND WAS DIAGNOSED

At external operation (Rubanyi and Kassay) we found a soft, vascular, encapsulated tumor which was about 5 cm. in each dimension; resection of the tumor and trachectomy were performed. The tracheal cartilages on the left side for a length of about 45 mm. were destroyed, and the soft tracheal wall collapsed into the lumen. Adenoma of the thyroid gland was diagnosed histologically. Removal of the tumor did not

troubled also with bad tempers, fits of depression, or some form of neurosis; and there is nothing to suggest that Caesar was ever troubled in any of these ways. Coming on at that time of life and not leading to any deterioration of mental or physical powers it is, in the light of our present knowledge, much more likely to have been a benign disorder such as Menière's Disease.

We are still left with the problem of deafness, and though I have been unable to trace any contemporary account of Caesar's being deaf, I shall always be grateful to the memory of Shakespeare, not only for the plays which we enjoy, but for suggesting an alternative and to me, plausible cause for Caesar's "falling sickness."

ALUMNI ASSOCIATION OF THE NEW YORK EYE AND EAR INFIRMARY

The Annual Spring Meeting of the Alumni Association of the New York Eye and Ear Infirmary last April was so well received that it has been decided to expand next year's meeting, which will take place from April 20-23, 1959.

Symposia and lectures on Hearing Rehabilitation, Endoscopy, and Ear Surgery will be conducted. It is also planned to offer refresher courses in Mastoid and Fenestration Surgery and Stapes Mobilization Techniques.

More complete information regarding the meeting will appear in a later issue of THE LARYNGOSCOPE.

by us, which would keep the tracheal lumen open and would not disturb him in his work.

Thus we designed a special tube for him which would hold itself in position, could be easily changed, occlude the stoma well and prevent the outflow or coughing out of tracheobronchial secretions Naturally we created first a longer stoma sewing the tracheal wall to the skin of the neck.

A metal tube (see Fig 1), with a 12 mm outside diameter was used Both ends were cut off obliquely, the anterior wall being longer than the posterior, which facilitated the introduction of the cannula The total length of the tube was 45 mm A screw was attached to the anterior wall, 12 mm from the upper edge of the tube A metal block, fitted precisely to the stoma and a wing-nut completed the instrument The block was 20 mm long and 11 mm wide, slightly less than the outside diameter of the tube, the depth of the block measured 14 mm on the top and 16 mm on the bottom At the proper point in the block, a hole was drilled for the screw The distance between the screw and the upper edge of the tube was shorter than the vertical diameter of the tracheal stoma

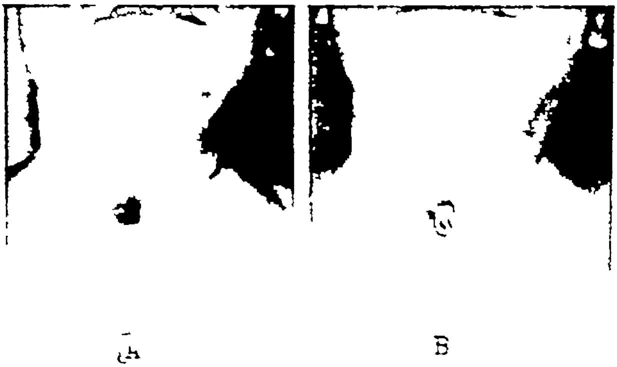

Fig 3 The open stoma (A) and the cannula in place (B)

At introduction the longer part of the cannula (below the screw) entered the trachea first until the screw touched the lower edge of the stoma, then the whole cannula was slid into

VICTOR GOODHILL, M.D., Los Angeles, Calif.
LELAND R. HOUSE, M.D., Los Angeles, Calif.
TERENCE CAWTHORNE, M.D., London, England

MODERATOR SOOY: First, I will introduce Dr. Victor Goodhill, who will talk to us on the principles of tympanoplasty.

THE SURGICAL PHYSIOLOGY OF TYMPANOPLASTY.*

VICTOR GOODHILL, M.D.,
Los Angeles, Calif.

INTRODUCTION

The term "tympanoplasty" has been applied to that group of surgical procedures in which the principles of reconstructive surgery are applied to the restoration of middle ear function.

For many decades, otologists have been aware of the necessity of such surgical reconstructions, and a number of attempts in this direction have been recorded. There are numerous instances of improvement in hearing following various forms of modified radical mastoid operations, but these occurrences were haphazard and usually not planned physiologically. No definitive methods and no techniques with predictability were available until the recent contributions of Wullstein,[1] Zollner,[2] Pietrantoni[3] and others.

---

*Presented as part of a Symposium on Tympanoplasty at the meeting of the Western Section American Laryngological, Rhinological and Otological Society, Beverly Hills, Calif., March 4, 1958.

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication March 4, 1958.

the trachea and lifted, so that the upper portion of the tube entered the lowest part of the larynx The block was slid over the screw into the stoma and fixed in position by the nut (see Fig 2-B)

This procedure (the change of the cannula) was performed by the patient himself once or, when necessary, twice a day The cannula did not injure the tracheal and laryngeal tissues because it followed the movements of the trachea and larynx precisely and kept itself in position without being anchored by any mechanical means except that described above (see Fig 3) When I left Hungary, more than a year ago, the patient had worn his cannula for six months without any complaint

After this successful attempt I looked for similar solutions in medical publications, and found only one Jackson's bronchoscopy, esophagoscopy and gastroscopy, published in 1934 Their retaining intubation tube was used for treatment of chronic laryngeal stenosis The tube was introduced through the mouth, and then a post was screwed in through the tracheal stoma and a block was slid into the stoma Similarity of the two methods is the use of screw and block for keeping the cannula in place, in the larynx or trachea The difference is that the Jackson's introduced the tube by laryngoscopy, which could not be performed by the patient, himself, and thus it would not serve our purpose, however, essentially, we adapted an older method to a newer purpose, which may be expressed by the old Hungarian proverb "Read wise old books and create new things"

Lankenau Hospital

shielded from air-borne sound. An intact ossicular chain is necessary so that a significant sound pressure difference will exist between the two windows and thus between the two scalae allowing basilar membrane motion.

The Eustachian tube has an important function in maintaining essentially equal pressures on both sides of the tympanic membrane, thus avoiding painful stretching of the drum following ambient pressure changes in the external canal. This equalization allows maximum response under wide pressure changes.

It is of course possible for conductive lesions to reach db loss values far in excess of the 26 db described above as the contribution of the drum membrane and ossicular chain to sound pressure transformer action. In cases with intact drum but ossicular discontinuity, the drum may become worse than useless, since it may both reflect and absorb sound energy. Ankylosis of one of the windows may add another 25 to 30 db of loss to the function of the middle ear, thus conductive lesions may reach losses of 60 db and more. In extreme conditions, where scar tissue may simultaneously immobilize both the round window membrane and the stapedial footplate, it is conceivable that such an "acoustic short circuit" may even further increase the transmissive loss, although such a loss actually involves some perilymph immobilization, and may not truly be described as a middle ear lesion *per se*.

In addition to the above, there are problems of tympanic physiology which may involve the tympanic muscles as well as the suspensory ligaments of the ossicles. Such physiological problems will be reflected in the functional efficacy of the ossicular chain lever action, but in addition may produce increased stiffnesses and frictional problems resulting in varying deficits to acoustic transmission.

There are rather marked differences between the numerical values obtained in the human and in various experimental animals. Thus, much of the recent research data from cat and guinea pig studies are not so readily transferred to the human as had previously been considered possible. We must be alert to these major species differences in our interpreta-

At present, we are beginning to see the emergence of a positive plan of surgical attack with increasing predictability for restoration of tympanic function, however, we are still far from the time when results can approach the predictability of fenestration and even of stapes mobilization surgery

It is not surprising that the emergence of this branch of otologic surgery had to wait until the maturation of the principles of plastic and reconstructive surgery and the acquisition of fairly substantial knowledge of tympanic physiology The latter is still far from complete, but is adequate for practical application in many instances

It is the purpose of this presentation to correlate some of the known details of middle ear physiology and possible surgical approaches to the solution of tympanic problems Basic principles only will be presented Neither technical details nor results will be reported in this paper

BASIC TYMPANIC PHYSIOLOGY

The middle ear mechanism is essentially an impedance matching mechanism, or a "transformer" to help air-borne sound travel with increased force into the liquid perilymph with no significant alterations in frequency characteristics This is accomplished primarily by a combination of two physical mechanisms *1* the difference in area between the effective vibratory portion of the tympanic membrane and that of the stapedial footplate, *2* the lever action of the ossicular chain Contrary to some conceptions, it is primarily the area difference which is responsible for the sound pressure transformer action In man this is approximately 22 1 The lever action of the ossicular chain is approximately 1 1 1, and the product yields a result of approximately 26 db, which is the essential contribution of the entire middle ear mechanism to the transmission of air-borne sound to the cochlear perilymph, however, there are other factors in middle ear physiology which must be considered before one can understand the application of tympanoplastic procedures

The normal tympanic membrane is essentially transparent to sound waves, and thus the round window is not primarily solution, and many of them may be solved by tympanoplastic procedures The well recognized congenital defect of the external auditory canal, tympanic membrane and ossicular chain is best treated by a properly selected tympanoplastic procedure It is generally not recognized, however, that there are a number of congenital defects of the middle ear which may present themselves with normal tympanic membranes These lesions may include not only anomalies of the malleus, incus and stapes, but also congenital fixation of the footplate They are frequently accompanied by absent stapedius and tensor tympani muscles, as well as by deformities of the round window niche and even the promontory

TYMPANIC PHYSIOLOGIC PROBLEMS

1 Acoustic reception lesions
2 Acoustic transmission lesions
3 Window fixations
4 Loss of sound pressure difference
5 *Acoustic* short circuits
6 Multiple combinations of above

Fig 2

b Infections and Trauma

The most common group of lesions requiring tympanoplastic surgery are those produced by the sequelae of otitis media in which there may occur various combinations and degrees of disruption of the tympanic membrane-ossicular chain mechanism Similar lesions may follow both direct and indirect trauma to the ear

c Cholesteatoma and Other Ear Tumors

The most common space occupying lesion of the middle ear is cholesteatoma, of which there are a number of varieties Here again the dissolution of continuity of the middle ear mechanism is best treated by tympanoplastic surgical principles

LESIONS REQUIRING TYMPANOPLASTY—THE FUNCTIONAL STATES

The functional lesions that may disturb middle ear physiol-tions of experimental data obtained in lower animal forms, and extrapolated for human application

In summary, normal tympanic or middle ear physiology demands the existence of a patent external auditory canal (see Fig 1), a normal receptor mechanism via a normally functioning tympanic membrane, continuity of the tympanic membrane and a normally functioning ossicular chain, with a mobile stapedial footplate, a normally yielding round window membrane, and finally a well regulated tympanic air space provided by normal Eustachian tube function In the absence of a functioning ossicular chain it is necessary for the round window also to be shielded)

TYMPANIC FUNCTION REQUISITES

1 Patent external canal
2 Normal drum (pick up)
3 Intact continuity of drum, ossicular chain and mobile footplate (transmission piston)
4 Yielding but shielded round window membrane (sound pressure difference in absence of ossicular chain)
5 Tympanic air space equalization by normal tubal function

Fig 1

Obviously, not all of these requirements can be satisfied in every tympanoplastic procedure, and many compromises are necessary in the application of tympanoplastic surgical principles to the solution of middle ear infections, congenital defects, and other lesions, furthermore, the evaluation of a given conductive loss requires a very careful analysis of all possible contributing factors from all regions of the tympanic mechanism

LESIONS REQUIRING TYMPANOPLASTY—THE PATHOLOGIC STATES

A number of conditions involving the middle ear may respond to tympanoplastic maneuvers They may be simply divided into the three groups, *a* congenital lesions, *b* infections and trauma, and *c* cholesteatoma and other ear tumors

a *Congenital Lesions*

A number of congenital anomalies present themselves for lear reserve It is of little value to subject a patient to a major reconstructive procedure or procedures, to attempt restoration of tympanic function in the presence of a lesion of the cochlea sufficiently great to thwart a possible significant restoration of hearing, therefore, a careful assessment of the integrity of cochlear reserve is the first necessary preoperative physiological study This can usually be done adequately by pure tone audiometry with quantitative masking for bone conduction thresholds, speech reception thresholds and speech discrimination scores In some instances, recruitment studies may be indicated, but usually these are not necessary The demonstration of an adequate air bone gap (at least 15 to 20 db), a bone conduction threshold not lower than 45 db and a speech discrimination score not lower than 50 per cent are necessary pre-requisites

PRE-OPERATIVE TYMPANIC FUNCTION TESTS

1 *Cochlear Reserve and Bone Air Gap Tests*
  A Pure tone audiometry (A C and B C)
  B Quantitative masking for bone conduction
  C Speech reception threshold
  D Speech discrimination scores
  E (Recruitment tests)
2 *Prostheses Tests*
  A. Drum covering
  B Columellization
  C Blocking
3 *Acoustic Probe Tests*
  A Mechanical (Pohlman) probe
  B Audiometric B C vibrator probe

Fig 3

With demonstration of good cochlear reserve, the next function of preoperative testing is an attempt to gather qualitative, as well as quantitative, differential audiologic data regarding the status of the various middle ear components This requires a number of techniques (see Fig 3), which may be tailored to suit the individual case The following are the basic procedures usually necessary in most cases *a The drum covering prosthesis* This is simply a patch applied over ogy (see Fig 2), may be divided into the following groups *a Acoustic reception lesions* involving the sound pick-up action of the drum membrane, and most commonly produced by perforations of varying sizes and locations In accordance with the well-known studies of Békésy[4] and others, there are major differences in the sequelae of perforations, depending upon their size and location in relation to the manubrium and to the annulus, *b Acoustic transmission lesions,* involving the ossicular chain These lesions may involve any of the three ossicles in whole or in part They may be manifested not only by loss of continuity, the most common example of which is the aseptic necrosis of the lenticular process of the incus, but also by increased stiffness states involving the ossicular joints through arthritic fixations Occasional atrophic elasticity of incus or stapes crura may decrease transmission,

c Fixation of windows, especially the oval window, by ankylosis of the footplate and occasionally osteogenic closure of the round window niche and effective blocking of the round window membrane *d Loss of the normal difference in sound pressures delivered to the two windows* There is normally an effective difference in force of the sound pressures reaching the two windows Usually, of course, this occurs through the trans-ossicular excitation of the footplate in the oval window and through some minor blocking of air-borne sound to the round window by the curtain action of the tympanic membrane In situations where there is a loss of ossicular continuity, there may be an equal sound pressure level reaching both windows, which will decrease the possibility of basilar membrane motion, *e Acoustic short circuit* between the two windows by the effect of a scar tissue band running between the footplate and in contact with the round window membrane, *f Multiple combinations* of any of the above lesions, and also combined with some degree of perilymph immobilization by chronic labyrinthitis

PRE-OPERATIVE ASSESSMENT TECHNIQUES

In one crucial respect, tympanoplastic surgery requires the same pre-requisite as fenestration and stapes mobilization surgery, namely, in the measurement and evaluation of coch-

The electro-acoustic or audiometric B C probe type of test yields similar qualitative data, but also yields quantitative information for more precise comparison of tympanic responses, as illustrated in Figs 4 to 9 At present, it is not possible to establish an accurate base line for "normal" responses, since there are major variables in the pressure of application, size of applicator, etc , however, the comparative data obtained are most informative, and such careful tympanic exploration will frequently be of decisive character in planning tympanoplastic approaches

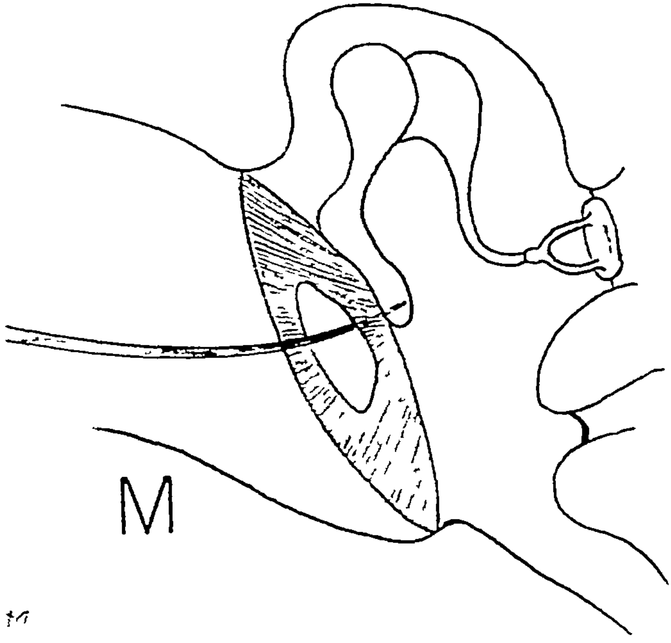

Fig 5 Probe in Contact with Malleus

The combined evaluation of data obtained by all of the above methods is invaluable in localizing the location and extent of middle ear lesions and in planning appropriate tympanoplastic solutions for these problems a perforation to increase the area of sound reception In the presence of an intact ossicular chain with no other obstructive lesions, such a test will usually reveal a significant improvement in hearing, *b A columellization prosthesis,* a capsule or Korojel (Pohlman) type of prosthesis applied to the incudostapedial joint, or to the capitulum of the stapes, will usually yield information regarding the status of the oval window in cases of suspected ossicular discontinuity or footplate fixation, *c Blocking prosthesis,* a similar capsule or Korojel (Pohlman) type prosthesis, or cotton oil plug applied to the

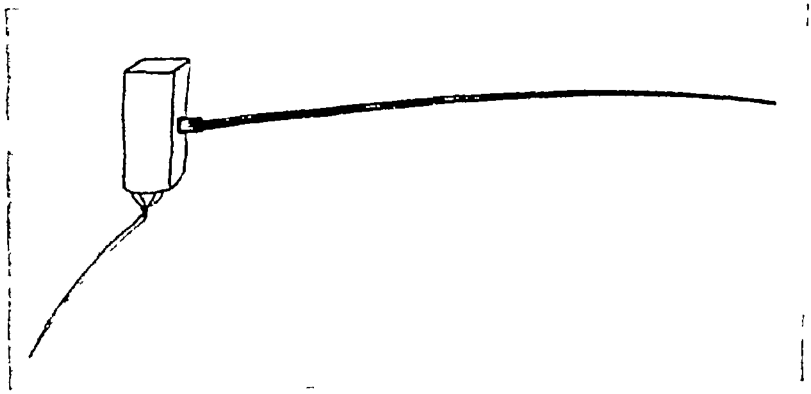

Fig 4 Electro-Acoustic Probe

region of the round window niche as a blocking prosthesis will give information regarding the sound pressure differences of the two windows, *d Probe audiometry* is of tremendous value in quantitative as well as qualitative estimation of integrity of the ossicular chain and the windows There is divided opinion as to the necessity of using probe audiometry in surgery, but its utilization diagnostically is conceded to be important by most workers in the field

Probe audiometry has been in use for a number of years after its introduction and popularization by the late A G Pohlman[5] His probe was a simple mechanical rod attached to a vibrating plastic membrane This mechanical probe test yields valuable differential tympanic information of qualitative nature middle ear scarring with not only obliteration of the air space, but partial immobilization of the stapes by a "blanket" of thickened mucoperiosteum In these cases there is justification for tympanolysis alone without any of the tympanoplastic procedures listed below

Tympanolysis can be divided into an anterior and posterior type In some instances it is necessary to use only the one approach, and in others both approaches are indicated

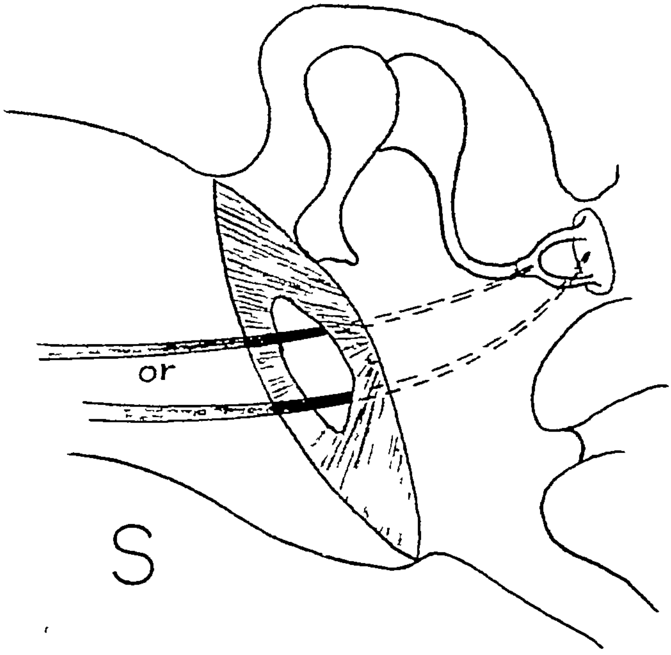

Fig 7 Probe in Contact with Either Stapes Capitulum or Footplate

Posterior tympanolysis is the most common type required, and can be accomplished by an exploratory tympanotomy, utilizing the typical stapes mobilization middle ear incisions in which the posterior one-third to one-half of the middle ear is adequately exposed (see Fig 10), and scar tissue lesions can be removed (see Figs 11, 12) In instances where clin-

BASIC TYMPANOPLASTIC OPERATIONS

The basic surgical approaches for restitution of middle ear function may be described under the two heads of, *a* Tympanolysis, and *b* Tympanoplasty

a *Tympanolysis*

This term applies to the surgical treatment of scars and fibrous tissue masses partially or completely immobilizing an otherwise normal drum membrane and ossicular chain (In addition, there is the necessity for removal of such scar tissue bands in many of the tympanoplastic procedures listed below) There are many cases of conductive deafness with intact drum membranes and anatomically and physiologically intact ossicular chains Here the entire problem is that of

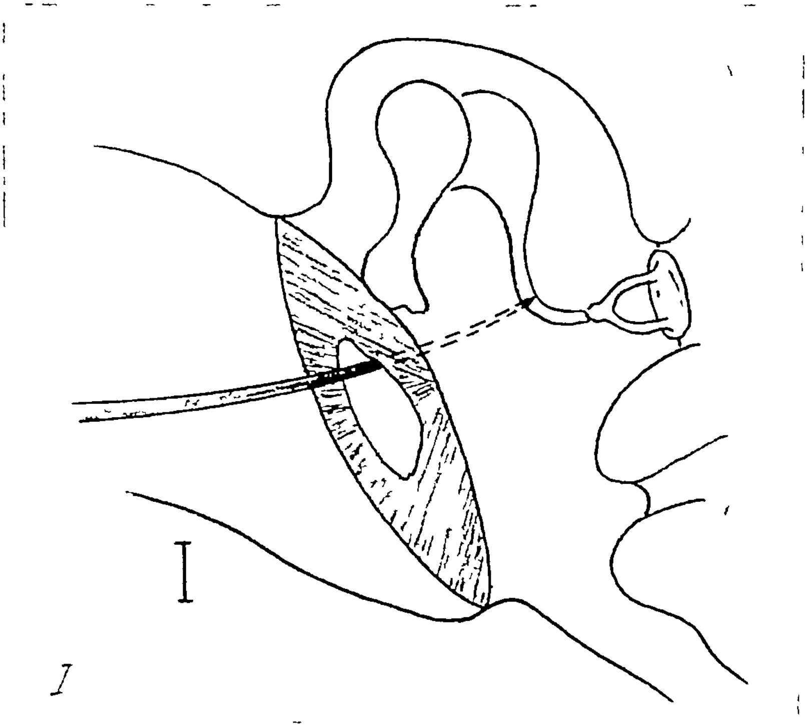

Fig 6 Probe in Contact with Incus

b Tympanoplasty

Wullstein made an excellent contribution to progress in this branch of surgery by giving us his schema, in which he presents five types of tympanoplasty based upon anatomical and pathological findings Since these five types have been widely adopted and have simplified discussions, it appears logical to utilize them in this presentation In the following tables and charts, the designations "Tympanoplasty Types I, II, III, IV, and V" will apply to the Wullstein classification to be given below

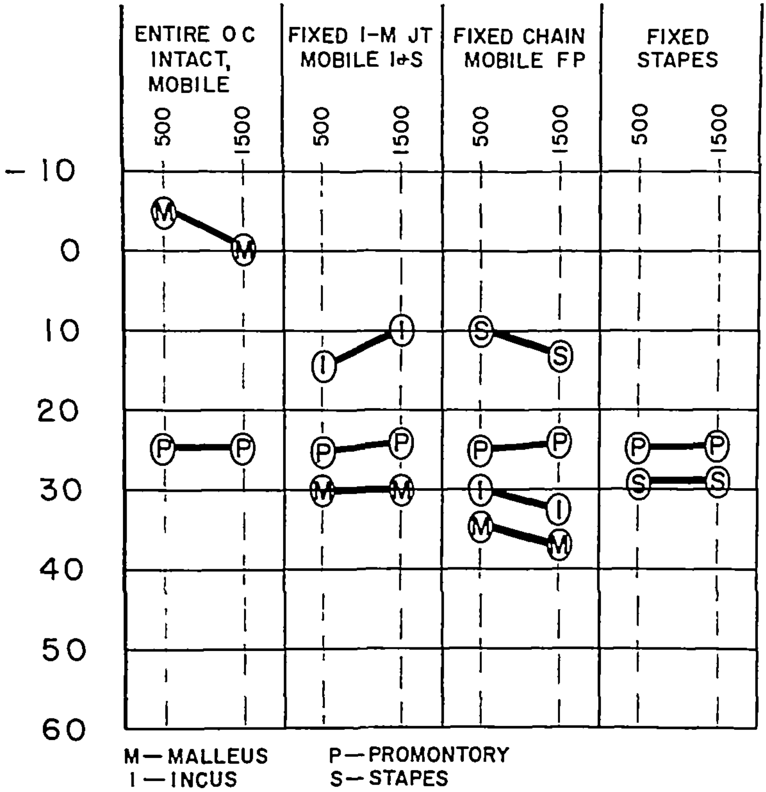

Fig 9 Representative Probe Audiograms

ical as well as operative findings in a posterior tympanolysis indicate a lesion anteriorly, an anterior tympanolysis is then performed This involves a triangular incision of the tympanic membrane as illustrated in Fig 13, in which the anterior portion of the tympanic cavity is exposed, particularly in relation to the Eustachian tube orifice After the exposure has been made (see Fig 14), appropriate instrumentation is performed for scar removal and the incision closed In the closure, occasional middle ear support for the flap is necessary with one or two pieces of gelfoam Occasionally a small skin graft is indicated to cover any anterior defect produced by retraction of fibers of the fibrous layer of the tympanic membrane

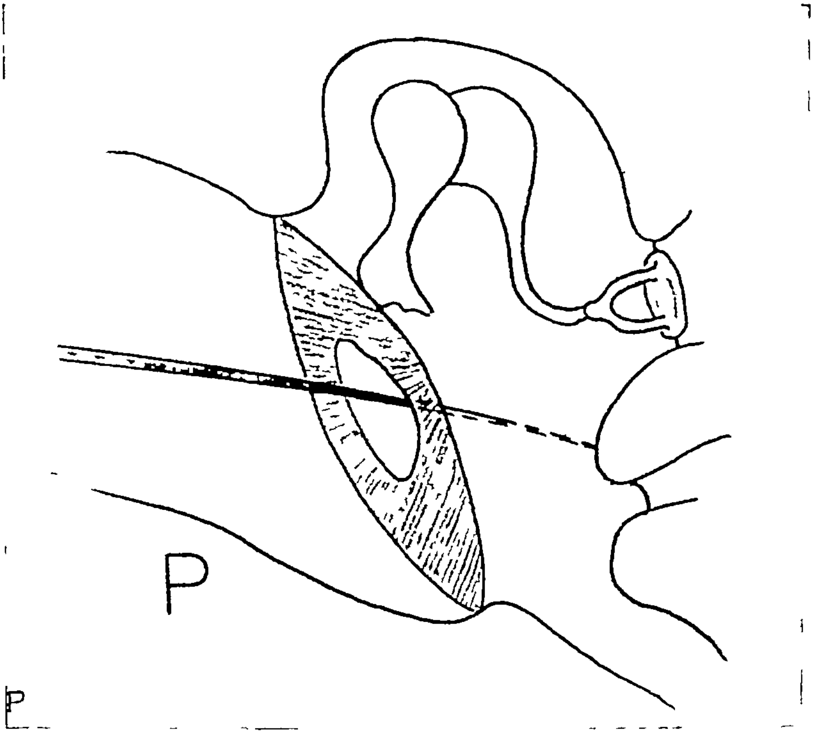

Fig 8 Probe in Contact with Promontory

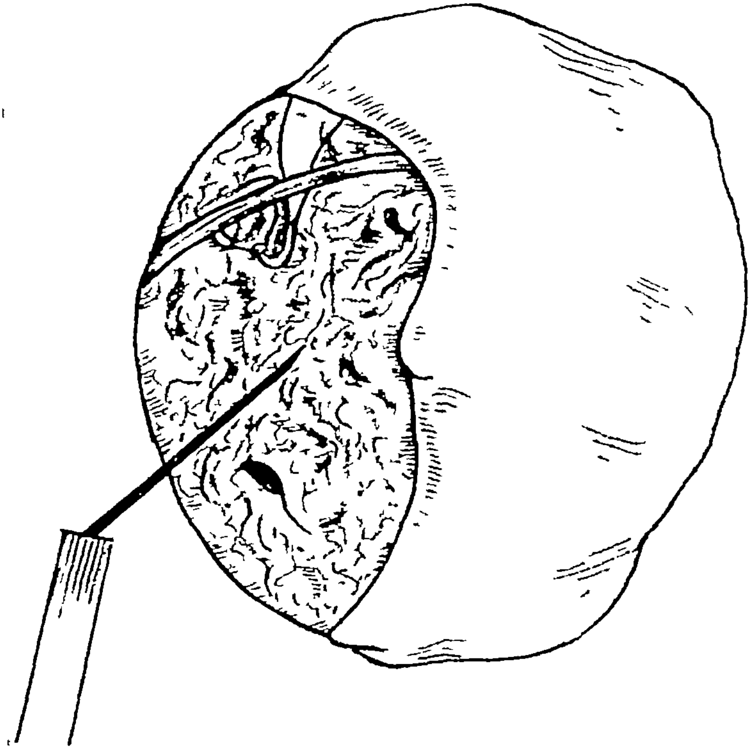

Fig 11 Posterior Tympanolysis with Removal of Diffuse Posterior Scars

procedure involving only the repair of the acoustic receptor, so that the area difference between the drum and the stapedial footplate may be restored, thus restoring the sound pressure transformer action

Type III (Columellization Operation or Myringostapediopexy)

In this very important type of procedure applied to cases where there is dissolution of continuity of function of malleus and incus, but normal anatomical and physiological integrity

Type I (Myringoplasty)

This is the simplest problem to solve surgically in tympanoplasty It refers to the closure of a perforation in the drum where there is an intact normally mobile ossicular chain and there are no other significant pathologic findings (see Fig 15)

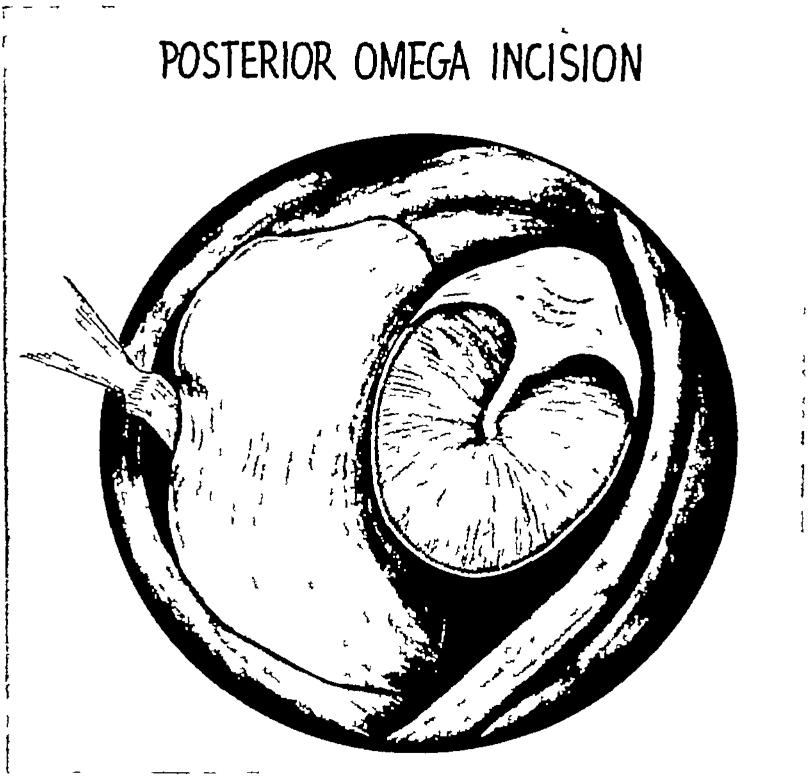

Fig 10 Posterior Omega Incision

Type II (Myringoplasty)

In this more advanced version of myringoplasty, there may be absence of a portion of the malleus or incus (see Fig 16), but there is still physiological continuity of the entire ossicular chain in spite of these defects This may be termed an expanded myringoplasty, but basically it is the same sort of

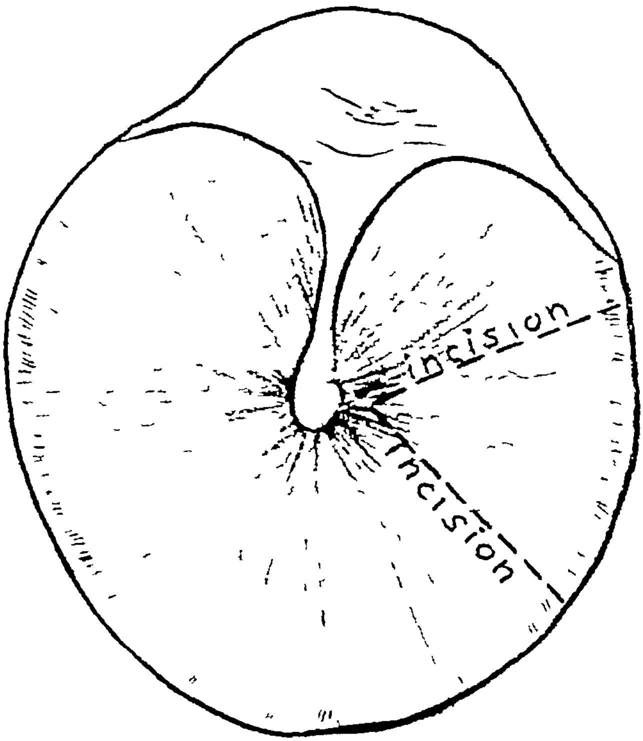

Fig 13 Anterior Tympanolysis Incisions

is still maintained, and the sound pressure transformation can be restored to a very efficacious degree, notwithstanding the loss of the lever action of the malleus and incus

Type IV (The Cavum Minor Operation or Sound Baffle Operation or Round Window Operation)

In instances where there has been a loss of stapedial capitulum and crura, but where the footplate is still mobile, the creation of the Cavum minor, or closed hypotympanum, may yield sufficient sound protection to the round window mem-

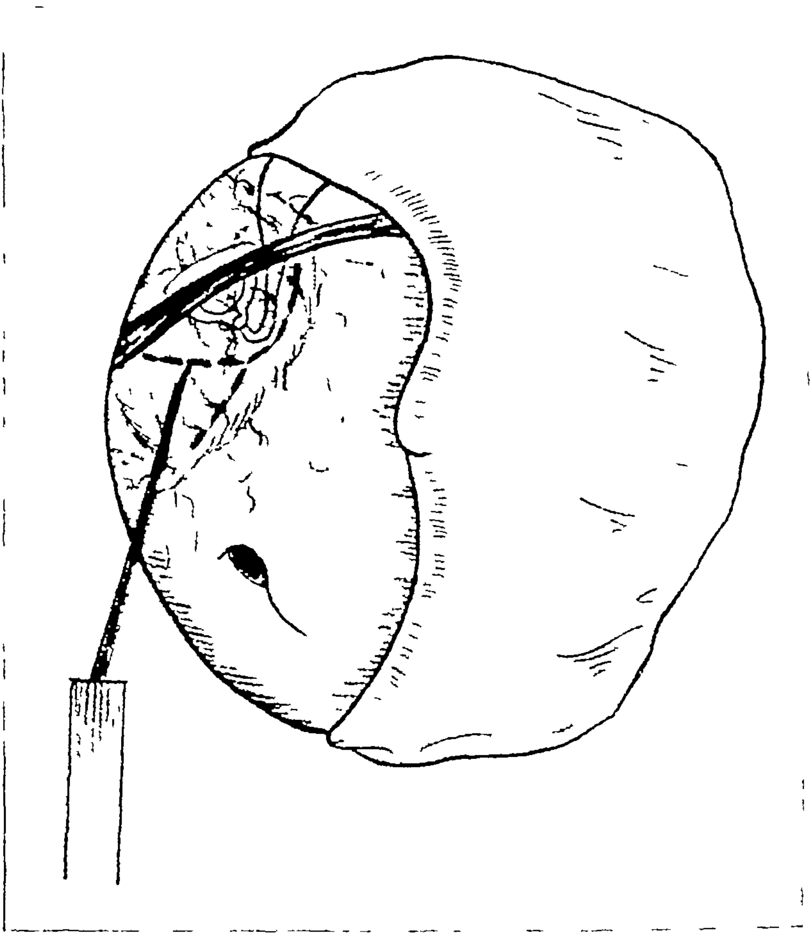

Fig 12 Posterior Tympanolysis with Dissection of Peri-stapedial Fibrous Tent.

of the stapes and the stapes footplate, a graft is applied directly to the head of the stapes (see Fig 17) This may either be done in cases where there is still a serviceable peripheral tympanic membrane remnant, or in instances where there is no tympanic membrane at all, as in post radical mastoidectomy cases In the latter instance a larger and thicker graft may be necessary, but the basic principle remains the same, namely, that the tympanic membrane (either restored or recreated) is anchored directly to the head of the stapes In this approach, the piston action of the drum to the stapes footplate the sound pressure difference may be adequate for sign gains in hearing

Type V The Fenestration Operation Combined with the Cavum Minor Operation

In instances where there is a fixed stapedial footplate there may still be hope for restoration of hearing by an adequate

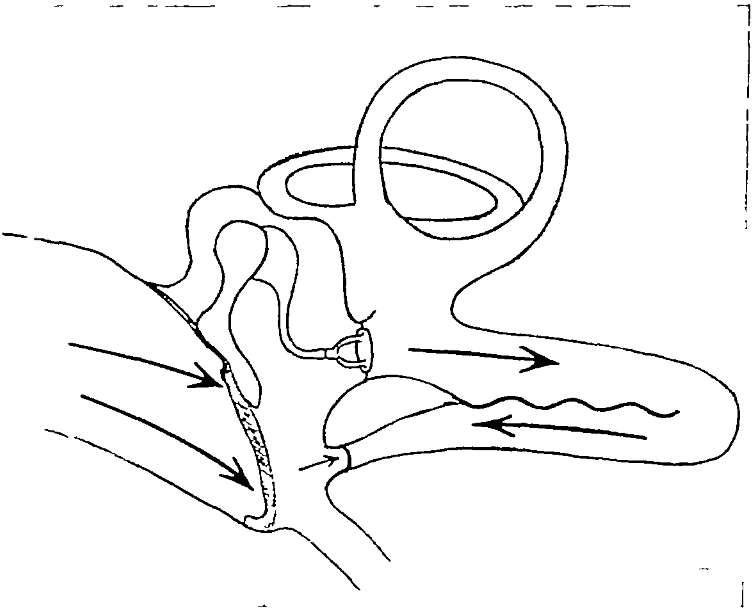

Fig 15 Type I—Tympanoplasty (Myringoplasty) Note normal ossicular chain with graft covering drum perforation

round window baffle procedure as described above, combined with fenestration of the horizontal semicircular canal, again yielding a level of possibly 30 db or better in some instances (see Fig 19)

(In certain instances where it is possible to mobilize the footplate with ease, one may combine a stapes mobilization with a Type IV, instead of resorting to a fenestration)

The approach to Types I, II, III, and IV tympanoplasty may

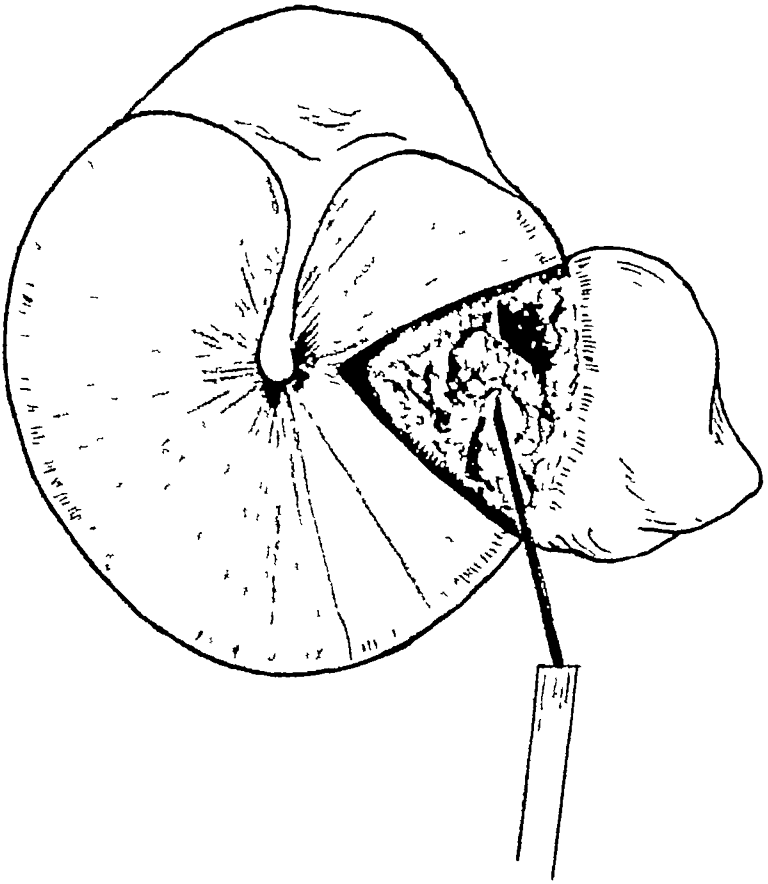

Fig 14 Anterior Tympanolysis with Dissection of Peri-tubal Fibrous Tissue

brane so as to restore the sound pressure difference between the two windows (see Fig 18-A) In this procedure, a mucosal graft is rotated inferiorly from the promontory over the round window niche and covered with a skin graft in continuity with the Eustachian orifice, thus creating a small middle ear which has tubal continuity and in which the oval window region is exteriorized to air-bone sound (see Fig 18-B) The round window acoustic baffle effect will frequently allow restoration of thresholds to the 30 db level The obvious loss of the transformer action of the middle ear still exists, but

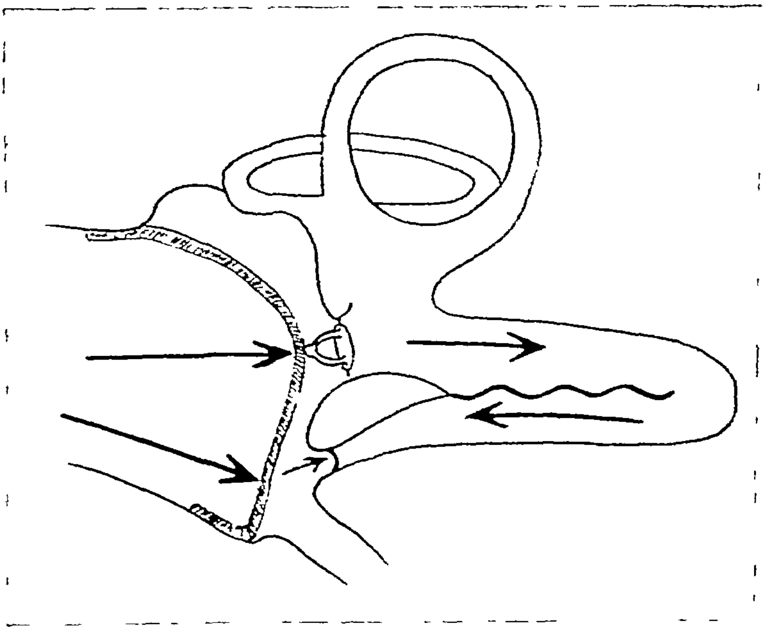

Fig 17 Type III—Tympanoplasty (Columellization or Myringostapediopexy) Note absence of malleus and incus Graft covers perforation and is in contact with stapedial capitulum

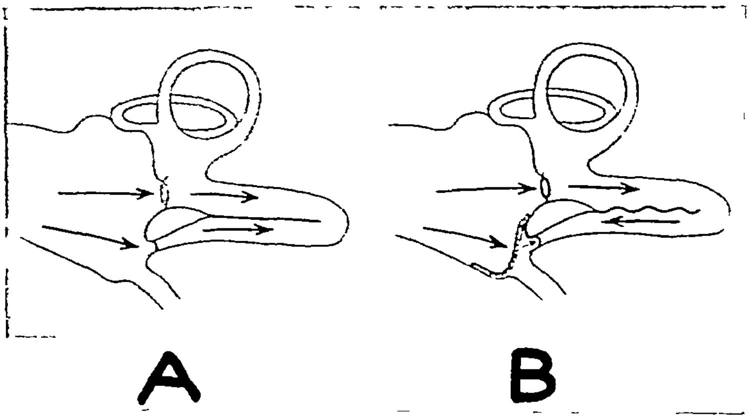

Fig 18 Type IV—Tympanoplasty (Cavum Minor or Sound Baffle or Round Window Operation) A Note loss of stapedial crura but mobile footplate Nevertheless because of lack of sound pressure difference the basilar membrane does not move B Creation of cavum minor blocks the round window membrane and re establishes a sound pressure difference. Note basilar membrane in motion

be either transmeatal or transmastoid The transmastoid approach varies quite a bit as to route of entry, thus the post-auricular, supra-auricular, and endaural approaches are all in use at the present time Type V tympanoplasty cannot be done transmeatally, since it involves a fenestration and must always be done through a transmastoid approach

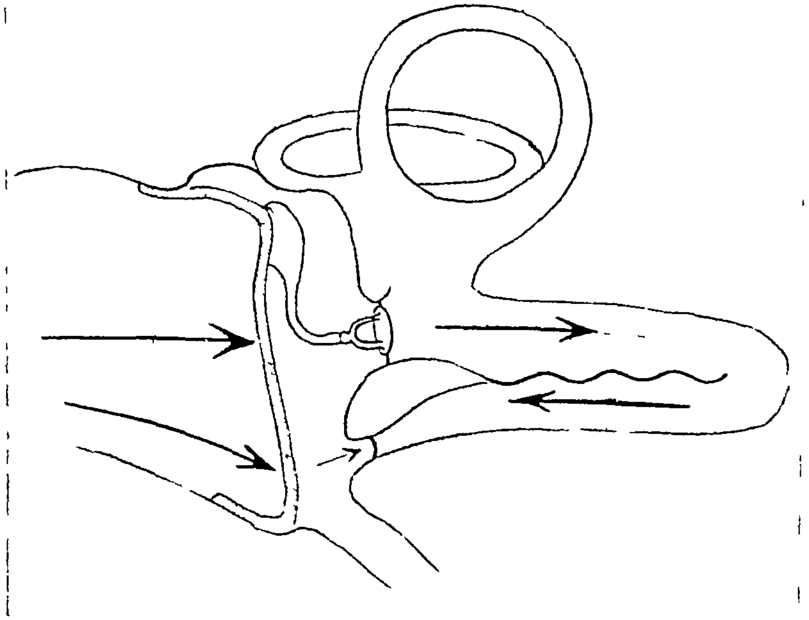

Fig 16 Type II—Tympanoplasty (Expanded Myringoplasty) Note absence of malleus with skin graft covering perforation and in contact with incus

SURGICAL AUDIOMETRY

At the present time there is no uniformity of practice with regard to surgical audiometry in tympanoplasty Some otologists prefer to do this type of surgery under local anesthesia with great reliance upon surgical audiometry, while others feel that the audiometric information obtained pre-operatively is adequate, and that the observations under the dissecting microscope fulfill the necessary criteria for decisions and, therefore, they do their procedures under general anesthesia gap apply just as forcefully to tympanoplasty as they do to stapes mobilization surgery

REPRESENTATIVE MIDDLE EAR PROBLEMS AND THEIR TYMPANOPLASTIC SOLUTIONS

Scores of pathologic possibilities may present themselves to the otologist for solution In an attempt to classify some of these problems, the following table (see Fig 20), was devised It lists a number of possible combinations of lesions, all of which have been encountered by the writer It must be remembered that all of these conditions may exist, either alone or in combination with some degree of mastoid disease Accordingly, the solution of these problems may be approached either through tympanotomy alone or through a combination of tympanotomy and mastoidectomy Thus, almost 80 possibilities may be considered in this tabular presentation Actually, the number of possibilities is infinitely greater when one considers the various combinations and cross combinations that may be encountered

EVALUATION OF RESULTS

It is not the purpose of this presentation to discuss results, except to point out that the evaluation of surgical results in this surgery should be no different from the method of evaluating the results of any type of middle ear surgery, including stapes mobilization and fenestration surgery As the author and his associates have pointed out in the past, and as has been pointed out by others, the only valid method of assessing *efficacy of surgical technique* in middle ear surgery is in the measurement of the degree of closure of the air-bone gap This evaluation technique must be considered, notwithstanding the practical aspect of the restoration of hearing to economic and socially desirable levels, (usually the 30 db level) We are all agreed that the latter is an extremely important final goal, however, when we are in the early stages of development of a branch of middle ear surgery, and are anxious to evaluate varying techniques and approaches, no method of evaluation other than that involving the degree of closure of the air-bone gap can yield any valid data It

There probably is a place for both local and general anesthesia in this group of cases There may very well be problems which can be solved better by surgical audiometry in some instances than in others Further experience and reports of many observers will help to answer this question

Of the methods available for surgical audiometry, two seem to be of greatest importance *a* the utilization of acoustic probe audiometry as described previously and as illustrated in Fig 9, in which definitive information of various portions of the ossicular chain may be obtained, and *b* surgical audiometry utilizing a modified nomograph, as described by the author and his colleagues in stapes mobilization surgery The latter may be applied to tympanoplastic surgery in certain instances, since the basic principles of closure of the air-bone

MODERATOR SOOY I am sure I speak for all of us when I say how grateful we are to Dr Goodhill for giving us this excellent paper The next paper has to do with the clinical experience in tympanoplasty It will be presented by Dr Leland House of Los Angeles

CLINICAL EXPERIENCES IN TYMPANOPLASTY [*]

Results in Sixty-One Cases [†]

LELAND R HOUSE, M D ,

Los Angeles, Calif

Since "Plastic Surgery" means repair or reconstruction of a part, I have chosen to include any procedure which is done to repair or reconstruct any of the tympanic structures within the subject of "tympanoplasty "

This would then include surgical repair of simple perforations of the tympanic membrane alone, or combined with any changes in the ossicles and middle ear membranes and windows for the purpose of eradicating disease, and/or preserving or restoring hearing Various names are appropriately applied to more specific procedures, such as myringoplasty, transmeatal tympanoplasty (Bell), myringostapediopexy (Juers), tympanomalleolar stapedopexy (Bell), endaural tympanoplasty, and others

It seems appropriate to include all of these procedures in our general thinking on the subject of tympanoplasty, but time and experience plus usage will encourage the use of more specifically identifying terms Time will not permit elaboration on each type of the above mentioned procedures In

[*] Presented as part of a Symposium on Tympanoplasty at the meeting of the Western Section American Laryngological Rhinological and Otological Society Beverly Hills Calif., Jan 18 1958

[†] Department of Otolaryngology College of Medical Evangelists

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication March 4 1958

is the feeling of the author that the per cent improvement technique which we have previously described in stapes mobilization surgery, should also be used in the evaluation of results in tympanoplastic surgery This per cent improvement technique is easily arrived at by dividing the decibel gain post-operatively by the air-bone gap

$$\text{Per cent Improvement} = \frac{\text{A C Gain (db)}}{\text{B C A C Gap (db)}}$$

SUMMARY AND CONCLUSIONS

1 Basic physiological principles underlying tympanoplastic surgery are presented Pre-operative and operative evaluative techniques are described, and the multiple possibilities of tympanoplastic approaches are tabulated

2 A methodology for evaluation of results is presented involving the per cent improvement technique, based upon degree of closure of the air-bone gap

3 Tympanoplastic surgery is in a very early stage of development It is based largely upon the application of plastic surgical principles to recently acquired knowledge of tympanic physiology It is interesting to speculate on the increased knowledge of tympanic physiology which will accrue as the result of tympanoplastic surgery itself Never before has it been possible to acquire as much quantitative data under microscopic inspection conditions of the middle ear as during this present new era of tympanoplastic surgery

4 Tympanoplastic surgery must be based upon careful evaluation of the physiologic state of the middle ear in every patient No simplified rote operation can be used without such evaluation It is better to think of tympanoplasty as a surgical approach than as an operation *per se*

several cases One case was a boy 11 years old, in whom I did the Wullstein approach on one side and the endaural on the opposite side In my experience, postoperative care is a little easier through the meatus created by the endaural incision than by the postauricular incision One case which developed a localized perichondritis of the auricle around the tragus and antitragus occurred with the postauricular incision In some cases a limited procedure may be accomplished through the normal meatus without an external incision

Surgical Attack If pathology is obviously limited to the tympanic membrane, I do not elevate the membrane to inspect the middle ear nor open the antrum or attic In most cases, however, I am now following the plan of opening the mastoid antrum and the attic Complete removal of mastoid cells, or the removal of disease from around the ossicles, is done according to what pathology is found The posterior superior segment of the tympanic membrane is elevated from the annulus in most cases for inspection of the middle ear Continuity and mobility of the ossicular chain and middle ear windows is studied An effort is made to remove diseased polypoid mucosa, granulation tissue and cholesteatoma If this can be done without interrupting the intact ossicular chain the ossicles will be left The entire pars flaccida and the pars tensa may be removed without breaking the ossicular chain if indicated

If cholesteatoma or granulations completely surround the ossicles, or if disease has caused erosion, they will be removed In several cases the ossicular continuity had been destroyed by disease with fairly good preservation of the pars tensa In these cases the incus was removed, the head of the malleus was removed, and the remaining drum membrane was used to seal off the tympanic cavity below the oval window creating a small tympanum

Skin Grafts Grafts are used to replace or cover areas where the tympanic membrane has been damaged or removed The usual source is a free, full thickness graft from the postauricular area Tympanomeatal flaps or flaps from the canal preparation for this study, I have reviewed the surgical records of some 125 cases which have been done at the White Memorial Hospital during the last three years, including 61 which I have personally been able to follow in more detail

In general, we have followed the principles of Dr Wullstein and have followed his classification for the purpose of this study Many details, no doubt, have fallen short of the perfection which he has attained, because of our limited experience As I reviewed our cases I was impressed with my change in attitude toward temporal bone disease in the last few years In previous years the available procedures for the management of the diseases of the temporal bone resulting from infection consisted principally of the modified radical mastoidectomy and the radical mastoidectomy The question usually was, "Do we do a radical mastoidectomy or not?"

Thanks to the influence of Drs Juers, Baron, Zollner, Wullstein, and many others, our thinking has changed from surgery of destruction to that of restoration or preservation As evidenced by our results, there is much progress to be made I anticipated that our results might not justify any great sense of pride in accomplishment I do feel encouraged, however, to find that we have helped many of these patients in a manner that would not have been accomplished by our routine procedures a few years ago Now, instead of a cut-and-dried procedure, each case is a challenge, with its own particular problem to solve It is approached with the idea of doing whatever seems necessary to eradicate the disease and still conserve and reconstruct the hearing functions

I have studied 61 cases in quite detail and will review points of interest

Anesthesia By far the most cases were done under general endotrachial anesthesia There is no hesitancy to use local anesthesia when desirable, especially for the less extensive procedures

Incisions In most all cases I prefer the endaural incision I have not used the Heermann incision, as advocated by Zollner I have, however, used the postauricular approach on cases resulted in good healing with intact tympanic membranes, and five had a recurrence with a secondary perforation in the graft Nine had good hearing (above 30 db), two had poor hearing, and two had no record of postoperative hearing test

In this group, which admittedly is very small, I find no correlation in the incidence of the breaking down of the graft and the size of the original perforation Some of these had a repair of a limited localized perforation and others had the entire tympanic membrane replaced by a graft

Type II in this classification include those which have a slight defect involving the ossicles as well as the tympanic membrane The ossicular defect is such that the ossicular chain can still be considered functional in the repair I have included those cases in which granulations, cholesteatoma, or fibrous tissue was found in the attic or tympanum, but still could be removed without a major dislocation of the ossicles

TABLE II

TYPE II—22 Cases

Healing—	
Satisfactory	16
Perforations	6
Hearing—	
Incomplete Data	4
Not Improved	6
Slightly Improved	4
Good Hearing	8

In this group I reviewed 22 cases Sixteen of these had satisfactorily healed cavities This means that the graft is intact and apparently viable, and that the mastoid cavity is dry or free from suppuration with no more than a modest amount of crusting and debris Six developed secondary perforations in the graft, one of these was during an episode of re-infection after an intact membrane had remained healed for 18 months The audiometric data was incomplete in four cases, leaving 18 cases for hearing comparison Eight cases had good hearing (above 30 db average), and ten had poor wall may be used occasionally for small defects. Before applying the graft, all epithelium is removed from the recipient area to avoid burying epithelium. The promontory will be denuded in some cases to provide better source of nutrition for the graft. If the mastoid cavity is large, I prefer not to line the entire cavity with skin, but to allow it to granulate in and epithelize itself. So far I have not used delayed grafting.

To maintain separation of the graft from the middle ear mucosa, and to prevent obliteration of space, very small pieces of soaked gelfoam have been used in the hypotympanum, the Eustachian tube area and the round and oval window areas.

TABLE I

TYPE I—13 Cases

Healing—	
Satisfactory	8
Perforations	5
Hearing—	
Incomplete Data	2
Poor Hearing	2
Good Hearing	9

The physiologic demands necessary for preserving and restoring hearing have been well presented in former literature and reviewed by Dr. Goodhill. These requirements must be continually in mind when approaching each case.

For the purpose of discussing this series I will briefly summarize our cases from each group. Two factors were considered, the type of healing result and the comparison of preoperative and postoperative hearing.

Type I, as classified by Wullstein, includes those cases which have an intact and functioning ossicular chain and round window with some defect in the tympanic membrane. In these cases a successful repair will result in an essentially normal ear.

In this group, Type I, I reviewed 13 cases. Eight of these two there was no improvement, and the hearing remained at the preoperative level below 30 db

From a theoretical estimate there should have been a better percentage of good hearing cases in this group As near as I can determine, the chief cause for poor hearing was the reformation of adhesive processes with fixation of the flap and obliteration of the tympanic space This impaired the freedom of one or both of the two windows

Type IV are those cases in which the ossicular chain is entirely lost except for a mobile stapes footplate The ideal repair in these cases seems to be to create a small tympanum with a pneumatic space which communicates with the Eustachian tube and the round window The oval window niche is not covered at all with the graft, and is left open to receive air-transmitted sound pressure directly The round window is protected from direct sound pressure by the tympanic membrane This provides the phase differential that is necessary in hearing

TABLE III

TYPE III—10 Cases

Healing—	
Satisfactory	7
Perforation or Drainage	3
Hearing—	
Incomplete Data	1
Not Improved	2
Slightly Improved	4
Good Hearing	3

The small tympanum may be made ideally by the intact pars tensa if it has not been destroyed by disease In six cases I found this possible The ossicles were all destroyed, and the attic was diseased, but the pars tensa was sufficiently intact to use it to seal off the tympanic cavity just below the margin of the niche of the oval window If the pars tensa is inadequte to create this small tympanum, then a skin graft is applied in one piece to cover all of the tympanic area and extend upward to cover the attic. A small button hole is cut hearing Of those with poor hearing, four showed definite improvement, but were still below the 30 db level

There were three significant complications One was followed by a dead labyrinth A very large cholesteatoma had eroded a segment of both the posterior and horizontal canals On removing the mass of cholesteatoma, some of the endolymphatic labyrinth was pulled away About ten days after surgery this same patient developed a perichondritis Fortunately, this remained localized relatively well in the lower portion of the meatus near the tragus and antitragus, but was slow to clear The organism was pseudomonas which, of course, is resistant to most antibiotics, and in my experience is a trouble maker The postauricular approach had been used on this patient, but may not have had any bearing on this complication

Another patient developed a facial paralysis which at first was partial During the first week it became complete, but started to recover after the third week Recovery was slow, but was complete after 16 weeks

Type III cases are those in which there is a major defect in the ossicular chain requiring the removal of the incus and malleus, but preserving the stapes This leaves the capitulum protruding slightly above the level of the margins of the niche of the oval window The tympanic membrane or graft then is laid over the capitulum in contact with it The newly created tympanic membrane then lends sound pressure transmission directly to the stapes, this being spoken of as the columellar effect Because the graft lies close to the promontory and the pneumatic space of the middle ear is thereby made shallow, it is much easier for adhesions to form and obliterate the space

I reviewed 10 of these cases In seven the cavity was considered to have healed satisfactorily, in two small perforations recurred, and in one there was active secretion from an unhealed mastoid cavity Three cases had good hearing (above 30 decibel level) Four cases had distinct and useful improvement in hearing, but still below the 30 decibel level In this series one case with a fixed stapes footplate was included in my Group III above A mobilization of the footplate was done and the graft placed across the capitulum Hearing result was not good, further surgery is contemplated

I will summarize our findings in these 61 cases by combining the results of all of the types presented

TABLE V

SUMMARY—61 Cases

Healing—		
Satisfactory	46	75%
Perforations or Discharge	15	25%
Data Incomplete	8	
Hearing—		
		% of 53
Not Improved	13	25%
Slightly Improved	10	19%
Good Hearing	30	56%

Forty-six (or 75 4 per cent) were considered to have satisfactory healing with no perforations Fifteen had perforations or active discharge In eight the audiometric data was incomplete, leaving 53 cases for preoperative and postoperative hearing comparison Of the 53 cases, 30 (56 6 per cent) showed a hearing level above the 30 db loss in the speech range Eleven were improved but below 30 db Twelve were not improved

Admittedly, this is a relatively small series of cases and does not justify any fixed long range conclusions It does lend encouragement for further efforts in this field Time and experience may never solve all of the problems we face in this work It does seem that another new field of otology has been opened up and that many advances may be expected in the future

I am indebted to others on my staff who have allowed me to review their cases and assisted by giving me clinical and audiometric data Dr Emery Pick, who was the first to bring Wullstein's and Zollner's work to this city, has been especially helpful out of the graft corresponding to the oval window, leaving it uncovered Several cases in this group have given surprising results with hearing in the speech range averaging 18 to 22 db

The records of 16 patients of this type were studied In 15 cases the cavity and graft were considered to have healed satisfactorily and one developed a secondary perforation from re-infection Ten cases (62 per cent) had good hearing (above 30 db), two showed improvement, but below 30 db, and three showed poor hearing with no improvement

TABLE IV

TYPE IV—16 Cases

Healing—	
Satisfactory	15
Perforation	1
Hearing—	
Incomplete Data	1
Not Improved	3
Slightly Improved	2
Good Hearing	10

Percentage wise this group gave the best results of all groups, and Group III gave the worst Factors favoring Group IV are

First, only a small pneumatic space is needed, and this is in the region where the tympanic cavity is the deepest and most easy to preserve

Second, the short length of skin graft bridging from one point of contact to the next makes the nutrition of the graft less critical

Third, in these cases the greatest damage by the disease was in the attic with a relatively less severe change in the hypotympanum The skin graft is less likely to adhere to a normal mucous membrane surface

Wullstein's Type V are those which have a fixed stapes footplate In these cases a stapes mobilization or a fenestration must be combined with other procedures as indicated In

Though it has not been mentioned I do not doubt that our speakers advise using the Zeiss microscope for tympanoplasty Wullstein, himself, makes the point that his work consists of two things first, microscopic control in the eradication of infection, second, the restoration of function

Anyone who has seen Prof Wullstein will realize that tympanoplasty is not a set operation What is done depends upon what is found, and an operation may take several hours This is necessary in order that all infectious material is removed from the tympanic space before it is closed in by skin

I have always felt that the danger in tympanoplasty comes from burying sepsis under skin Wullstein and Zollner are fully aware of the danger of this, but I know from my own experience and from what I have seen of others that not everybody is so careful and painstaking in eradicating every little bit of pathology so that nothing is left behind One of my friends who is very keen on this work and whose opinion I value highly, said that for every ten cases in which he hoped to end up with a Wullstein Type II operation—that is to say, leaving the ossicular chain more or less intact—this happened only in three In the remainder, he had to remove the malleus and incus in order to eradicate the infection After what we have heard from Dr House today, it looks as though it might be a good idea to clip off the crura of the stapes as well

In stressing the importance of not burying sepsis under skin, I have in mind that our first duty to a patient with a chronic suppurative otitis media is to make that ear safe If we sacrifice that principle in the hope of saving or restoring hearing—laudable though the idea may be—then we are not doing our duty to the patient Infection and its ever present danger of spread intracranially, must be eradicated before starting to save or restore hearing

When it comes to the question of the skin graft, the speakers this morning, like Wullstein and Zollner, use full thickness skin taken from behind the ear Some workers are claiming good results when using split thickness grafts which they find are less irritating, and are more likely to survive than whole skin It is, however, maintained that the whole skin

MODERATOR SOOY Thank you, Dr House We will now have Dr Cawthorne's contribution to this Symposium

Summary and Remarks

TERENCE CAWTHORNE, M D (London, England) I still do not quite know why I was called on to summarize this discussion, because my experience and knowledge of tympanoplasty is very slight, however, I have learned a great deal from the discussion this morning

I think we all realize what a great debt we and the whole world owe to Prof Zollner and also to Prof Wullstein for their original work in this field, and for arousing our interest in the restoration of function where it was always assumed that it was not possible to restore function

Dr Goodhill mentioned the importance of the differential sound pressure, and we are indebted to Dr Wever and to Dr Lawrence for the clear explanation of this, which appears in their book "Physiological Acoustics"

Dr Goodhill also mentioned ankylosis of the stapes Now I cannot resist saying that it is not very often that the stapes becomes ankylosed in the true sense of the word "Ankylosis" and "fixation" as applied to a joint mean that the joint is fixed, that it won't move, I do not believe that in otosclerosis the stapes is often so fixed If it were, little or no sound would get through and the patient would be very deaf, indeed I think that usually it is impeded When it is really fixed, and I have under the microscope seen the stapes buried up to the neck in otosclerotic bone, that patient has had a 95 decibel loss in hearing Such a hearing loss does not necessarily indicate poor cochlear reserve I think that it is probably one of the physical effects of complete ankylosis of one or both windows, and that cochlear function may be unimpaired

With regard to the question of approach, I have always thought that one should be familiar with any of the three approaches to the middle ear posterior, endaural or endomeatal Only then is one really in the position to be able to choose the approach most suited to the operation charge granulations or cholesteatoma, a good functional result is not necessarily sacrificed by a thorough clearance of the middle ear including most of the ossicular chain.

PROGRAM OF THE SEVENTH INTERNATIONAL CONGRESS OF BRONCHOESOPHAGOLOGY

Meeting Place—Kyoto University, Kyoto, Japan

Friday, September 12th, 1958

8 00 P M -10 00 P M—Reception (Party) Shimomura House in Kyoto

Saturday, September 13th

8 00 A M—Inaugural Session (in Kyoto University Hall)

9 00 A.M -12 00 M—First Scientific Session

12 00 M -2 00 P M—Luncheon (Reception The Place not decided)

2 00 P M -6 00 P M—Sightseeing in Kyoto

8 00 P.M—Banquet, Miyako Hotel

Sunday, September 14th

8 00 A.M -11 30 A.M—Second Scientific Session

11 30 A M -12 00 M—Closing Ceremony

12 00 M—Departure for sightseeing in Nara

1 00 P M—Luncheon, Nara Hotel.

2 00 P M -6 00 P.M—Sightseeing in Nara

7 00 P M—Return to Kyoto

gives a better chance of maintaining an air space in the lower part of the tympanic cavity

Now this is very important, because for good hearing it is necessary to have an air space including the round window and the Eustachian tube but separated from the oval window Both Zollner and Wullstein lay great stress on this, and they start inflating the Eustachian tube soon after the operation

There is one other question which has not been mentioned yet which is of interest Should tympanoplasty be advised for unilateral ear disease or should it be reserved for bilateral cases? Probably when one is beginning it would be quite a good plan to start on unilateral cases, because failure to improve hearing would not be so disappointing for the patient

I have one final word about the Type I type of case, myringoplasty One of my colleagues, Stuart Mawson, has been doing quite a number of myringoplasties and has been getting remarkably good results He works through an endomeatral incision on ears with large perforations The ear must be dry and there must be no suggestion of any chronic disease within the attic The patient is laid up for a day or two at the most The perforation is covered with full thickness skin, and in a very large proportion of the cases, the perforation is permanently closed

Besides improving hearing it usually prevents the recurrent bouts of otitis media, which with large perforations so often follow on moisture getting into the ear This avoids having to take special care when swimming, having a shower or a hair shampoo

Finally, I was very interested to note that in the series just quoted by Dr Goodhill and his colleagues, their best functional results followed either myringoplasty or where the only part of the ossicular chain left as the footplate of the stapes (Wullstein Type I and Type IV), thus if the surgeon can satisfy himself that he is dealing only with a case of recurrent otitis media with a large central perforation, myringoplasty is a safe and functionally satisfactory operation Where the tympanic sepsis is persistent, and particularly when there is evidence of bone disease or erosion in the shape of foul dis-vocal process on each side. It appears as a grayish-white, sometimes red, wrinkled dry thickening of the mucosa.

Microscopically, keratosis is recognized by thickening of the epithelium, especially in the cornified stratum. As in leukoplakia, there may be evidence of chronic inflammation in the other mucosal layers or in the sub-mucosa. This is recognized by the presence of lymphocytes and plasma cells, however, the most important factor in determining the malignant tendency of a growth is the presence of cell atypism. In the most serious type of hyperkeratosis there is proliferation of the prickle-cell layer, and also the basal layer of cells, but the basal layer in the true keratotic lesion will remain unbroken. The epithelium may send projections into the subepithelial tissue, but the cells of the basal layer remain intact.

It is felt that those showing evidence of chronic inflammation and those showing involvement of the deeper layers of epithelium are more likely to metamorphose into malignant growths. At any rate the presence of atypical cells in the epithelium signifies beginning carcinomatous changes, and if these are pronounced enough the diagnosis is "carcinoma *in-situ*." When the microscopic picture shows infiltration into the subepithelium tissue, that is, the basal layer of cells are broken through by groups of carcinomatous cells, we have a true invasive carcinoma.

Since the appearance of a lesion cannot always help us in determining the presence of malignancy we must depend upon the biopsy, but frequently a biopsy may be taken from an area that does not yet show the malignant changes. The entire lesion, if it is a large one, cannot be examined microscopically, and the malignant changes may take place over a long period and at the time of the biopsy, none of these changes as yet have occurred.

We must, therefore, approach the problem with constant awareness of the danger of complacency and treat a keratotic lesion with atypical cells as though it were malignant, and yet we must not be too radical in all cases of hyperkeratosis. We come to the conclusion, then, that cases must be considered individually, according to the site of involvement, the extent,

THE MANAGEMENT OF HYPERKERATOSIS OF THE LARYNX *†

ARTHUR J CRACOVANER, M D ,

New York, N Y

The management of hyperkeratosis of the larynx is fraught with difficulty because some of these lesions are considered precancerous, and the problems involved may defy even the most experienced laryngologist

We know that hyperkeratotic areas in the larynx may slowly and without changes apparent to the eye, develop definite malignant characteristics Since these changes frequently are not recognizable by visual examination, we must depend upon the microscopic diagnosis, second, we must consider the hyperkeratotic lesion as a malignant one, always aware of the fact that at any time the metamorphosis into cancer may take place

Hyperkeratosis of the larynx appears as a thickening of the layers of the epithelium, especially the cornified portion When it is seen as slightly raised, rather dense and thickened, white superficial plaques with evidence of inflammation, it is sometimes called leukoplakia Hyperkeratosis, also referred to as keratosis, may be localized or diffuse in the larynx It may occur on one cord as a grayish white, sessile growth or it may be seen occasionally as a red thickening on the cord It may appear as a white, warty growth with sharp, spiny protuberances It may involve all or a portion of both vocal cords, or spread to the ventricle and/or subglottic areas A typical diffuse type of hyperkeratosis is known as pachydermia of the larynx This is an involvement of the interarytenoid area that extends onto both vocal cords, usually up to the

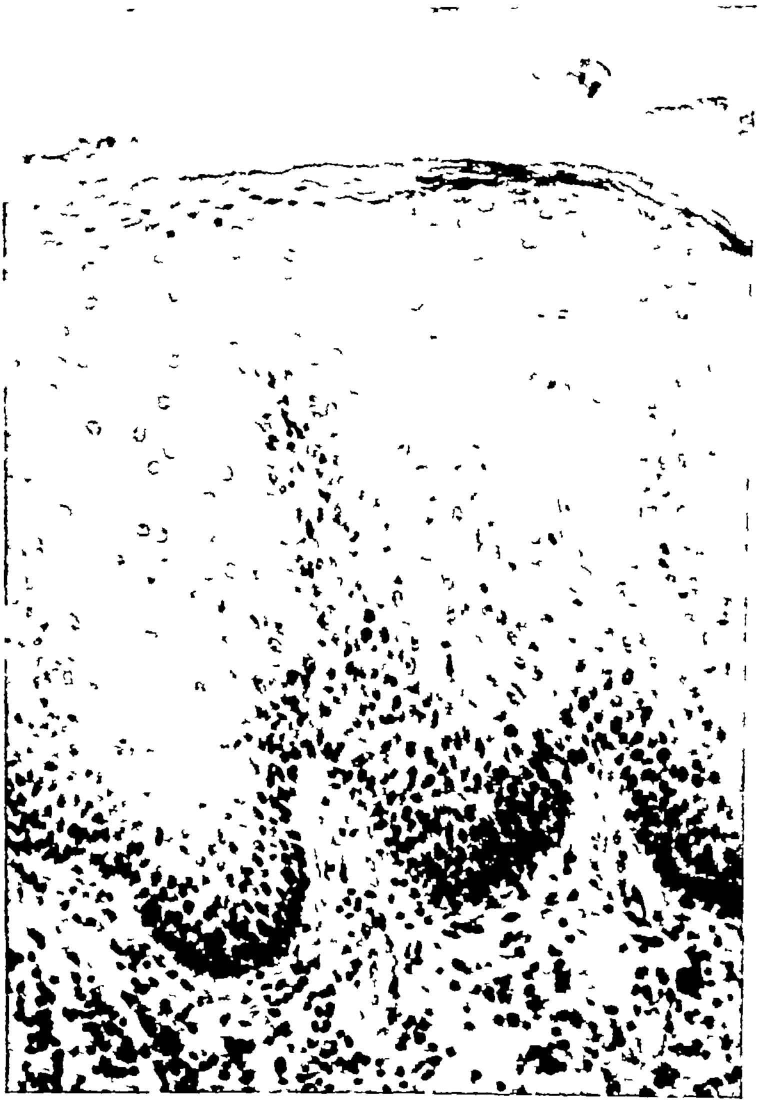

Fig 2 Leukoplakia Thickening of the corium not marked thickening of the deeper epithelial layers more marked than on Fig 1 adjacent connective tissue contains lymphocytes some cell atypism (dark staining in basal layer)

size and appearance of the lesion as well as the microscopic findings It is hard to formulate hard and fast rules, but we hope to indicate what we feel is best in certain typical cases

On examination of an early hyperkeratotic lesion, one would see a small white, elevated, thickened patch on a vocal cord, perhaps several plaques on both vocal cords They are usually seen on the upper surface of the cord, perhaps on its edge

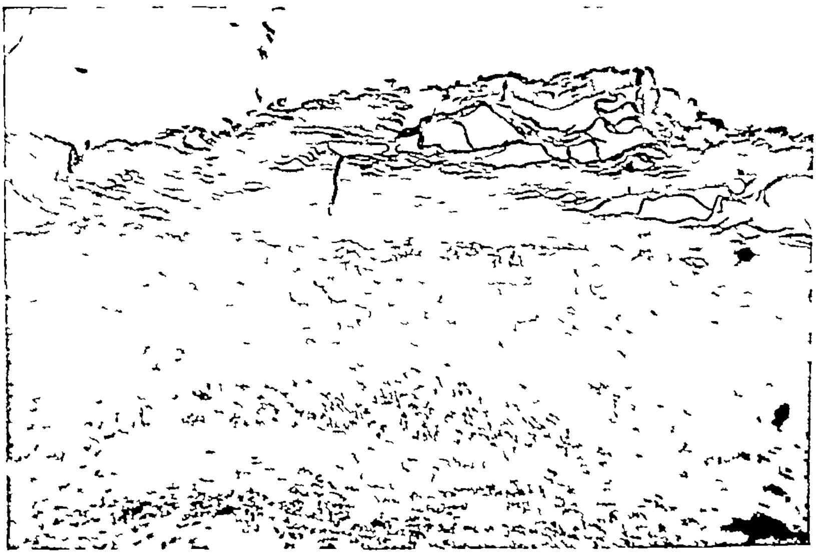

Fig 1 Hyperkeratosis Marked thickening of the corium moderate thickening of the deeper epithelial layers no significant cell atypism no inflammatory reaction in the underlying connective tissue

It is felt that hyperkeratotic lesions in general are due to chronic irritation Such irritation may be caused by excessive smoking, by excessive use of alcohol, by abuse of the voice, by inhalation of fumes and dust, they may also be caused by repeated upper respiratory infections brought on by chronic infection in the sinuses and pharynx (see Case 3) If these etiological factors can be eliminated then the hyperkeratotic areas may subside or at least not increase in size, so that this is the first advice that is given, and the patient is kept under close observation If this type of lesion does not disappear it is removed by direct laryngoscopy

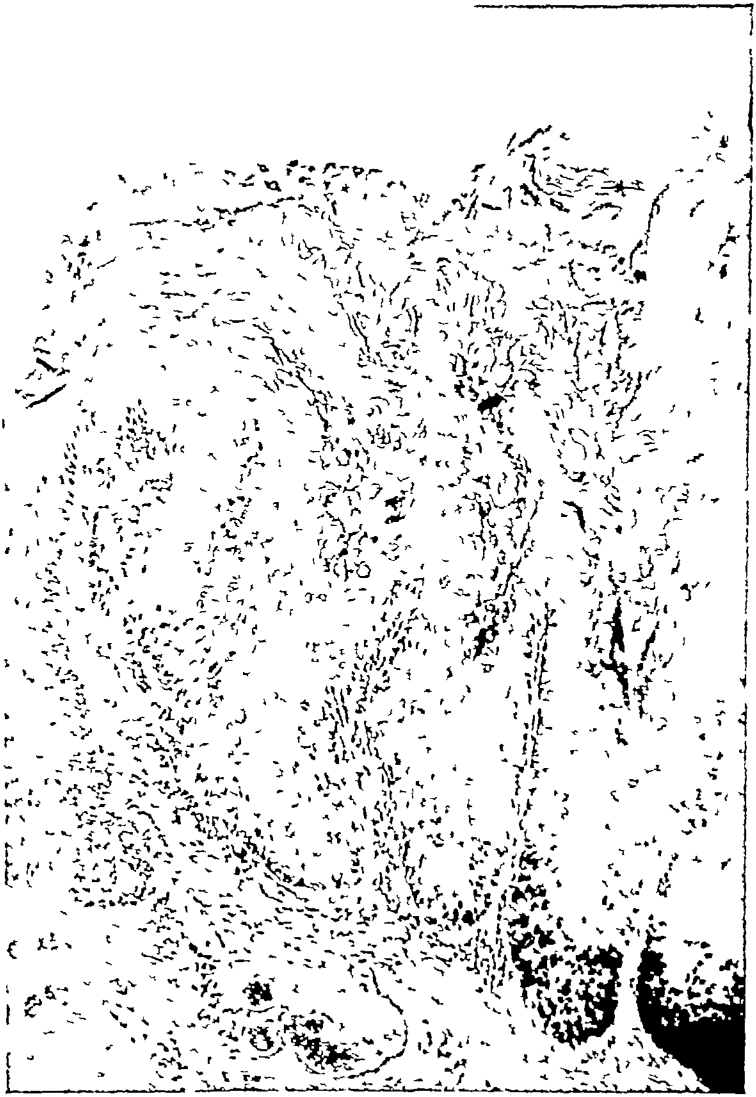

Fig 3 Carcinoma in situ As in Fig 2 but the basal layer of cells are quite atypical and show the characteristics of carcinoma i e. large nuclei atypical chromatin arrangement large nuceoli hyperchromatism large atypical shaped differentiation of squamous cells

The keratosis may appear as localized unilateral or bilateral thickenings The lesion may present itself as a grayish-white area on the cord that shows evidence of chronic inflammation The hyperkeratosis may take the form of white, warty, brittle appearing excrescences on one or on both cords Other keratotic lesions appear as whitish or red papillary growths It is felt that the presence of inflammation in or around the lesion or the warty, papillomatous growths are more likely to become malignant and yet the sessile, red thickening of the vocal cord may on occasion be reported as "carcinoma *in-situ*" Some of the above mentioned growths may subside under the regimen of elimination of the causative factors already indicated (see Case 2), but usually it becomes necessary to remove the keratotic lesion by biting off the involved areas or stripping the cords under direct laryngoscopy (see Case 1) Careful and frequent observation is most important, since at any time the lesions may recur (see Case 4) If they do, more radical therapy is indicated, since we know we are dealing with a growth that may become malignant

Perhaps we would attempt several removals of the growth by direct laryngoscopy, but we will note that with each recurrence the interval is shorter, the growth seems to grow faster (see Case 8) It is best, then, to remove the lesion by doing a laryngofissure operation For those accustomed to the technique, there may be cases with lesions small enough to be removed by suspension laryngoscopy, as suggested by Dr LeJeune Perhaps in the case of the lesion on an inflamed cord and the warty, papillomatous lesion we would be more inclined to do a larynofissure without attempts at stripping the cord Clinical experience and judgment on the part of the laryngologist will dictate the procedure to be followed (see Cases 5, 7) Of course, if at any time the microscopic findings indicate the presence or the suspicion of malignancy the growth is treated as one usually treats a carcinoma There are some hyperkeratotic lesions that spread either to the subglottic area or to the ventricle These should also be removed by laryngofissure (see Case 6)

So far it does not seem complicated, but when we have a keratotic lesion recurring on both vocal cords, perhaps ex-

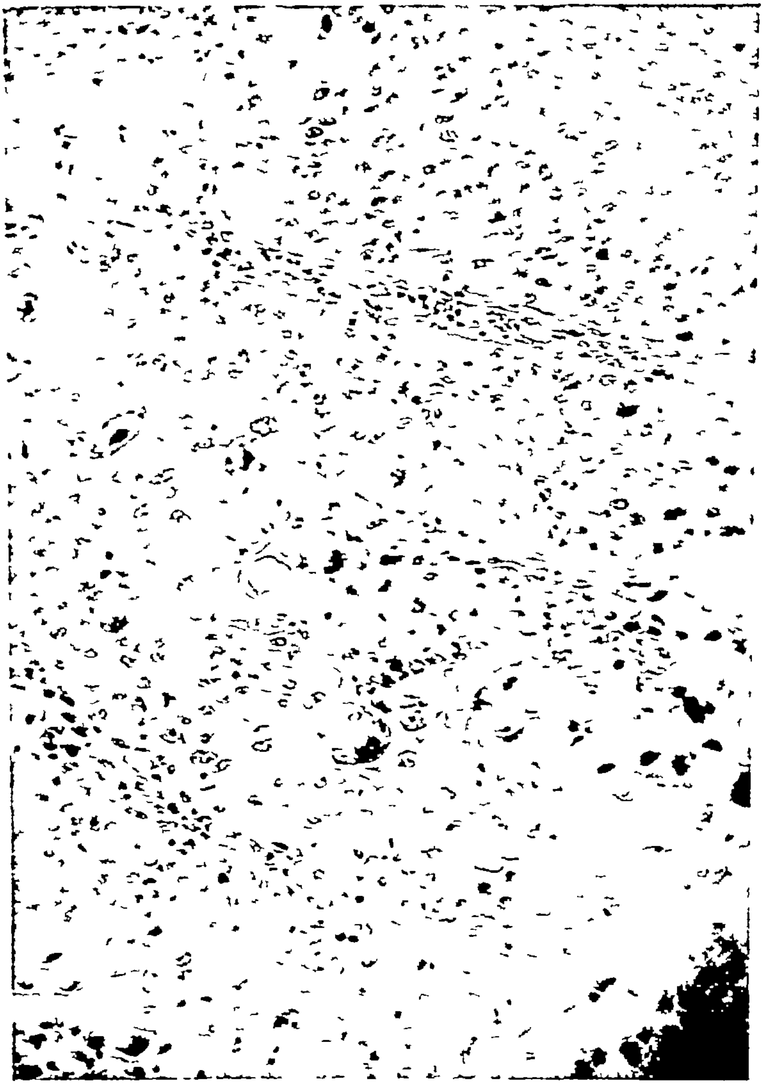

Fig 4 Squamous cell carcinoma, showing the characteristics of carcinoma mentioned in Fig 3

tending to the ventricle or the subglottic area, the situation is more serious We hesitate to do a laryngectomy in such a case when there is no definite microscopic evidence of malignancy Even if some metamorphosis that indicates beginning malignant changes is taking place, we will hesitate to do a laryngectomy, since the lesion is superficial, not infiltrating, and both cords move normally These cases sometimes do well under radiation therapy (see Cases 10, 12) Some recommend a partial tumor dose, others give a full tumor dose, according to the pathological picture and the progress during the therapy Some laryngologists state that the vocal cords return to their normal appearance, but that has not been my experience The cords seem to be thickened and white, and one must keep these patients under close observation for recurrence of a hyperkeratotic lesion It is felt that partial doses are less likely to cause mucosal changes within the larynx, and the cords approach the more normal appearance One wonders whether we should chance the partial dose Under radiation therapy one can never be sure of a cure, certainly not so sure as when a lesion is removed surgically We repeat then, a case of hyperkeratosis that would require a laryngectomy for complete removal is first treated by X-ray

Occasionally one encounters a case where an entire cord is involved, and the growth extends across the anterior commissure for a short distance on the other cord (see Case 7) This can be treated by doing a bilateral thyrotomy, as suggested by Kemler, or the partial anterior laryngectomy as suggested by Jackson

The cases that are puzzling are those known as pachydermia of the larynx, where the interarytenoid area and part of both vocal cords are involved To eradicate this disease surgically, one would require laryngectomy These patients are best treated by stripping the involved areas, by eliminating the irritating causes, and by close observation If any malignant changes do occur a laryngectomy becomes necessary

There is an occasional case where the tumor becomes very extensive, and, even though on repeated biopsy they are reported hyperkeratotic lesions, they should be treated by

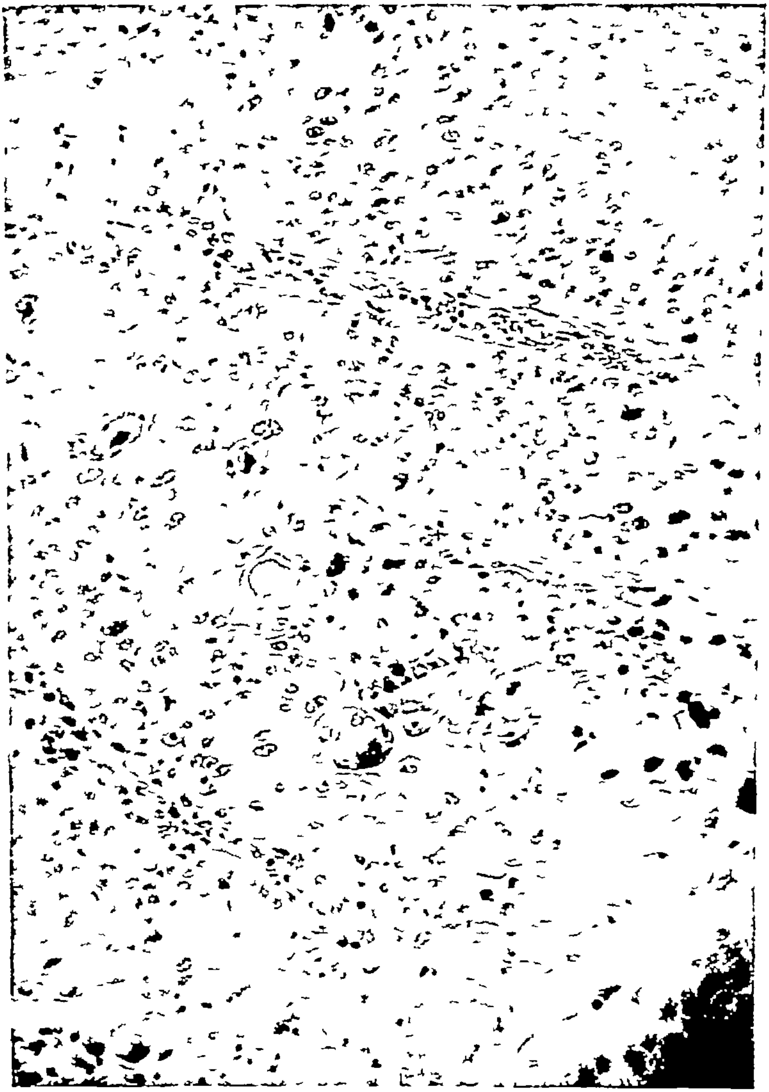

Fig 4 Squamous cell carcinoma showing the characteristics of carcinoma mentioned in Fig 3

laryngectomy (see Cases 9, 11). Recently we had the experience of procrastinating on just such a case because we found no evidence of malignancy microscopically, but clinically it was a carcinoma. It spread down the trachea, involving the tracheal stoma, infiltrated the tissue in the neck, and resulted fatally.

CASE REPORTS

Case 1. M. A.—White, male, age 70. Hoarseness for many years. There was a red thickening on the anterior two thirds of the left vocal cord. This area was stripped under direct laryngoscopy. The microscopic diagnosis was keratosis with some atypical cells, no evidence of malignancy. This patient has been under observation for three years, with no recurrence.

Case 2. E. M.—White, male, age 12. History of hoarseness for three months. There was a small irregular tumor in the anterior third of the left vocal cord. This was removed under direct laryngoscopy. The diagnosis was hyperkeratosis of the vocal cord with no evidence of malignancy. The patient was advised to undergo a regimen to eliminate irritation of the larynx. He has remained free from recurrence for over a year.

Case 3. S. H.—Age 59, W. F. The patient had a history of recurring attacks of laryngitis. The last attack had been present for four months. On examination she had a red, dry, granular appearing vocal cord. The diagnosis was laryngitis sicca. The patient had a chronic sinusitis, postnasal pus and atrophic appearing mucosa of the pharynx. On direct laryngoscopy there was thickened, irregular mucosa involving the arytenoid area and the vocal cords. The microscopic diagnosis of the tissue obtained was hyperkeratosis, no evidence of malignancy. The patient improved on treatment of the chronic sinusitis. It is important to point out that in this case there were no atypical cells and, therefore, it would not be considered a precancerous lesion.

Case 4. I. T.—Age 60, W. M. In May, 1955, he gave a history of hoarseness for three weeks. He had a lesion involving the left vocal cord, it appeared white and irregular. On direct laryngoscopy the cord was stripped. The microscopic diagnosis was keratosis with cell atypism of the left vocal cord. No evidence of malignancy. In May, 1956 the patient again complained of hoarseness for two months. There was a whitish superficial lesion on the right vocal cord extending from the anterior commissure to the middle third of the cord. This area was stripped under direct laryngoscopy. The microscopic diagnosis was hyperkeratosis of the right vocal cord with slight atypism but no changes indicative of carcinoma at present. In June 1956, there was a recurrence of the lesion that involved the middle third of the right vocal cord, the diagnosis was hyperkeratosis with granulation formation. This patient has been under observation and there has been no evidence of recurrence to date.

Case 5. A. S.—Age 69, W. M. This patient gave a history of hoarseness for three months. He had a large keratotic appearing lesion on the right vocal cord and subglottic area. Several specimens for biopsy revealed hyperkeratosis with suspicious areas of cellular activity and considerable inflammation. Because this was a warty, irregular appearing lesion that involved the subglottic area a laryngofissure was performed with removal of the entire growth. The pathological diagnosis of the laryngofissure specimen was carcinoma *in situ* in a hyperkeratotic lesion

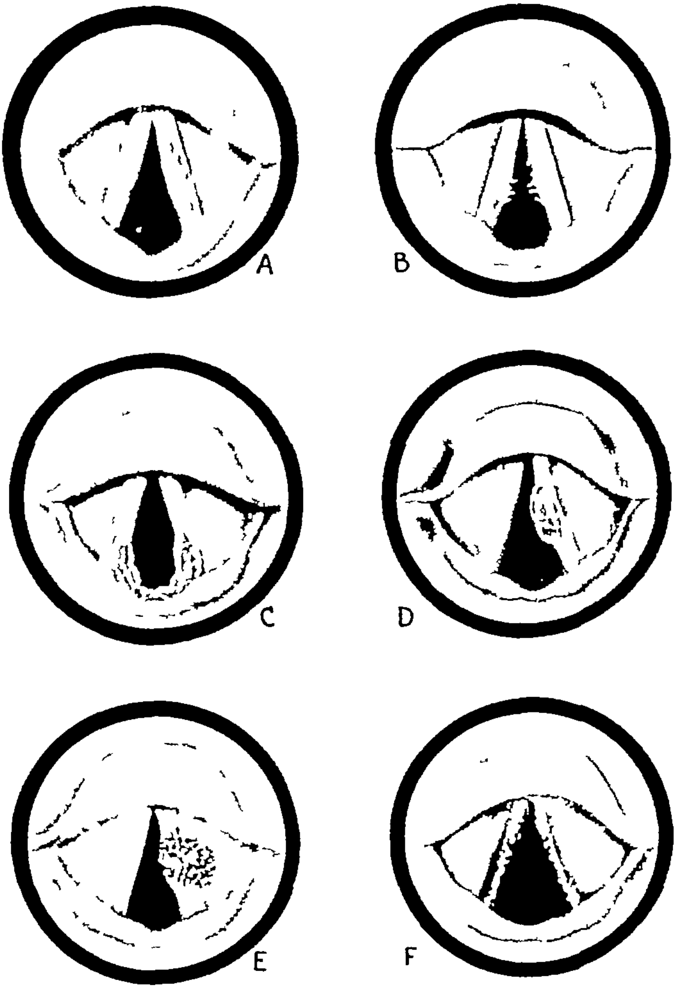

Fig 5 A.—Leukoplakia B—Keratosis C—Pachydermia D—Hyperkeratosis with carcinoma in situ E—Hyperkeratosis with carcinoma in situ F—Bilateral Hyperkeratosis

This patient unfortunately died of carcinoma of the right upper lobe with metastases a year later

Case 6 M C—Age 57 W M This patient had five endolaryngeal removals of polypi and keratotic lesions Two years prior to admission he had had a tracheotomy at another hospital At this admission he was having respiratory difficulty He had a large grayish white cauliflower lesion in the glottic lumen apparently arising from the anterior third of the left vocal cord After the preliminary tracheotomy a laryngofissure was performed and a sharply circumscribed, elevated whitish lesion was removed from the inferior surface of the left vocal cord and subglottic area The pathological diagnosis was hyperkeratosis of the larynx with no anaplastic changes noted The patient has remained well to date four years This is an example of persistent recurrence of a laryngeal hyperkeratosis and the growth of the lesion to such an extent that *it gives laryngeal obstruction It is significant too that no evidence* of carcinoma was found, even after the laryngofissure

Case 7 P P—Age 60, W M In April, 1955, complained of hoarseness for several months He was a heavy smoker and drinker On examination a whitish lesion was found covering the anterior two thirds of the left vocal cord, reaching the anterior commissure After a direct laryngoscopy, the biopsy revealed a keratotic lesion of the left vocal cord with some cell atypism malignant transformation not evident Because of the appearance of this lesion a laryngofissure was done The left vocal cord was removed and since the lesion extended across the anterior commissure on to the right vocal cord a small portion of the latter was removed The diagnosis was left vocal cord leukoplakia with carcinoma *in situ*, the right vocal cord showed leukoplakia of slight to moderate extent The patient has remained well, though he has a small web in the anterior commissure This case illustrates the fact that if the lesion is large and irregular and when the microscopic section shows some atypism, it is best to do a laryngofissure immediately A carcinoma *in situ* was found on complete removal of the growth

Case 8 H S—Age 49 W M This patient complained of hoarseness for six months There was a lesion on the middle third of the left vocal cord It was granulomatous grayish white in appearance It was removed by direct laryngoscopy The microscopic diagnosis was hyperkeratosis of the vocal cord There was evidence of inflammation in the underlying tissue Three weeks later there was a recurrence of the lesion in the left mid subglottic area This was removed and on microscopic examination revealed a carcinoma *in situ* Two weeks later a laryngofissure was performed and the diagnosis was epidermoid carcinoma very early, showing slight infiltration of the underlying tissue This is a case of hyperkeratosis in which the metamorphosis into a carcinoma occurred rapidly or perhaps as is more likely the tissue was taken from the areas where the carcinoma did not appear

Case 9 M D—Age 55, W M This patient appeared June, 1956, with a complaint of pain on the right side of his neck There was an enlarged node over the carotid on the right side On laryngeal examination there was a superficial grayish ulceration on the posterior surface of the right side of the epiglottis and right aryepiglottic fold extending down to the anterior commissure The left vocal cord was a little roughened biopsy was taken Diagnosis was hyperkeratosis with a few atypical cells no evidence of malignancy Since a carcinoma was not definitely found in the larynx we decided to remove the enlarged lympho node This was reported as chronic lymphadenitis In Sept 1956 the lesion looked about the same except that it seemed to extend on to the right vocal cord Another biopsy at this time revealed carcinoma *in situ* developing in hyperkeratosis of the larynx A laryngectomy was performed and the diagnosis was squamous cell carcinoma of the larynx microscopic examination of the vocal cord itself showed hyperkeratosis This patient has remained well for over a year The case illustrates again that the biopsy may be taken from an area that does not reveal carcinoma When one is suspicious of carcinoma the biopsy should be repeated

Case 10 E G—Age 49 W F This patient complained of hoarseness for two years Both vocal cords were thickened and dry, the right ap peared more involved than the left The interarytenoid area was also thickened and irregular The tissue removed from the larynx revealed a hyperkeratosis of the vocal cord and interarytenoid area with slight atypism This patient was referred for radiation therapy She has remained well for two years

Case 11 J G—Age 75 W M In December 1954 this patient had ulcerated appearing vocal cords but no fixation of the cords The cords were thickened white and had an irregular, warty appearance The diagnosis on biopsy was leukoplakia with considerable cell atypism not yet definite carcinoma Two months later the lesion looked worse and the biopsy revealed squamous cell carcinoma A laryngectomy was performed and the patient has remained well to date It is possible that a case of this sort should have been treated by radiation therapy but it was felt that this warty extensive lesion should be removed surgically

Case 12 H S—Age 63 W M Jan 1956 this patient had had hoarseness on and off for 15 years The recent attack of hoarseness had lasted four months He had a reddish thickening on the left vocal cord and a white plaque on the right vocal cord A biopsy of the left vocal cord was reported as malignancy of a low grade The right vocal cord was reported as leukoplakia He was sent for radiation therapy and has remained well however, he does have thickening of both vocal cords

CONCLUSIONS

1 Those hyperkeratoses that show cell atypism are serious because they are precancerous Since it is sometimes difficult to tell when the lesion will become cancerous it should be treated as a potential malignancy

2 The early lesions are treated by stripping the cords under direct laryngoscopy and eliminating irritation due to tobacco, alcohol, abuse of the voice, infection, etc

3 Recurrent lesions on one vocal cord or large warty lesions on one cord that involve the ventricle and/or subglottic area are treated by laryngofissure

4 Recurrent lesions on both vocal cords are treated by radiation therapy, and if unsuccessful by laryngectomy

5 Extensive laryngeal involvement should be treated by laryngectomy

I am indebted to Dr George K Higgins for his help in the pathological aspect of this paper

PROBLEMS THAT CONFRONT THE RHINOLOGIST*†

JOSEPH H. OGURA, M.D.,
St. Louis, Mo.

INTRODUCTION

To many otolaryngologists, the subject of reconstructive nasal surgery sounds broad and includes all phases of rhinoplasty. Actually rhinologists who perform this operation use this term in a more limited sense. Total nasal reconstruction, such as the use of forehead flaps for the replacement of partial or total loss of the external use, is in the realm of the plastic surgeon. One may justly wonder then, how this fits into our field of rhinology? The otolaryngologist, by training and everyday practice, has always concerned himself with the

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication May 26, 1958.

function and health of the nose A few, by greater experience, have become more involved with plastic surgery in its strictest sense Thus, a casual observer may consider a rhinoplasty as a purely cosmetic procedure, and naturally wonders about the functional improvement claimed by such an operation

I shall try to cover briefly four questions in a general way

1 What do you do?

2 Why do you do it?

3 Do you accomplish what you claim physiologically?

4 How important is this?

It is not my intent to compare different schools of thought or to answer these four questions specifically, but to give a fundamental philosophical concept of handling a nasal problem

It would be an easy matter to discuss this subject if the functional considerations for this surgery were clearcut We owe a great deal of the present knowledge on the physiology of the nose, the nasal mucosa, turbinates and sinuses to the pioneer work of Jonathan Wright, Zwaademaker, Gray, Yates, Hartz, Proetz, Hilding and many others Dr Proetz has said that the normal nose is one that is symptom free, smoothly breathing with slit-like passages[1] It is to him that we owe the understanding of how air currents pass through the nose

On the other hand, such functional alterations as deviation of air currents and direction of flow ascribed to minor anatomical variations of the external nasal pyramid and lobule from the "normal" are not so well known Some ideas have been expressed that traumatic injury which causes flattening of the lobule, and broadening of the base will convert elongated to round nostrils and may then alter air currents and cause symptoms

It has been further expressed that the surgical correction of the lobule, or a deviated pyramid, back to "normal" offers a more normal and harmonious relationship of the various anatomical parts with the objective of breathing better Good anatomical restoration can be quickly determined by comparing a preoperative photograph with the operative result, but one cannot always demonstrate a functional improvement The term function has been used all too loosely, and it may be invoked as a necessary prerequisite for a nasal operation

No one will deny that when the septum obstructs one nostril, or is deviated so as to cause persistent impairment of the airway, surgical correction will give a satisfactory improvement in that patient It does not necessarily follow, however, as far as very external nasal structure is concerned, that important physiological significance need be attached for every architectural aberration from "normal" An expression of an opinion is one thing, but facts documented on objective findings are another

Our problem then, is just what is the normal nose? Are anatomical variations from "normal" abnormal for that patient? The restoration of an obstructed nose to "normal," to some may be more in terms of function, to others an emphasis on cosmetic appearance The latter may be art, but it certainly is not science The rhinologist is concerned with *breathing* or the symptomatic counterpart *nasal obstruction* The restoration of such an airway is his interpretation of what an *adequate* airway should be Since the nose cannot be compared to the highly developed sensory organ, such as the ear or eye, in that we cannot objectively measure what is taking place with respiration, we have no unit of measurement similar to the audiometer and speech test in audiology One interprets the patient's complaint of nasal obstruction on the anatomical findings and can attempt to evaluate it only physiologically This is our one criterion for surgery

Since the impressive work of Proetz,[1] we have not advanced significantly in the field of physiology of the nose to the point where one can relate function with anatomic changes of the entire nose We have made remarkable advances in techniques of *rhinologic surgery in terms of preservation of* turbinates, and nasal mucosa and avoiding radical sinus surgery, but as yet we have no way of measuring nasal function in relation to the lower respiratory tract There are rough methods for measuring airway by breathing upon a cool, polished metal surface, or more refined methods using the nasometer or rhinometer We have taken measurements in various rhinologic diseases where nasal obstruction is present by using the rhinomanometer [2,3] While the latter observations are important, this does not tell us too much about the physiology of breathing or respiration from the nose to the lung Simultaneous observations on the nose and lung from a functional point of view that are being made under controlled laboratory situation, show that there may be some important relationship [4] Why is it that a person with chronic lung disease complains of nasal obstruction, and his symptom of dyspnea is relieved if he can breathe better through the nose? Why does the occasional patient with a badly obstructed nose complain of dyspnea? Such problems are now under investigation

The lack of objectivity in evaluating results (other than cosmetic improvement), the marked variation in complaints in patients with the same anatomic deformities (the psychosomatic and psychiatric aspects), the poor standardization of language among rhinologist and plastic surgeons, and the lack of a unit of measurement which is meaningful in terms of function, make it difficult to communicate with members of the profession, let alone our own colleagues in the field of rhinology This does not mean that we are not trying to explore means of solving these perplexing questions Measurement of architectural changes with growth and by trauma using nasal indices, cephalometric laminography are being investigated at the present time One could assume the view of simplifying function in terms of our knowledge today, that the nose is an airway, air conditioner, filter, humidifier and an olfactory organ

Our problems are quite similar to the field of orthodontia, and we are in a position of trying to establish this phase of rhinology as a science Orthodontia has developed greatly, and after years of precise observations, evidence has accumulated that alterations to the teeth in the child in no way predictably changes the growth of the maxilla or the mandible The restoration of teeth to their proper anatomical relationship cannot, to this day, be related to their function [5]

With such limitations from the accepted functional point of view, it is obvious that the criteria for restoration of the nose to their proper anatomic relationship will have to be explained on other factors The feeling seems to be prevalent that in a patient with a deviated septum or in another instance with a hump, physiologic needs are involved in order to justify the performance of a rhinoplasty While in some instances this is necessary, in many other instances this will not be true

The history of septal surgery reveals that the submucous resection, as advocated by Freer and Killian, was a satisfactory procedure when performed in certain types of deviated and obstructed septum It was the functional and cosmetic complications, perforations, immediate and late saddling, and the retracted columella that was feared Some of us knowingly, up to the 1940's, avoided operating upon a badly twisted septum, particularly when associated with a severely deformed external nasal pyramid with a tendency to sag on the dorsum, for fear of making this worse If we had more courage we still did an incomplete septum operation, and we had difficulty in obtaining a satisfactory airway If the patient asked for a repair of the hump, our deficiencies in handling this problem meant two separate operations, or calling in a plastic surgeon to handle the external nasal problem at the same time

In the deviated nose, it is recognized that one cannot adequately straighten the septum without operating on the external nasal pyramid Versatility of surgical approach for handling such problems is dependent upon the presenting anatomic problem

When the patient complains of unilateral persistent nasal obstruction and the septum obstructs this airway, this can be easily understood, on the other hand, there are just as many patients who have a badly traumatized nose with septal obstruction without any complaints Some atrophy of the interior of the nose may be present, and in this instance surgical correction may be indicated, even without complaints One explains the absence of complaints on the basis of the marked "compensatory process" of the nose Combined septal and external pyramid surgery in another patient with the identical deformity, but with the chief complaint of nasal obstruction may be warranted This patient may have subconsciously wanted his hump removed When one obtains a satisfactory esthetic and cosmetic result, the patient at the conclusion of the post-operative period may only comment, "I can now breathe better" To this day, this is about the only criterion we have for improving this patient from the physiologic point of view Of course, the patient will also be satisfied with his appearance, but one well knows how unreliable it is to depend upon what the patient says about his improvement of breathing and disappearance of many other secondary complaints Infrequently nasal obstruction is still present, in spite of what appears to be an adequate airway and satisfactory cosmetic operation

In some instances we can relate nasal obstruction to deformed upper lateral cartilages ("ballooned or collapse of the upper lateral cartilages"), and surgical techniques have been devised for preserving and correcting the so-called "valve" area Alae collapse in moderate forced inspiration has been seen, and pressure measurements in such instances have been made[3] Here surgical correction will require a total nose operation Total nasal procedures are necessary to correct septal perforation, utilizing the principle of preserving nasal mucosa and rotating tube flaps from under the upper lateral cartilages and from the floor of the nose

The problem of nasal obstruction in many cases is similar to that of the deaf patient Some deaf patients get along very well and do not want or need surgery Likewise, many patients with obviously obstructed septums do not complain of nasal obstruction, nor do they desire surgery

The indications for surgery on the total nose, where the septum is obstructive may be done for one of two reasons

1 To restore a proper airway which may entail cosmetic change Some cosmetic changes may not be requested by the patient Some patients desire this change subconsciously or only if brought to their attention In others cosmetic changes may become evident during or after surgery

2 For cosmetic purposes

It is assumed that the surgeon has taken precautions for not operating upon patients with psychiatric problems It is particularly hazardous to operate upon patients who use their noses as a "crutch"

Certain deformities of the nose, associated with the complaint of nasal obstruction, require surgery upon the septum as well as the external nasal pyramid The prize fighter's nose is a good example In another instance, a twisted external nasal pyramid will prevent a deformed septum from being brought into its proper relationship unless the pyramid is restored to the midline There are other examples The patient may desire only a cosmetic change, and surgery to the septum is necessary if one is to restore the nose to the midline It is recognized that the septum is the main supporting structure of the nose, and procedures which interfere with the septum the least, by gridding, cross-hatching, moving the maxillary crest to the midline, maintaining attachment of mucoperichondrium to one side and suturing the cartilage to the periosteum, it is believed that subtotal removal of the cartilage yields the best results for the septum and cosmetic appearance The more extensive the septum surgery the more difficult it becomes to achieve the desired cosmetic result This is particularly true when the caudal end is removed Immediate saddling may result, but this can be avoided or minimized by subtotal removal

Evaluation of the result is difficult when one is confronted with another type of problem A satisfactory cosmetic result is obtained with an obvious narrowing of the nasal airway The patient is quite happy with the appearance of his nose and he has no complaints of his airway This is sometimes the case when the patient's only presenting complaint is "to have the hump removed"

From the cosmetic point of view it becomes quite apparent, as one performs more of these operations, that one cannot become critical of the cosmetic or functional result obtained by other surgeons Beautiful or mediocre results depend upon the initial problem, furthermore, what looks like a satisfactory result may change with time Following surgery minor trauma may create further architectural deformity to the nose, such as a slight sag of the dorsum and a retraction of the columella What is most important in any given case is that the operator can predict prior to and during the operation what may happen, anticipate such complications and institute appropriate corrective measures

The decision has to be made as to whether to divide the operation into two procedures or whether it may be preferable to combine the operation as a one-stage procedure When one interprets in terms as to what is best for the patient, it is always better to do the operation in one stage if possible I cannot say that the plastic surgeon is concerned with cosmesis alone, and is not interested in the airway in all instances

The position in which the otolaryngologist finds himself is obvious A properly trained rhinologist should be the logical one to cope with a problem of this sort, which is complicated by consideration of improvement in function, cosmetic appearance and social well-being of the patient

HOW DO YOU GO ABOUT MAKING A DIAGNOSIS IN SOME OF THE MORE IMPORTANT RHINOLOGIC DEFORMITIES?[*][†]

HAROLD OWENS, M D ,

Los Angeles, Calif

If any one thing comes to mind it would be to say that making a diagnosis encompasses the whole totality of the nose, both inside and out One cannot merely say that the patient has a hump or a saddle, or the nose deviates We must know all the parts of the nose which produce the deformity and their relation to each other

To arrive at a diagnosis, some arbitrary classification is necessary in order that the surgeon can decide what to do With very few exceptions, one should have the diagnosis pretty well made and the operation mentally done before entering the operating room, however, the diagnosis may not be complete until the patient is anesthetized, or until part of the surgery has uncovered the deformity

A working classification for diagnosis should encompass the following

We are interested in the texture of the skin, whether it be thick and oily, thin and atrophic, or of relatively normal appearance

Thick, oily skin often interferes with proper narrowing of the nose, particularly in the lobular area An extreme example of this is a patient I operated recently who had had both lateral crura removed at a previous surgery and yet the tip was still quite thick, and there was no collapse of the nares Thin, atrophic skin offers problems of contractural deformities after surgery

Septal obstruction with minimal or no external nasal deformity

Obviously this is a personal matter with the physician A Killian or Freer septal procedure is quite adequate, and no external nasal pyramid surgery is needed

Septal obstruction with a dislocation of the caudal end of the septum off the nasal spine and premaxilla into the vestibule with minimal external deformity

This type of deformity will need a subtotal, or total removal of the septum, including a complete mobilization of the caudal end of the septum in the maxillary spine area External pyramid surgery may or may not be indicated

The deviated or twisted nose, usually of traumatic origin

Such a nose has been discussed fully by Huffman and Lierle * This type of nose runs the gamut of diagnostic problems One should note the deformity of the dorsum, or more correctly the sagittal alignment Is it "C" shaped, "S" shaped, or merely deviated Sagittal alignment with other structures of the face and teeth must be considered Other accompanying deformities of the maxilla and teeth might propose the question whether a nose should be replaced in the midline

The nasal bones are usually uneven and asymmetrical, and there may be a hump These conditions are of prime importance in determining hump removal and the level of lateral osteotomies

The relationship of the upper lateral cartilages to the nasal bones, as well as the septum must be determined Often the deviation may involve only the cartilaginous vault and septum, and correction of this area is all that is necessary The upper lateral cartilages may be torn from their attachment to the nasal bones, and present inequalities

The lobule-septal relationship should be noted Is the twisted tip and columella due to septal dislocation or it is due to lobular deformities, particularly the medial crura?

---

*Huffman W C and Lierle Dean M. The Deviated Nose Ann Otol Rhinol and Laryngol Vol 63 Mar 1954

The deviated nose offers the most difficult problems in diagnosis and management, as it requires the mobilization of the septum and external nasal pyramid as complimentary procedures, and in most cases the procedures should be done at the same time This type of nose should be the great concern of the rhinologist

A high narrow nose with an excessively long septum

This type of nose often appears like the tip is hanging on the end of the septum and is most pronounced when the patient smiles or purses the lips One should note the lobular cartilage development, as the lack of projection of the tip may be more apparent than real, and all that is necessary is to decrease the projection of the bony and cartilaginous dorsum, this must include the dorsum of the septum also The nose actually must be widened

We sometimes see a low flat nose with a deviated caudal end of the septum

This type of nose usually results from poor tip development as a result of childhood injury, and most of the pathology will be in the cartilaginous pyramid and septum One should decide whether the cartilaginous saddling is due to loss of septum, atrophy of the upper lateral cartilages, or both

The caudal septum may lie almost at right angles in the nose, or be quite short The latter is often accompanied by a poor maxillary spine and retraction of the naso-labial angle These areas must be carefully studied, as the correction of this deformity usually requires the use of implants of various types

The straight humped nose with or without a drooped tip offers little problem

This is the so-called "cosmetic type" and can be and is handled by a typical Joseph rhinoplasty The only problem is that the septum should be studied, as many of these patients have a good cosmetic result, but they will often tell you they cannot breathe well after the surgery

In any work of this type the psychological diagnosis is important

A large percentage of patients come to us merely because they want cosmetic improvement, although this may not be the presenting complaint Many of these patients have used their nasal problem as a crutch, and we must be careful not to remove this crutch and in so doing possibly convert a psychoneurotic into a psychotic personality

These are just a few of the problems to consider in arriving at a diagnosis of basic nasal deformities

SURGICAL MANAGEMENT PHASE*

RUSSELL I WILLIAMS, M D ,

Cheyenne, Wyo

It is my deep conviction that it is in the best interest of all that one school of thought not be pitted against another It is rather my belief that a discussion will bring to all of us a better understanding of the many facets of this perplexing problem In turn, this will stimulate study and advancement in our field of rhinology

From a broad, philosophical standpoint, our concept considers the total nose, the total relationship of all of the components of the nasal septum, the external nasal pyramid and the internal nose, therefore, the surgical procedure for restoration of proper anatomical relationships must, of necessity, not be limited to only one portion of the nose

We all agree, I believe, that the nasal septum is the main supporting structure of the external nasal pyramid Modifications of the nasal septum create problems in direct proportion to the extent of disturbance of septal totality With extensive disturbance, complications such as saddling, retraction of the columella, and widening of the nose may occur

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication May 26 1958

Many of us have observed these complications during and following surgery It is our belief that these complications should be anticipated, and methods of correction instigated during surgery and, of course, avoided if possible

The versatility of the approach by application of rhinoplastic techniques, not necessarily original, to septum surgery, the preservation of the mucosal flaps and preservation of the skeletal portions, as well as the soft structures, allows the freedom to perform surgery on the nasal septum and the adjacent external nasal pyramid and, in many instances, the internal nose, in one surgical procedure This flexibility, in my experience, allows us to modify and attempt to restore proper relationship of the component structures, and to restore totality to the best of our ability This results in a better nose from a cosmetic aspect, and allows the patient to breathe better

Now, what is a normal nose? Dr Proetz[1] defines the normal nose as follows "The normal nose, or perhaps better the symptom-free, smoothly breathing nose, is characterized by slit-like passages—slit-like everywhere and not merely above, in the olfactory area "

The normal nose is difficult to define because each individual nose has its own peculiar characteristics, structural variations, as well as functional, when we consider the total personality

We are all aware of the tremendous inherent compensatory powers of the nose We are also aware of variations which in one person may produce symptoms, in another they may not, and on clinical examination very little difference can be observed in the structures of the nose

We do feel, however, that there should be a proper relationship of the vestibule to the *os internum* of the nose, and also a proper relationship of the lateral walls of the nose to the nasal septum Here again it is difficult to put into figures just what this relationship is

Studies of the various indices, such as the choanal index and the clinical nasal index, as well as the X-ray nasal index, give us figures which are only relative, but which do help in evaluation to some extent

The attitude of the nostrils plays an important role When the nostrils are round and wide, usually the *os internum* is similar, and an excessive amount of space is usually present between the lateral nasal wall and the nasal septum We are particularly concerned with injuries to the Caucasian nose which may simulate, in many respects, a nose of a different ethnic origin A study of embryology is quite revealing in this respect, neither can anthropological considerations be ignored In reconstructive surgery, an attempt is made to restore these relationships to what we feel is normal for that particular nose

What do we mean by "breathing" and what is an "adequate airway?" My conception of an adequate airway is one in which there is not an excessive amount of space in the nose from the nares to the posterior choana, but rather one in which the passages are comparatively narrow and streamlined One is struck by the fact that the passages are slit-like, and many structural prominences are noted which seem to encroach upon the lumen Breathing is an esthetic sense, and to date we have not found a satisfactory definition

Our knowledge of the exact function of the entire nose or, for that matter, the exact function of any integral portion of the nose is limited We feel that the nose should function as a unit and complement the other structures of the respiratory apparatus To my knowledge, we do not have a satisfactory explanation clearly establishing the nose-lung or the mouth-lung relationship

It is true, that anatomical shapes and relationships may be mistaken for functional necessity, but again as Dr Proetz mentions, the structural variations may be useful as a starting point, providing that we recognize our limitations

Deformities of the external nose are frequently the result of injuries or developmental abnormalities The deformities may involve any or all parts of the external nasal pyramid and the nasal septum

To reconstruct and to restore, or provide totality to the best of our ability, it may be necessary to separate the component structures, either partially or completely, and to move and reposition, or remove and replace the component parts

The modifications of the septum may require conservative or extensive procedures In either case, it should be feasible to accomplish the result with, *1* minimal injury to the mucosa, *2* with rigidity restored to the nasal septum, *3* with sagging of the cartilaginous dorsum prevented, or corrected if it was present or occurred, and *4* with prevention or correction of post-operative or post-traumatic widening of the nose[3]

The exposure to the septum should afford us opportunity to observe adequately and to perform surgery on any portion or portions of the nasal septum

Frequently the septum operation alone is inadequate to restore proper anatomical relationships We will concern ourselves with four categories of deformity which may require attention in conjunction with the septum operation

The first category includes those which require surgery of the lobule in addition to modification of the nasal septum

The second category involves those which require surgery of the external nasal pyramid, but in which a hump removal is not needed A good example of this is the injured nose that is leaning to one side and possibly twisted

The third category comprises those patients who require rather extensive modification of the septum, removal of the hump, modification of the cartilaginous vault and the lobule The classic example is the severely twisted or deviated nose

In the fourth category, the typical boxer's nose would be the classic example This nose would require extensive septum surgery, moving of the bony external nasal pyramid, modifications of the cartilaginous vault and lobule

Preservation of the mucosal flaps and their attachments in entirety or in part, makes the combined operation possible

In addition to this, if possible, preservation of the attachments of the upper lateral cartilages and the attachments of the nasal bones to the septum, help support the nasal pyramid If at all possible, we like to leave a portion of these structures attached to the septum, however, if we have an intact mucosal tunnel, by preservation of the mucosa, the intranasal dressing will serve to hold the structures in position for adequate healing

These attachments may be severed and still preserve the mucosal flap by separating them intraseptally or extranasally The nasal bones may be separated from the bony septum in a similar manner If the septal flaps have not been elevated, it is possible to perform a rather extensive submucosal elevation of the upper lateral cartilages and the undersurfaces of the nasal bones The upper lateral cartilages and nasal bones can also be separated via this approach This procedure is also rewarding in attempting to close a septal perforation by merely continuing the elevation from the undersurface of the upper lateral cartilages and the nasal bones onto the septum, and allowing the mucosa to drop, and also raise the mucosa from the floor of the nose so as to close the hole of the perforation

There are many procedures which can be used to remove the hump Certainly the saw is very effective, the chisel is likewise effective Other methods have been advocated and they are very useful

We believe, however, that by not being bound by any procedure or routine, the flexibility of approach, the preservation of mucosal flaps and the selective use of various techniques, in part or in whole, at will, and as may be indicated in a given circumstance, enables us to gain our ultimate objective

In summary, our concept is in no way original It involves the application of rhinoplastic techniques, providing us with a versatile approach to many variable problems encountered in reconstructive surgery of the nose

Preservation of the mucosal flaps and preservation and modification of the structures provide us with a method whereby restoration of anatomical relationships can be accomplished and the totality of the nose restored to as near normal as possible

We do not know all the answers to the surgical phase Neither do we know the answers to the functional phase We are critically reviewing our results and hope that this will lead us to the solution of the many problems with which we are faced

DISCUSSION

Irving B Goldman M D (New York, N Y) I am in accord with the basic philosophy of all the panelists and agree that total reconstruction of the nose be left to the general plastic surgeon where restoration is primary and function secondary The problem of nasal physiology I shall leave to Dr Proetz I should prefer to consider the practical aspects of rhinoplasty

Before I do so I should like to discuss the antagonistic attitude to the term "rhinoplasty' by many physicians and surgeons The various synonyms require reevaluation of what constitutes the correct term for "cosmetic" plastic surgery of the nose

Some of the names and phrases indicating the same procedure are rhinoplasty nasoplasty nasoseptopexy reconstruction of the nose and reconstruction of the nasal pyramid Some surgeons classify the same procedure under three different headings This is confusing to the operating room staff as well as to the assisting resident surgeons as a matter of fact in some hospitals the use of the word rhinoplasty" is forbidden—taboo In filling out charts, the surgeon must state he performed a nasal reconstruction when actually he had carried out a corrective rhinoplasty

Why should we at the present time conceal correction of external nasal deformities which are so frequently associated with internal ones under such a great variety of nomenclature? The term rhinoplasty' should be used today without verbal camouflage The patient understands this terminology much more than the phrase 'reconstruction of the nasal pyramid' Many a patient spontaneously declares that "I have had a rhinoplasty '

The term "rhinoplasty' is derived from the Greek "rhis'—nose and "plassein'—to form It is obvious then that a change in the form of the nose or any component part, constitutes a rhinoplasty It does not matter whether it is restorative corrective cosmetic, complete or incomplete In other words it is the correct term for the operation despite its questionable implications

It has been my policy when teaching corrective surgery of the external nose to use the term "rhinoplasty " I was greatly surprised to learn that physicians from different parts of the country objected to the use of this word The objection was not personal, but rather to the effect this would have on their medical colleagues It is obvious that in the various parts of the country they must conform to the usage of the term "rhinoplasty " It is a simple inclusive one Its ancient implications have been disspelled It has taken on a dignified and well merited status The art has reached a high degree of development The scientific journals welcome articles on rhinoplasty, and medical societies accept papers on rhinoplasty, indicating that the term is becoming a widely acceptable one

The basis of all corrective rhinoplastic procedures is preoperative diagnosis Analysis, relying on the rigid use of measurements, laws, and formulas, cannot supplant taste, judgment, and experience, essential in fine nasal plastic surgery As there are no two noses alike, no set of rules can be drafted that would fit all shapes of noses Certain principles when applied to every nose, will disclose its abnormalities The routine analysis considers forms, proportion, and harmony in relation of the nose to the rest of the facial features The fundamental artistic cannons must be fully understood by the rhinoplastic surgeon who is seeking a good esthetic as well as functional result

In planning to correct any nasal deformity, careful attention must also be given to the nasal septum which has a great bearing on the method of operation Is the septum a minor or major factor in the rhinoplasty? What should be the method of approach? The intranasal examination is supplemented by palpation of the septum This may reveal thickness and distortions

Planning begins with visual examination Is the correction feasible? Is the operation corrective or does it require much reconstruction, *e g* a harelip nose bifid nose, a dish face deformity? Has the operation limitations, *e g*, a short columella or an atrophic lobule, or very thick skin? The surgeon must plan to compensate, where to over or under correct

The visual examination is followed by palpation to determine the size, position, and character of the nasal bones, the form and position of the upper lateral cartilages, the texture of the skin, and shape of the lower lateral cartilages

The nasofrontal angle may not have a glabellar depression Palpation may reveal a thick procerus muscle A roentgenogram of this region is advisable to determine the depth of the bone and the relation to the frontal sinuses

Palpation at the base of the nose in case of a naso labial web may reveal a projecting nasal spine or the curved overhanging margin of the septal cartilage A recessed naso labial angle may be more retracted when pressure is made with the examiner's finger or instrument A retrusion caused by absence of septum contraindicates a complete transfixion on the other hand, restoration of the naso labial angle in the congenital variety requires a complete separation of the membranous septum from its septal attachment for mobilization necessary for reconstruction

Properly scaled photographs with a study of the nasal components in relation to the face forehead and chin are important for analysis diagnosis medicolegal and clinical records Each view lateral frontal nasal, may reveal a feature requiring correction Nasal deviations and irregularities are better shown in color photography

Photography is also important because it serves as a common meeting ground between the patient and the doctor By reversing the photo and placing it in an illuminating box the surgeon can easily draw the profile line which he considers esthetic This may or may not meet with the patient s approval and is a good way to avoid pitfalls of operating upon a neurotic individual who seeks a nose not compatible or attainable with his or her features

The diagnosis of a nose requiring revision of a rhinoplasty although subjected to analysis must be considered to be an exploratory operation Not until all of the parts are surgically exposed manipulated and reassembled can the surgeon make his precise decision for correction *e g* in many patients I found that complete osteotomies had not been performed

The wide nose creates problems because of the tendency to recurrence If it is present as a racial feature as in the Negro an implant or graft, as a rule is required without performing an osteotomy Otherwise if the lateral walls are of insufficient height to cover the vault one must decide whether an osteotomy and repositioning of the nasal processes of the maxillae has to be carried out prior to dorsal implantation

Width caused by excessive thickness of the nasal bones requires radical excision of these structures mesially and laterally I prefer to depress the nasal processes on mesial shifting after osteotomy in order that the septum perpendicular plate and nasal spine of the frontal project in the midline and become the summit of the nasal pyramid producing a narrow nose Ventral surfaces of a thick septum are thinned and redundant tissues such as mucous membranes lying between the bones and upper lateral cartilages are removed

Correction of a nasal deformity associated with a deviated septum frequently presents surgical problems These range from timing of the septal operation to the variety of the operation to be performed The questions which usually arise are Should septal correction be carried out prior during or after the rhinoplasty? If a deviated septum is present which operation should be performed to alleviate nasal obstruction and permit correct alignment of the nasal structures? Will a contemplated nasal profile and columella be placed in jeopardy with the production of a saddle of the upper cartilaginous vault a dropping of the lower cartilaginous vault or collapse of the entire nose?

Complete resection of the septum and replacing it in part based on a ' tie-in of the upper lateral cartilages with the septum has not proved reliable It was believed that the former structures alone could support the cartilaginous nasal dorsum because they were an integral part of the septum and were attached subjacently to the nasal bones and the frontal processes of the maxillae They were thus able to furnish adequate stability to maintain profile projection under static conditions Nevertheless removal of the cartilage and insertion of strips or resected cartilage did not prevent secondary cicatricial contraction and did not prevent an external dorsal depression or columellar retraction The cartilaginous implants between the mucoperichondrial layers frequently became twisted often to a degree that produced nasal obstruction

Subtotal or complete resection of septal cartilage with insertion of implants between the mucoperichondrial layers may be required in a depressed variety of septal deformity The sunken or fragmented septum cannot be shifted into its normal position and must be sacrificed As a rule however this kind of septal deflection is already accompanied by an external saddling deformity This would require insertion of dorsal grafts under any circumstances

The procedure I prefer restores the normal anatomic relationship of the deflected septum without or with minimal sacrifice of its structures The principles of the operation consist in mobilization of the septum to the midline by use of pedicle flaps of caudal septal sections, central replacement of posterior osseo-cartilaginous section resection, if necessary, of a small cartilaginous or bony bulge which can be obstructive No columellar retraction develops with this technique Straightening the caudal distortion, and thus elongating the septum, frequently corrects the columellar retraction Neither drooping of the nasal tip nor saddling occurs The septum gives the nose the same relative support after it heals as one that has not been operated upon It is, therefore, not so vulnerable to trauma in which septal components have been widely resected

Both sides of the caudal part as well as the remainder of the septum must be freed A unilateral or hemitransfixion does not liberate the distorted mucoperichondrial layers and thus prevents correct alignment of the replaced septal parts Postoperatively, healing is interfered with, owing to traction of the unelevated mucoperichondrium In consequence, there often is recurrence of the deformity This becomes obvious if one considers the pathogenesis of the caudal deformities Fracture of the cartilage occurs, and in the process of repair a fibrous invasion takes place between both sides of the mucoperichondrium and the cartilaginous fragments, and/or overriding fragments become intermingled with the mucoperichondrium

Experience has shown a rhinoplasty following a previously adequately corrected septum may also be followed by collapse of the nasal dorsum This occurs after osteotomy and meatal shifting of the nasal processes The remaining osseo-cartilaginous structures, despite supportive intranasal packing are unable to support the nasal dorsum The earlier rhinoplastic surgeons through sad experiences aware of this potential hazard, were wise to retain as much of the septum as possible in the carrying out of a concurrent rhinoplasty Obviously, there were many examples where nasal obstruction had to be corrected subsequently

The recent trend has been to perform a simultaneous rhinoplasty and submucous resection The septal correction whereby the structures are mobilized but are essentially intact is, in my opinion, the answer to the combined operation The upper lateral cartilages can be cut from the septum and appropriately trimmed

A combined rhinoplasty and submucous resection is also preferred by the patient for economic reasons for convenience and for time saving factors and the avoidance of two hospital admissions The rhinoplasty and an adequately performed septum operation can be concurrently accomplished with a good functional and assured esthetic result This is of benefit to the patient and of advantage to the surgeon

Certain nasal deformities require multiple procedures such as in children with saddle noses caused by trauma and/or infections resulting in loss of septal support Retrusion of the middle third of the face may form owing to lack of development Preserved cartilage implants reinserted until full nasal growth helps build up and raise the nose Harmless nonabsorbably foreign material may be more useful I inserted a large piece of ivory in a young patient whom I observed for ten years The original ivory implant was so adequate that at the age of adolescence, she refused further surgery and the nose was in good proportion to the rest of the face Today I would consider using an acrylic or polyethylene implant in a child in order to avoid many operations

Among the other conditions is the short columella This is essentially a skin condition and elongating the inadequate columellar skin without manifest scarring is difficult. After insertion of an implant on the columella reinsertion and another procedure to lengthen it may be necessary

The unusually small underdeveloped lobule often accompanied by flaccid crura is difficult to model despite the insertion of implants This is also a skin problem, as it cannot provide an adequate bed for the necessary implant. If the profile line cannot be lowered to meet the apex of the tip without producing a dorsal depression increase in size of the lobule can be attained only by an implant or graft, after reconstruction of the soft parts

Occasionally the surgeon attempts a rhinoplasty in which he removes the hump without modelling the tip or correcting the tip without modifying the osseous or upper cartilaginous vaults A non satisfactory result will require a revision with insertion of the omitted operative step Flaring alae not corrected at the time of the rhinoplasty may require correction at a later date.

It is well known that among the other nasal conditions frequently requiring more than one operation are the harelip nose nasal atresia dish face deformity and bifid nose

Healing plays an esssential part in the final rhinoplastic result. It is common knowledge that a nose which appears perfect at the end of a rhinoplasty or when the external dressing is removed may assume an undesirable form as early as the tenth post-operative day One may be asked What is the nature of this process in tissue repair which militates against the welfare of the patient? Rhinoplastic surgeons have become aware of the risks of oily thick and pre-acne rosacea varieties of the skin nevertheless sooner or later the surgeon operates upon such patient and the skin behaves badly as healing takes place producing an unsatisfactory esthetic result Ideal situations for rhinoplasty are not always encountered

The time has come for the otolaryngologist interested in rhinoplastic surgery not to confine his thoughts solely to the technique or diagnosis If he is to continue to advance rhinoplasty he must undertake research in the process of skin healing for on this hinges the more acceptable results

The panelists have been using the word crutch' To attain recognition of his position in rhinoplasty the otolaryngologist has had to pave the way by exploiting various representations like nasal physiology for example The time is approphiate for the otolaryngologist to refrain from hiding behind subterfuge of disturbed nasal physiology as the single indication for his interest in rhinoplasty It is generally conceded that the nasal septum requires correction in from 60 to 70 per cent of all rhinoplasties rhinologic training the skillful use of the head mirror or headlight intranasal tools and correct manipulation are the *sine qua non* for an overall cosmetic rhinoplasty The time has come for the rhinologist to declare that he is rightfully entitled to correct a nasal deformity for cosmetic and psychologic reasons It should be made clear that a rhinoplasty is not performed solely for the preservation and restoration of nasal function If a functional cause exists this of course adds to the necessity for operative intervention

Finally it is my belief that too much emphasis has been placed on the ill-effects of intranasal incisions and preservation of the valve areas Patients complain of nasal obstruction following a rhinoplasty when excessive vestibular skin has been sacrificed causing synechase between the lateral crura and septum Various degrees of alar collapse causing disturbance in breathing accompany the pinched tip Although the septum and upper lateral cartilages caudally form the so-called valve' severance of these structures in a rhinoplasty is not followed by disturbed physiology after reattachment on healing whether the excessive cartilage is removed *in toto* or submucosally Evidently, the scar tissue formed at the valve region does not appear to interfere with its presumptive function It is only when the redundant protruding upper lateral cartilage is not removed that it acts mechanically to obstruct the airway producing nasal obstruction With the removal of the excessive projection, adequate airway is restored The important structure in rhinoplasty requiring preservation is the membranous septum Sacrifice may cause columellar retraction and loss of service should a strut be required

Arthur W Proetz, M D, (St Louis Mo) I have listened with great interest and attention to the presentations of my colleagues and have been at some pains to read as much of their writings as I could find since my assignment was directed to the physiological aspects of the subject and not too much has been said on that score during the preceding discussions

I have also brought along a specimen Forty five years ago this nose had a terrific spur removed from its septum through a submucous resection, and parts of both inferior turbinates were trimmed away with scissors Before and after the operation the ridge pole ran in two directions and ended in an unsightly lump—and still does Whether this deformity blighted its owner with an inferiority complex I must leave to you Physiologically it is perfect

There has been much controversy over the propriety of combined operations on the nose, and before launching on my theme I should like to contribute one or two views from the sidelines

1 If a nasal inlet needs widening or narrowing, or the septum straightening, and besides this the profile needs fixing—if in short, combined operations are indicated, it seems axiomatic that they should be done at one time and by one operator If done in two stages, the second operator is almost bound to be hampered by scar tissue and by someone else s leavings which are not part of his plan, and the patient suffers double pain and expense

2 If Dr John Smith is a competent surgeon familiar with the specific anatomy, physiology, pathology and surgery of all the parts concerned and has the necessary judgment, based on experience then, and only then, he is the man for the job All other qualifications combined cannot compensate for the lack of any one of these After that, whether Dr Smith is called a plastic surgeon or a rhinologist or a proctologist, could not matter less to the patient or his tissues Jurisdictional disputes are as transparently commercial in this field as they are in others

3 Let us honestly face the distinction between physiology and cosmetology and never not ever confuse the two for the purpose of making any surgeon or any operation seem more respectable or more attractive or for any other reason

And so to work

With the surgical procedures discussed here and their purpose, I have nothing but agreement and approval in particular with some of Dr Owens' straightforward remarks within the limits of my experience On physiological grounds I fear we part In all frankness I cannot get away from the feeling that there is a good deal of groping for some new scientific background to fit surgical procedures already current which to me has all the disadvantages of walking backward and has in the past led to too many untenable hypotheses

We all agree that as stated a nose that isn t working needs fixing

As to what to do and how far to go Dr Ogura laments the lack of any concise standardizing measurements such as we have for sight and hearing I doubt that they would be of much help if we had them for as Dr Ogura himself observes the two cases are scarcely parellel Only the olfactory portion of the nose is a special sense organ like the eye and the ear and the sense of smell has not been brought up in this discussion We are dealing with something much simpler and less critical I have no doubt that anthropologists have scientifically measured and classified our hands and feet (they come in all sizes shapes and colors) but while anthropological indices are helpful in such projects as tracing our remote ancestors we do not use them to find out how we all run or dance or write or who can stretch an octave It simply isn t that complicated

We know that one asymmetry here is often compensated by another asymmetry there and put together they make a healthy nose That also is not too difficult to determine

Although the shape of the nostril is less important than its size and direction even in the last much latitude is permissible and minor variations in the angle of tilt are of small consequence—physiologically that is

From the standpoint of warming and humidification the vestibule is practically negligible being too small and made of the wrong things

The submucous resection of Killian and Freer has been mentioned as a satisfactory procedure when performed in certain types of deviated and obstructed septums" but fears are expressed regarding cosmetic complications perforations saddling and retracted columellae as though these were common accidents In incompetent hands they may be but that is true of any operation Perforations we have all had most of them negligible unless they whistled in which case they were promptly repaired

So long as I can remember rhinologists worthy of the name have diversified the standard procedures to fit cases and have variously revised faulty passages without ado It is my observation that those who have had many unsatisfactory results from septal surgery have not been very good at it. While certainly not implying that complaints from the patient are the only justification for operating I do not quite follow Dr Ogura when he says (I copy him verbatim) "The feeling seems to be prevalent that a patient with a deviated septum or in another instance with a hump physiologic needs are in order to justify the performance of a rhinoplasty While in some instances this is necessary in many other instances this will not be true Unless Dr Ogura is talking now of pure cosmetics I wonder what these many other instances could be

I cannot agree that as has been stated this morning our knowledge of the exact function of the nose is unduly limited Merely because a function is simple we need not feel obliged to postulate something more complicated and as yet unknown I would say that our present knowledge serves us very well and in the same breath enthusiastically encourages new discoveries and conceptions but I would insist that they rest upon firm scientific foundations and I should prefer that they were practical

On last Friday I had a letter from Dr Williams saying that 'for reasons of time limitation he had decided to delete four pages of his presentation By some unfortunate coincidence these were the four pages dealing with the physiological aspects which I am here to discuss

As however they do constitute some of his thinking and that of his group and I do have the time I should like to quote some of the material he was obliged to skip and to bring it up for discussion since I think it too important to overlook.

of these structures in a rhinoplasty is not followed by disturbed physiology after reattachment on healing whether the excessive cartilage is removed *in toto* or submucosally Evidently, the scar tissue formed at the valve region does not appear to interfere with its presumptive function It is only when the redundant protruding upper lateral cartilage is not removed that it acts mechanically to obstruct the airway producing nasal obstruction With the removal of the excessive projection, adequate airway is restored The important structure in rhinoplasty requiring preservation is the membranous septum Sacrifice may cause columellar retraction and loss of service should a strut be required

Arthur W Proetz, M D (St Louis Mo) I have listened with great interest and attention to the presentations of my colleagues and have been at some pains to read as much of their writings as I could find since my assignment was directed to the physiological aspects of the subject and not too much has been said on that score during the preceding discussions

I have also brought along a specimen Forty five years ago this nose had a terrific spur removed from its septum through a submucous resection and parts of both inferior turbinates were trimmed away with scissors Before and after the operation the ridge-pole ran in two directions and ended in an unsightly lump—and still does Whether this deformity blighted its owner with an inferiority complex I must leave to you Physiologically it is perfect.

There has been much controversy over the propriety of combined operations on the nose, and before launching on my theme, I should like to contribute one or two views from the sidelines

1 If a nasal inlet needs widening or narrowing or the septum straightening, *and besides this the profile needs fixing—if, in short,* combined operations are indicated, it seems axiomatic that they should be done at one time and by one operator If done in two stages, the second operator is almost bound to be hampered by scar tissue and by someone else's leavings which are not part of his plan, and the patient suffers double pain and expense

2 If Dr John Smith is a competent surgeon familiar with the specific anatomy physiology, pathology and surgery of all the parts concerned, and has the necessary judgment based on experience then and only then he is the man for the job All other qualifications combined cannot compensate for the lack of any one of these After that whether Dr Smith is called a plastic surgeon or a rhinologist or a proctologist could not matter less to the patient or his tissues Jurisdictional disputes are as transparently commercial in this field as they are in others

3 Let us honestly face the distinction between physiology and cosmetology and never, not ever confuse the two for the purpose of making any surgeon or any operation seem more respectable' or more attractive or for any other reason

And so to work

With the surgical procedures discussed here and their purpose, I have nothing but agreement and approval in particular with some of Dr Owens straightforward remarks within the limits of my experience On physiological grounds I fear we part In all frankness I cannot get away from the feeling that there is a good deal of groping for some new scientific background to fit surgical procedures already current, which to me has all the disadvantages of walking backward and has in the past led to too many untenable hypotheses

We all agree that as stated a nose that isn t working needs fixing

As to what to do and how far to go Dr Ogura laments the lack of any concise standardizing measurements such as we have for sight and hearing I doubt that they would be of much help if we had them for as Dr Ogura himself observes the two cases are scarcely parellel Only the olfactory portion of the nose is a special sense organ like the eye and the ear and the sense of smell has not been brought up in this discussion We are dealing with something much simpler and less critical I have no doubt that anthropologists have scientifically measured and classified our hands and feet (they come in all sizes shapes and colors) but while anthropological indices are helpful in such projects as tracing our remote ancestors we do not use them to find out how we all run or dance or write or who can stretch an octave It simply isn t that complicated

We know that one asymmetry here is often compensated by another asymmetry there and put together they make a healthy nose That also is not too difficult to determine

Although the shape of the nostril is less important than its size and direction even in the last much latitude is permissible and minor variations in the angle of tilt are of small consequence—physiologically that is

From the standpoint of warming and humidification the vestibule is practically negligible being too small and made of the wrong things

The submucous resection of Killian and Freer has been mentioned as a satisfactory procedure when performed in certain types of deviated and obstructed septums' but fears are expressed regarding cosmetic complications perforations saddling and retracted columellae as though these were common accidents In incompetent hands they may be but that is true of any operation Perforations we have all had most of them negligible unless they whistled in which case they were promptly repaired

So long as I can remember rhinologists worthy of the name have diversified the standard procedures to fit cases and have variously revised faulty passages without ado It is my observation that those who have had many unsatisfactory results from septal surgery have not been very good at it While certainly not implying that complaints from the patient are the only justification for operating I do not quite follow Dr Ogura when he says (I copy him verbatim) 'The feeling seems to be prevalent that a patient with a deviated septum or in another instance with a hump physiologic needs are in order to justify the performance of a rhinoplasty While in some instances this is necessary in many other instances this will not be true ' Unless Dr Ogura is talking now of pure cosmetics I wonder what these many 'other instances could be

I cannot agree that, as has been stated this morning our knowledge of the exact function of the nose is unduly limited Merely because a func tion is simple we need not feel obliged to postulate something more complicated and as yet unknown I would say that our present knowledge serves us very well and in the same breath enthusiastically encourages new discoveries and conceptions but I would insist that they rest upon firm scientific foundations and I should prefer that they were practical

On last Friday I had a letter from Dr Williams saying that for reasons of time limitation he had decided to delete four pages of his presentation By some unfortunate coincidence these were the four pages dealing with the physiological aspects which I am here to discuss

As however they do constitute some of his thinking and that of his group and I do have the time I should like to quote some of the material he was obliged to skip and to bring it up for discussion since I think it too important to overlook of these structures in a rhinoplasty is not followed by disturbed physiology after reattachment on healing whether the excessive cartilage is removed *in toto* or submucosally. Evidently, the scar tissue formed at the valve region does not appear to interfere with its presumptive function. It is only when the redundant protruding upper lateral cartilage is not removed that it acts mechanically to obstruct the airway producing nasal obstruction. With the removal of the excessive projection, adequate airway is restored. The important structure in rhinoplasty requiring preservation is the membranous septum. Sacrifice may cause columellar retraction and loss of service should a strut be required.

Arthur W. Proetz, M.D., (St. Louis, Mo.): I have listened with great interest and attention to the presentations of my colleagues and have been at some pains to read as much of their writings as I could find since my assignment was directed to the physiological aspects of the subject and not too much has been said on that score during the preceding discussions.

I have also brought along a specimen. Forty-five years ago this nose had a terrific spur removed from its septum, through a submucous resection, and parts of both inferior turbinates were trimmed away with scissors. Before and after the operation the ridgepole ran in two directions and ended in an unsightly lump—and still does. Whether this deformity blighted its owner with an inferiority complex I must leave to you. Physiologically it is perfect.

There has been much controversy over the propriety of combined operations on the nose, and before launching on my theme, I should like to contribute one or two views from the sidelines.

1. If a nasal inlet needs widening or narrowing, or the septum straightening, and besides this the profile needs fixing—if, in short, combined operations are indicated, it seems axiomatic that they should be done at one time and by one operator. If done in two stages, the second operator is almost bound to be hampered by scar tissue and by someone else's leavings which are not part of his plan, and the patient suffers double pain and expense.

2. If Dr. John Smith is a competent surgeon familiar with the specific anatomy, physiology, pathology and surgery of all the parts concerned and has the necessary judgment based on experience then and only then, he is the man for the job. All other qualifications combined cannot compensate for the lack of any one of these. After that, whether Dr. Smith is called a plastic surgeon, or a rhinologist, or a proctologist could not matter less to the patient or his tissues. Jurisdictional disputes are as transparently commercial in this field as they are in others.

3. Let us honestly face the distinction between physiology and cosmetology and never, not ever confuse the two for the purpose of making any surgeon or any operation seem more respectable or more attractive or for any other reason.

And so to work.

With the surgical procedures discussed here and their purpose I have nothing but agreement and approval in particular with some of Dr. Owens' straightforward remarks within the limits of my experience. On physiological grounds I fear we part. In all frankness I cannot get away from the feeling that there is a good deal of groping for some new scientific background to fit surgical procedures already current which to me has all the disadvantages of walking backward and has in the past led to too many untenable hypotheses.

We all agree that as stated, a nose that isn't working needs fixing which is the vestibule has obsolutely nothing to do with it It could be replaced by a little round pipe or big square tank or a slide trombone So long as the hole is pointed in the right direction, it does not make a bit of difference what comes before To point the airstream below the rostrum of the sphenoid a major distortion would be required a flattened nose, a saddle nose, or something else that is pretty easily diagnosed If the jet veers to one side enough to create a dry spot, and the dry spot can be shown to make trouble it should be straightened I believe it is as simple as that.

SEVENTH INTERNATIONAL CONGRESS OF BRONCHOESOPHAGOLOGY

The Seventh International Congress of Bronchoesophagology will be held at Kyoto (Japan) University, September 12-14, 1958, under the direction of Prof Mituharu Goto, M D, Otorhinolaryngological Clinic, Kyoto University Hospital, Kyoto, Japan

A registration fee of $25 00 U S.A. will be charged all physicians and a fee of $10 00 for wives or non-medical guests Registered members are admitted free to banquet, receptions and sightseeing tours

If I misquote Dr Williams in anything, I hope he will stop me

Dr Williams stated 'We are aware of variations which in one person may produce symptoms, in another they may not, and on clinical examination very little difference can be observed in the structures of the nose" Again, I wonder whether I interpret him correctly as proposing surgery on these symptomless cases when he continues "We do feel, however, that there should be a proper relationship of the vestibule to the os internum of the nose, and also a proper relationship of the lateral walls of the nose to the nasal septum" I hope not, since he admits in his next sentence that "it is difficult to put into figures just what this relationship is" and that "the various indices, such as the choanal index, and the clinical nasal index, as well as the X ray nasal index gives us figures which are only relative"

I cannot say whether I agree with some of the other statements or not, since I do not understand just what they are meant to imply For eyample "When the nostrils are round and wide, usually the os internum is similar and an excessive amount of space is usually present between the lateral nasal wall and the nasal septum" Excessive by what standards? Injurious? Symptom producing? Or merely larger than *some ethnological mean?* "We are particularly concerned with injuries to the Caucasian nose which may simulate, in many respects a nose of different ethnic origin" Does that mean that if my nose had the characteristics of a negroid nose it would not serve me as well as it would my African friend next door? Presumably it is meant that such a nose would be disproportionate to the rest of my Teutonic cranium and that its function would thereby be upset This could be sometimes, but the ethnical reference seems remote Dr Williams adds "A study of embryology is quite revealing in this respect," but he does not tell us what it reveals, or what is its surgical importance

"Neither can anthropologic considerations be ignored," but he does ignore them in his discussion and it would have been interesting to know what they are and what they show

Still on the physiology of the nostrils, I can summarize only by saying that I regard it as much more definite and much simpler than it is being painted To put it in one sentence "The function of the nostrils and the pyramid is to pass an adequate amount of air in a generally upward direction into the nose' I say 'generally" upward because the angle is not very critical

There have been recurring refrences to "philosophies, concepts, indices, ethnics" "the disturbance of septal totality" and so on It all sounds very profound and very scientific, and very new, frankly I cannot see it as being very much of any of these When the fury of the tempest dies away it all ends up in a teapot and the teapot is a familiar piece of antique crockery described by Charles Bell a century ago and by others since

The teapot also is a fine example of the vestibule and how it works If you will permit me, I will make a sketch of it (drawing on the board) The teapot is a hollow object spouting a jet The nature of this jet is determined by the size and shape and direction of the opening at the tip and by nothing else The teapot represents the vestibule and the opening represents what one has lately been calling the os internum which by the way my dictionary defines as "the uterine end of an oviduct"

So long as the jet is directed *generally* upward things are all right. It can be almost anywhere between straight up and straight back so long as it does not fall below the rostrum of the sphenoid and bypass the functional part of the nose altogether The size and shape of this teapot, which is the vestibule has absolutely nothing to do with it It could be replaced by a little round pipe or big square tank or a slide trombone So long as the hole is pointed in the right direction it does not make a bit of difference what comes before To point the airstream below the rostrum of the sphenoid a major distortion would be required a flattened nose a saddle nose or something else that is pretty easily diagnosed If the jet veers to one side enough to create a dry spot, and the dry spot can be shown to make trouble it should be straightened I believe it is as simple as that.

CANCER OF THE NASOPHARYNX AND OROPHARYNX

JEROME A HILGER, M D
St Paul, Minn

An enlarged lymph node in the cervical area is frequently a metastasis from a quiet primary carcinoma The diagnosis is properly made by identifying the primary lesion, not by removing or sampling the node If thorough visual and tactile search reveals no primary, multiple biopsies from the innocent appearing nasopharynx may reveal it In addition a submental-occipital view of the skull base should be obtained An infiltration arising from the lateral nasopharynx can produce distinctive alterations in this view, though nothing is seen, felt or obtained by biopsy in the nasopharynx[1] In any case, this sequence properly precedes direct approach to the nodal enlargement

When the latter is necessary the use of the needle biopsy

offers many advantages over node excision A new needle has recently been described for this purpose[2]

CANCER OF THE NASOPHARYNX

Cancer of the nasopharynx constitutes 0 4 per cent of all cancer in occidental countries,[3] it constitutes 5 per cent of cancer in China[4] The reason for the difference is not known In order of frequency the symptoms of cancer of the nasopharynx are *1* Enlarged gland or glands in the neck, *2* nasal symptoms, obstruction or epistaxis, *3* Vth nerve pain (in clinical analysis of this symptom a routine submental-occipital X-ray view is a useful addition to clinical examination), *4* signs of auditory tubal obstruction, and, *5* paralysis of cranial nerves other than the Vth cranial nerve

In 50 per cent of cancers of the nasopharynx a metastatic node is the first evidence of disease. In 70 to 80 per cent metastatic nodes are present at the time of diagnosis A high posterior cervical triangle node is the most frequent individual nodal involvement[5]

The average patient waits three months after the appearance of first symptoms of cancer of the nasopharynx before consulting a doctor, the correct diagnosis is not made for an additional four months in the average case, and proper therapy is not applied to the average cancer of the nasopharynx until ten months have elapsed from initial symptoms[6] While 10 to 15 per cent of cases present cranial nerve paralyses as the first symptom of disease, nerve involvement has increased to 20 to 25 per cent of all cases by the time correct treatment is initiated[3]

Lack of microscopic differentiation of a high percentage of nasopharyngeal cancers has resulted in varied pathologic classifications Division into squamous cell epitheliomas, lymphoepitheliomas, and lymphosarcomas delineates treatment and prognosis satisfactorily The above order is that of frequency of occurrence[1] Favorable prognosis, however, is in reverse order Thirty to 50 per cent of lymphosarcomata can be expected to be well five years after treatment This is reduced to 25 per cent with lymphoepitheliomas and to 15 per cent with squamous cell carcinoma [1,5,7]

Cranial nerve involvement, decalcification of the skull base, and presence of metastases are ominous prognostic signs in a given case [7]

Cancer of the nasopharynx cannot be cured by surgical methods Principal dependence is on radiation therapy There is a wide variance in methods of applying it

Since diagnosis centers on the surgical techniques of the otolaryngologist he frequently maintains an interest at the therapy level This is usually expressed in terms of surgical exposure of the tumor, as with palatal fenestration[8] or partial septectomy,[9] in fulguration of the tumor, or in techniques of intracavitary radiant applicators [10,11] The primary tumor that persists to kill the patient, however, is that cell most remote from the cavity and from fulguration and local radiant sources For more complete blanketing and homogeneous distribution through the tumor zone it is probably true that external, multiple-port irradiation most nearly fulfills the ideal [7,12,13] Combinations of intracavitary and external ray sources have no advantage and some disadvantage to deliverance of the total dose by multiple external ports as the primary treatment The intracavitary techniques are most applicable for tumor persistence where the skin will tolerate no further external irradiation [9]

Because of skeletal parts that must be traversed by the beam, the increased penetration of the Gamma rays of cobalt 60 are preferable for external treatment to the radiations of the more universally available 250 kilovolt equipment

Since 70 to 80 per cent of cancers of the nasopharynx have or develop cervical nodal metastases treatment of the anterior and posterior cervical triangles should be included with treatment of the primary Because over 30 per cent of cases metastasize eventually to the contralateral side also, the supra-omohyoid cervical lymphatics should be included on that side If metastasis is already present on this second side the field should be extended to the clavicle [13]

Total irradiation dosage with any technique is a factor of individual response Here the real skill of the radiation therapist becomes apparent The otolaryngologist serves best who is most critical in his selection of a therapist

The usefulness of neck dissection for persistent metastatic node involvement has to be analyzed in the light of two considerations *1* The uncertainty of primary control, *2* the unresectable lateral pharyngeal node, the highest node in the chain A case in this predicament requires the application of the most thorough irradiation effort to the metastasis before surgical resort[14 15]

Persistence of primary tumor, as evidenced by reappearance after a quiet interval, should be pursued by additional irradiation The technique may have to be modified by skin tolerance This may be carried to a third and a fourth series Thus, though "cure" and "survival" are not synonymous, the latter is desirable to the limit of a reasonably comfortable life In one small series the three year survival was increased from 21 per cent to 57 per cent by these persistent tactics[16]

CARCINOMA OF THE OROPHARYNX

The oropharynx is that anatomic segment extending from the arch of the atlas to the hyoid bone Its anterior limit is the buccopharyngeal sphincter comprised of anterior faucial pillars and soft palate, and the base of the tongue to which the sphincter closes Malignancy in the area occurs principally as squamous carcinoma of the soft palate, squamous carcinoma, lymphoepithelioma, and lymphosarcoma of the tonsil, squamous carcinoma, lymphoepithelioma, and lymphosarcoma of the lingual base, and squamous carcinoma of the linguo-tonsillar and glosso-pharyngeal sulcus and vallecula Malignancy of the posterior oropharyngeal wall and of the lateral wall posterior to the posterior faucial pillar is uncommon

Cancer of the Soft Palate

Carcinoma of the soft palate is typically squamous and differentiated True primary involvement, as distinguished from extension of tonsillar cancer is not common Metastasis, when it occurs, is to the upper deep cervical nodes External irradiation therapy may be combined with irradiation through the open mouth Neck dissection should be done for uncontrolled metastases if the primary appears controlled The *five-year control rate through these treatment methods* approximates 25 per cent

Cancer of the Tonsil

Cancer of the tonsil comprises 2 to 3 per cent of all cancer Only cancer of the laryngopharynx is more common in the upper respiratory tract Lymphosarcoma occurs on an average at an earlier age than does lymphepithelioma or squamous carcinoma The latter occurs preponderantly (nine to one) in men It usually spreads quite rapidly to the soft palate, the anterior pillar, or the linguo-tonsillar sulcus Metastasis to the upper deep cervical lymph node is usually present It may be the outstanding first symptom with an inconspicuous primary The latter may be palpable in the tonsil when it is not actually visible A punch biopsy of the suspected area is a sounder approach to diagnosis than is enucleation of the tonsil The lymphatic flow from the malignant area will increase in direct proportion to the trauma and extent of the biopsy procedure

As a method of primary treatment surgery has no place in the treatment of tonsillar cancer External irradiation is the best therapy Bilateral fields include the immediate upper deep cervical lymphatic area The best assumption is that these are involved metastatically even in the absence of clinical evidence The metastatic disease is more uniformly responsive in tonsillar cancer than in other oropharyngeal cancers This is the most important part of the disease, and treatment should be carried to full dosage even though the nodes disappear early in the course of treatment Neck dissection is indicated for the infrequent case where there is primary control with persistent metastases The dissection must be carried well above the level of the digastric muscle

One of the most distressing complications of the irradiation treatment of tonsillar cancer is mandibular radionecrosis It may develop years later The usual immediate cause is extension of infection from carious teeth and peridental infection into the partially devitalized bone This can be avoided by the removal of the teeth before therapy is begun

The presence of metastases in cancer of the tonsil has an important bearing on prognosis In one series of 160 patients metastases were present in three-fourths of the cases In 11 per cent these were bilateral The five-year control rate in the absence of metastases was 20 per cent In those cases presenting unilateral metastases it was 4 per cent When bilateral metastases were initially present the salvage at the end of five years was zero [17]

The best prognosis in tonsillar cancer is in the lymphosarcomata The outlook is approximately twice as favorable as with squamous cancer, 30 to 40 per cent five year control as compared with 15 to 20 per cent The lymphoepitheliomata lie somewhere between

Cancer of the Lingual Base

That portion of the tongue posterior to the circumvallate papillae has well known histologic differences from the mobile anterior lingual two-thirds Cancer involves the posterior area less frequently, in a ratio of five cancers in the anterior segment to one posteriorly Cancer in the lingual base is a disease primarily of males Squamous cancers far outnumber the lymphoepitheliomata and lymphosarcomata Upper deep cervical node metastases (at and below the level of the hyoid horn) are the rule in all three types, 80 to 90 per cent have metastases The spread is often bilateral, in one-third if the primary is confined to one side of the base, and in two-thirds when the primary is on both sides of the midline

External irradiation is easily applicable to the primary, and necessarily crosses both lateral lymphatic zones Special applications of radium needles and radon seeds have been advocated,[18] but on theoretical grounds lack homogeneity and add nothing in total dose to what is accomplished through external irradiation Unfortunately, in the squamous cancers five-year control of the disease is obtainable in fewer than 10 per cent of cases by either method Again, the results are twice as good with lymphoepithelioma and lymphosarcoma

Surgical resection of the primary area is not feasible in cancer of the lingual base Since X-ray sterilization of the primary occurs only infrequently, there are few instances where neck dissection for the uncontrolled metastatic bed is indicated in this miserable disease

Cancer of the Linguo-Tonsillar and Glossopharyngeal Sulcus and Vallecula

Occurring, as they do, in a natural anatomic fold these tumors can be overlooked with the flashlight-tongue blade routine of the casual examiner It will be a real accomplishment when the otolaryngologists indoctrinate their medical conferees in the simple routine of mirror examination and forefinger palpation of the oropharyngeal area Sulcus cancer can be deeply infiltrating and present only a fissure-like ulcer at the surface [19, 20]

As with all of the oropharyngeal cancers, the sheltering effect of the mandible and the proximity of the cartilaginous larynx demand careful external irradiation of sulcus and vallecular cancer Penetrating Gamma irradiation, as with Cobalt 60 on theoretical grounds, offers distinct advantages [21, 22, 23] Tumor residuum is treated by some with implantation of radon emanation seeds Special techniques with radium needles and emanation seeds have their greatest usefulness where further external irradiation for persistent tumor is not possible because skin tolerance would be exceeded

Surgery is useful for persistent metastasis if the primary is controlled This combination of circumstances is not common In addition the metastatic involvement has a way of infiltrating the carotid sheath In the presence of uncertain primary control, the prospect of carotid resection *en bloc* is discouraging to temperate surgical minds, indeed, it is a rare cancer in this area that lends itself to surgery for the primary or the secondary Sulcus tumors do not have as favorable outlook for cure as does tonsillar cancer As a group, they do, however, have a better outlook than cancer of the lingual base

Surgical resection of the primary area is not feasible in cancer of the lingual base Since X-ray sterilization of the primary occurs only infrequently, there are few instances where neck dissection for the uncontrolled metastatic bed is indicated in this miserable disease

Cancer of the Linguo-Tonsillar and Glossopharyngeal Sulcus and Vallecula

Occurring, as they do, in a natural anatomic fold these tumors can be overlooked with the flashlight-tongue blade routine of the casual examiner It will be a real accomplishment when the otolaryngologists indoctrinate their medical conferees in the simple routine of mirror examination and forefinger palpation of the oropharyngeal area Sulcus cancer can be deeply infiltrating and present only a fissure-like ulcer at the surface [19 20]

As with all of the oropharyngeal cancers, the sheltering effect of the mandible and the proximity of the cartilaginous larynx demand careful external irradiation of sulcus and vallecular cancer Penetrating Gamma irradiation, as with Cobalt 60 on theoretical grounds, offers distinct advantages [21 22 23] Tumor residuum is treated by some with implantation of radon emanation seeds Special techniques with radium needles and emanation seeds have their greatest usefulness where further external irradiation for persistent tumor is not possible because skin tolerance would be exceeded

Surgery is useful for persistent metastasis if the primary is controlled This combination of circumstances is not common In addition the metastatic involvement has a way of infiltrating the carotid sheath In the presence of uncertain primary control, the prospect of carotid resection *en bloc* is discouraging to temperate surgical minds, indeed, it is a rare cancer in this area that lends itself to surgery for the primary or the secondary Sulcus tumors do not have as favorable outlook for cure as does tonsillar cancer As a group, they do, however, have a better outlook than cancer of the lingual base [7] ence of patients with malignant disease, but when our desire is accomplished, we often lack the index of suspicion which would direct us to the investigation which in turn would lead to the diagnosis

The early symptoms and signs are in no way indicative of the lethal disease which is causing them Unilateral epistaxis, nasal obstructions and discharges, and widening of the nasal bridge are by no means uncommon in nonmalignant disease Even when the symptoms and signs become more severe, pain radiating to the teeth, the cheek and the orbit, ocular proptosis, and tender swellings of the palate and antral area, the physician who does not possess a healthy curiosity will not undertake the appropriate diagnostic studies

Malignant disease of the nasal cavity and paranasal sinuses must be constantly suspected as an explanation of such symptoms and signs as I have just listed It must be considered to be present until it is proved not to be, under the following conditions

1 When unilateral masses are present in the nose

2 When polypoid masses have been present in the nose and sinuses for a considerable time, and their removal is attended with abnormally free bleeding

3 When there is prolonged unilateral nasal blockage, with a blood-tinged purulent discharge

4 When the complaint of pain in the cheek or upper teeth is disproportionate to the clinical findings

5 When a purulent sinus infection fails to respond to adequate treatment within a reasonable period of time

6 When unilateral swelling and tenderness occur in the nasal area

These symptoms and findings require a diagnostic survey, in which a careful local examination and nasopharyngoscopy are the first steps

Roentgenologic examination comes next The positive signs include opacity of the nasal cavity, irregularity of the soft

THE NASAL CAVITY AND PARANASAL SINUSES*†

HAROLD G TABB, M D,

New Orleans, La

A discussion of cancer of the nasal cavity and paranasal sinuses which does not begin with an admission of the distressing fact that the results of treatment are generally poor, is simply not realistic One reason for the poor results is anatomic, the structural continuity of the area is an invitation to rapid spread of any disease process Another reason is clinical, the usual textbook description, though unfortunately it very often fits the state of the patient when he is first seen, is the picture of advanced disease, not of early, curable disease Diagnosis will be delayed and treatment will be ineffective until this mistaken concept is overturned

Patients are generally late in seeking medical advice A delay of three months is about average, but a delay of six to nine months is not at all unusual, and every series contains cases in which the delay is a year or more One reason why patients delay is that the symptoms of cancer in these areas are often the symptoms of diseases which they have had for months or years The etiology of malignant disease of the nasal cavity and paranasal sinuses is still unsettled, but in many instances it is related to such conditions as chronic sinusitis, allergies of various kinds, polypi, and nasal obstructions in which there is interference with proper ventilation and drainage, and to which the patients have become accustomed

Another reason why patients are seen late is that the physicians and dentists, whom they have first consulted, have treated them on the basis of the symptoms they presented, without investigating what underlies them Otolaryngologists themselves are often at fault We plead for the early refer-

---

*Read as part of a Symposium at the Sixty-First Annual Meeting of the American Laryngological Rhinological and Otological Society Inc. San Francisco Calif May 21 1958

†From the Department of Otolaryngology Tulane University of Louisiana School of Medicine

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication May 26, 1958

by hospital blood banks, and the availability of wide-spectrum antibiotics

The Weber-Fergusson incision is used to expose the facial surface of the maxilla, and the entire maxillary bone, with the maxillary sinus, ethmoids, and orbital contents, is removed *en bloc* To accomplish this, the palate must be split in the midline and the maxilla and portions of the zygoma and ethmoid bones separated from their attachments The sphenoidal, frontal, and posterior ethmoids are curetted and fulgurated, as are any other suspicious areas The cribriform plate may be removed and the underlying dura cauterized, to care for possible extensions The eye is always included in the dissection unless an obviously clear margin of normal tissue can be demonstrated between it and the lesion If there is any doubt, the eye must be sacrificed

Since cancer of the nose and sinuses is characteristically late in metastasizing, radical neck dissection, although it can be performed with maxillectomy, is usually deferred Often it is not employed until the indication for it becomes evident

During the operation, the entire cavity is irrigated with a cancerocidal solution, to reduce the number of viable cancer cells in the wound washings When the tumor is highly malignant, it is well to follow its surgical removal with some appropriate chemotherapeutic agent Perfusion techniques, which have given very promising results in some regions of the body, for anatomic and other reasons do not seem applicable at this time to cancer of the nasal cavity and paranasal sinuses

The solution to this particular problem lies with the general practitioner, the dentist, and sometimes the ophthalmologist even more than with the otolaryngologist It is our duty to be eternally on guard, ourselves, and to acquaint those who are not practicing this specialty with the real facts of this disease, otherwise, many a patient will continue to lose his only chance of life Until diagnosis is achieved earlier, radical surgery followed by maximal radiation, which, given a fair chance, *can* control the disease, will often prove palliative rather than curative, and the results will be poor as well as tissues, and bony destruction Cytologic examination by the Papanicolaou technique is valuable when it is positive, but useless and possibly misleading when it is negative The same holds for aspiration biopsy

Even frozen section has a margin of error, yet there is no room for error when mutilating surgery, such as is necessary in this variety of cancer, must be undertaken If repeated biopsies are negative and the suspicion of cancer still persists, an exploratory procedure is warranted The pathologist must be supplied with a representative section of tissue, and he must be given ample time to study it

These facts may be elementary, but they constitute the background of successful therapy Until the disease is recognized, treatment will not be instituted Unless the disease is recognized early, the most potentially useful treatment will be useless

Irradiation, which was formerly generally employed, was used, as Frazell has well put it, more by default than by any proved superiority of results, in fact, it has decided disadvantages, including severe ocular complications It may also cause infection and prolonged disability because of the edematous obstruction of normal drainage channels by infected and necrotic cancer tissue The corrective procedures required when this happens are often of such magnitude that radical surgery might as well have been employed to start with

It is true that with the advent of supervoltage therapy, irradiation promises for the future better results with fewer disastrous side-effects That day, however, has not yet arrived At the present time, the optimum treatment is radical surgery combined with maximum doses of radiation by both the intracavitary and external techniques

The surgery must be radical Anything less than wide exposure and *en bloc* removal of the involved tissues is inadequate treatment Surgery of such magnitude is now practical because of improved techniques of anesthesia, including hypotension, the liberal use of whole blood provided exists in any part of the larynx or hypopharynx and whether there is direct extension or metastases Other characteristics such as size, presence of edema, surface growth, or deep ulceration may be of further assistance in classification

III Diagnosis

The diagnosis of cancer in the areas under discussion can usually be made by biopsy and microscopic examination of the tissue Other aids in establishing diagnosis are, Papanicolaou's stains of extruded cells, tomography, contrast media Roentgen studies and palpation Further surgical procedures may be required for correct diagnosis such as repeated biopsies and thyrotomy If it is necessary to resort to the latter, the operating room should be set up and the surgeon prepared to carry out definitive surgical treatment after the diagnosis is established by microscopic frozen sections

In our experience, over 99 per cent of the cancerous lesions in this area have been of the squamous cell variety Generally, if the site of origin of the lesion is other than the true vocal cords, one may expect to find the neoplasm less well differentiated microscopically According to Broder's classification, most cordal squamous cell carcinomas are of Grades I and II Only recently, we have seen a case with a small cancer of the true vocal cord which was remarkably anaplastic in its growth patterns, and was considered by our pathologist to be Grade IV

IV Treatment

Surgery and radiation therapy are the only two forms of therapy available today for the treatment of patients with cancer of the larynx In no sense of the word, should these two methods of treatment be competitive, but should be closely integrated even in the same patient when indicated

Illustrative cases with various types of lesions will be presented

Patients with early Stage I cordal squamous cell carcinomas should be treated by peroral removal and fulguration, rather than with radiation therapy mutilating With earlier diagnosis and correctly applied therapy, the proportion of five-year results will readily be doubled

CANCER OF THE LARYNX AND PHARYNX DIAGNOSIS AND TREATMENT *

WALTER P WORK, M D ,

San Francisco, Calif

I *Introduction*

My part of the symposium is to discuss the diagnosis and treatment of squamous cell carcinoma of the larynx and hypopharynx I can only outline our experiences with this disease in the time allocated

II *Classification*

We classify cancer of the larynx and the surrounding anatomical areas according to the International Radiological Congress' proposals made in Copenhagen in 1953 Of the many proposals for classifying cancerous lesions of the larynx and hypopharynx, the above appears to be workable and useful Frequently, clinicians will make modifications in any classification according to their needs and to the needs of their patients

Cordal, supraglottic, subglottic, hypopharyngeal and postcricoid are descriptive terms used for anatomical areas in which lesions are placed Often the dividing line between these areas is not sharply defined, and in some patients it is difficult to determine the true anatomical site of the origin of the lesion Lesions are further graded in Stages I to IV Such staging is an aid to the clinician in planning therapy and evaluating results The staging of lesions by the clinician is an attempt to determine whether impairment of function

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication May 26 1958

the initial surgery, so that contralateral block dissection may be carried out as early as possible if nodes appear

Advanced Stage II supraglottic lesions in the region of the petiolus of the epiglottis are difficult to treat by any method These lesions must be considered as potentially metastasizing to the lymph nodes in both sides of the neck Widefield laryngectomy plus initial unilateral block dissection of the neck, and later block dissection of the contralateral side are frequently indicated This is particularly true when microscopic lymph nodes are found in the original operative specimen Patients with Stage II lesions on the lateral surface of the epiglottis and upper aryepiglottic fold areas, must be considered candidates for similar surgical treatment Cases with Stage II lesions of the aryepiglottic fold proper extending into the false cord and pyriform sinus must be considered for similar treatment This is true also for patients with Stage II lesions in the arytenoid area All patients with Stage III lesions in those areas should be treated likewise, providing the lymph node metastases are resectable

Patients with lesions in other portions of the epiglottis, not noted above, should be treated surgically Cases of cancer of the free upper surface of the epiglottis suitable for peroral removal are rare indeed Such lesions would fall into Stage I, and we have seen none in our series of cases Likewise, patients with lesions in this area, early Stage II, suitable for transhyoid resection are rare We have seen one patient who had an extensive Stage II cancer in this area which was treated by radiation therapy in 1950 In 1956 there was a recurrence on the free upper border of the epiglottis which was removed surgically by the transhyoid approach

Patients with lesions of the entire epiglottis are usually seen in Stages II and III Their prognosis is poor, even with extensive surgery or radiation therapy, or with both Patients with early Stage II lesions of the central posterior surface of the epiglottis should be treated by widefield laryngectomy Unilateral lesions of the epiglottis are most often seen in late Stages II or III, and require widefield laryngectomy in combination with unilateral or bilateral block dissection

Cordal lesions, Stage I, slightly more advanced than in the above cases, are ideal for either radiation therapy or laryngofissure I cannot specifically recommend surgery or radiation therapy for a given patient since many factors, such as age of patient, general health, etc, will influence the doctor's choice of treatment Patients with carcinomas *in situ* localized to a small area of the true vocal cord should be treated surgically

If we consider more extensive lesions of the vocal cord, such as a cordal lesion, Stage II, where function is impaired and there are no palpable cervical lymph nodes, surgery should be considered in lieu of radiation therapy The Som[1] operation for posterior one-third cordal lesions, and hemilaryngectomy or the modification of this procedure with primary skin graft, as advocated by Figi[2] should be considered

In patients who have a cordal lesion, Stage II, (even with both vocal cords involved), with marked limitation of motion and the cancer is still confined within the cartilaginous larynx, the procedure of choice is widefield laryngectomy Patients with late Stage II and III cordal lesions will require widefield laryngectomy and simultaneous unilateral block dissection Many of these cases with advanced lesions will have ventricular or subglottic extension or both Cancer arising on both vocal cords may be so extensive that a later contralateral block dissection may be necessary if metastatic nodes appear

Patients with supraglottic squamous cell carcinoma are usually first seen in late Stage II or Stage III, however, occasionally a patient with an early Stage II lesion in this area will be seen In our series of cases, we have seen none with a Stage I lesion in these areas Stage II ventricular lesions require widefield laryngectomy Stage II false cord lesions, particularly if their growth is exophytic, will require widefield laryngectomy Stage II false cord lesions have potentially metastasized to the cervical lymph nodes when the patient is first examined Such individuals must undergo widefield laryngectomy and elective block dissection Further, metastases may occur on the contralateral side of the neck, and patients must be examined carefully and frequently following

MODERN CRITERIA FOR DIAGNOSIS AND THERAPY OF MALIGNANT DISEASE IN THE UPPER RESPIRATORY TRACT*

JOHN J CONLEY, M D ,

New York, N Y

Melanoma of the head and neck presents us with significant clinical diagnostic, therapeutic and statistical data that warrant careful analysis Approximately 25 per cent of all the melanomas of the body occur in the head and neck area This of course, highlights the importance of diagnosing this condition accurately Fifty per cent of all the patients that we see, with melanomas in the head and neck give a history of having had a brown or black mole present all of their lives This means that you cannot disregard the lesion which has been present for a 20-, 30-, 40-year period Fifty per cent of the melanomas that we see give a history of repetitive trauma, not a single incidence of trauma, but repeated trauma, whether shaving, cleaning the teeth, combing the hair, at the collar line on the neck, in the mouth, on the lips, etc The same situation applies to fingers, feet, penis, anus, from the brassiere strap on the shoulder, from the belt buckle at the waist, etc

As far as the diagnosis is concerned, we feel that any change in color or clinical appearance, or any subjective change such as itching, stinging or burning, warrants careful observation of the pignmented lesion Certainly if the pigmented lesion begins to grow, if it gets blacker and larger, and if there is

*Read as a part of a Symposium at the Sixty-First Annual Meeting of the American Laryngological Rhinological and Otological Society Inc. San Francisco Calif., May 21 1958

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication May 26 1958

Pharyngeal and postcricoid lesions will be considered next Surgery is the treatment of choice for these A high percentage of patients with these lesions fall into Stage III when first examined Hence, most all of the cases with pyriform sinus lesions require some form of extensive pharyngeal and laryngeal surgery and block dissection of the neck Patients with early Stage II lesions of the lateral hypopharyngeal wall carry a good surgical prognosis, providing partial pharyngectomy and block dissection are carried out in continuity Patients with posterior hypopharyngeal lesions encroaching upon the upper esophagus require extensive surgery, both as to the local primary lesion and to the lymph bearing areas on both sides of the neck In addition, plastic repair of the pharyngeal and esophageal defects must be done The extent of such lesions usually precludes the saving of the larynx itself Since a high percentage of these cases have palpable cervical lymph nodes on initial examination, it must be decided by the surgeon whether the nodes are resectable before surgery is attempted

In our series of cases, we have had only two patients with primary subglottic squamous cell carcinoma One patient's lesion was classified late Stage II while the other's was classified as Stage III In neither patient was the disease arrested, in spite of extensive surgery Subglottic lesions metastasize early to the lymph channels in both sides of the neck and upper mediastinum As far as our limited experience is concerned, we believe that any known form of treatment for Stage II or Stage III subglottic squamous cell carcinoma is inadequate This is in contrast to those cordal cancers which have extended directly to the subglottic areas

V *Conclusions*

Many patients with carcinomas of the larynx and hypopharynx are still being examined initially in later stages of the disease, when only palliative therapy could be recommended In fact, approximately 20 per cent of our cases were classified as late Stage III and Stage IV The remaining 80 per cent of the cases underwent treatment directed at arresting the disease Surgical treatment was the treatment of choice in most instances the procedure. If it is reported as a malignant melanoma then I think you are obligated to go back and do a wider local resection, because no excisional biopsy technique is considered adequate treatment for malignant tumor.

So far as the treatment is concerned, irradiation is not effective. The salvage rate here approaches zero. Surgical excision is certainly the method of choice in all cases, when possible. The head and neck, fortunately, lend themselves better to technical excision than almost any other area of the body. We are not faced with the complex problem here of an individual with a melanoma on the sole of his foot or on his big toe, which poses the question of whether the entire leg should be amputated or disarticulated. Our areas are neat and tidy as far as regional activity is concerned. My own personal feeling is that if the melanoma is less than 2 cm. in size and there is no evidence of clinical metastasis, and if it is not necessary to operate in the neck to excise it, I no longer feel that any continuity resection is indicated. I do a wide resection of the primary lesion. If the melanoma is large—over 2 cm. in size—regardless of its position, but particularly if it is located on the neck, then an elective neck dissection is included in the absence of obvious metastatic disease.

If there is evidence of metastasis in the neck, the neck dissection is always included with the excision of the primary lesion. The salvage rate in our group of cases is not significantly higher where elective neck dissections have been done in the treatment of what we classify as situations with a high possibility of microscopic metastatic melanoma. I think the difference is only about 5 per cent and that is the reason I have retreated to a more reasonable position.

Unfortunately, melanoma can metastasize by any of three routes. Its most frequent mode of metastasis is hematogenous. When it does metastasize by the hematogenous route, the prognosis is hopeless. The next most common is in the regional lymphatic bed. Here the prognosis is between 25 and 30 per cent for the five year cure. I think that if we will appreciate that originally this disease was considered to be almost totally hopeless from a prognostic point of view, a 25 per cent cure is a reasonable figure; however, I would like to ulceration, it has to be considered as a melanoma Those which do not have such dynamic change in their biology of course are suspicious, but those that change in color and size, and which ulcerate, have to be considered as melanomas Here I think we must be careful not to be trapped by a condition which resembles this, called the pigmented basal cell cancer, also we have to be careful not to be trapped by the amelanotic melanoma which resembles the ulcerating squamous cell cancer but grows so rapidly without pigment mobilization that it may be confused with the squamous cell cancer

I think the other point in the differential diagnosis is what to do about the innocent or benign pigmented lesion, the neuronevus The most important factor here is separating the nevi which can undergo malignant deterioration from the ones which ordinarily do not This is an important clinical observation The nevi that are puckered like a wart, the nevi that have large hairy deposits in them—two or three big black hairs coming out of them—hardly ever undergo malignant deterioration, and I don't think that it is necessary to remove these prophylactically in anyone, unless it is desired for cosmetic purposes, however, the nevi that are flat, or smooth, either black, or dark brown, or blue-black, or buff colored, ordinarily can be troublemakers No one can tell with the naked eye the differentiation between an epidermal nevus, a dermal nevus, a subdermal nevus or a junctional nevus Actually, I think the feeling at the present time is that melanoma comes only from the junctional nevus, but those that we are interested in are the flat ones, not those that are puckered up like a wart and contain hair

As far as the biopsy is concerned, no incisional technique should be carried out In other words, you should not cut into this black ulcerating area to obtain tissue for biopsy This is a very strict rule If the lesion is ulcerating, you may apply fibrin foam or wash it and have a Papanicolaou examination done I believe the safest thing, however, is to do an excisional biopsy of the entire area In other words, you are at least a centimeter or two around the peripheral margin of the lesion you suspect, and this is sent *in toto,* en masse, to the laboratory If it is reported as a benign lesion, that is the end of

THE NOSE AND PARANASAL SINUSES *

HEINRICH KOBRAK M D,
Detroit, Mich,

and

G EDWARD TREMBLE, M D,
Montreal, Canada

About a year and a half ago, Dr Heinrich Kobrak approached me to see whether I would collaborate with him on a film He had in mind a movie of the nose and sinuses It was decided to show some of the anatomy and physiology of the nose and to conclude with a few clinical cases On his suggestion I was to supply the animation, pictures of ciliary movement and some of the cases Dr Kobrak was to take pictures of the skull to show the sinus openings and also some common conditions encountered It was thought that the film would be of use to senior students and internes A number of meetings were held to place the sequences in their proper order The last time Dr Kobrak was in Montreal was about the middle of September He was confident the film with the narration would be ready for the Academy meeting in Chicago in October Two days before the Chicago meeting, I received a letter from him asking me to meet him to go over the picture before it was shown at the general meeting

On arriving in Chicago, I learned the sad news that Dr Kobrak had suffered a fatal coronary attack a day or so before the meeting After searching his home and laboratory without avail, the film was finally found in the back of his car Whether he had just received it after being processed or whether he intended to drive to Chicago, I do not know As a result, it was up to me to carry the ball alone, so to speak

When I saw a preview of the film I was a bit disturbed Parts of it were overexposed, especially the microscopic slides

state that five years in melanoma is not the answer to the problem because at the end of ten years the 25 to 30 per cent figure has dropped down to about 15. The third method of spread is in the subdermal lymphatics, and when melanoma behaves like this, it is, in my experience, practically uncontrollable.

I would make one statement about melanoma in children. As you know, the incidence of malignant tumors in children is very low. Shortly after birth it is about 20 per 100,000. Cancer in children is extremely rare. Melanoma does occur in children, but it does not have the same clinical significance as it has in adults. It does not metastasize as readily. It is usually handled by a local extirpative operation. Consequently, most of the nevi we see in children can be handled with impunity.

Melanoma of the oral cavity or any mucous membrane area has had almost a uniformly fatal ending.

ANNUAL OTOLARYNGOLOGIC ASSEMBLY UNIVERSITY OF ILLINOIS

The University of Illinois College of Medicine Department of Otolaryngology announces its Annual Otolaryngologic Assembly from September 29 through October 5, 1958. The Assembly will consist of an intensive series of lectures and panels concerning advancements in otolaryngology, and evening sessions devoted to surgical anatomy of the head and neck and histopathology of the ear, nose and throat. Interested physicians should write direct to the Department of Otolaryngology, 1853 West Polk Street, Chicago 12, Ill.

IRRIGATION OF THE MAXILLARY SINUS THROUGH THE MIDDLE MEATUS *†

MERVIN C MYERSON, M D ,

Beverly Hills, Calif

This paper is written primarily to stimulate interest in irrigation of the maxillary sinus through the middle meatus, preferably by way of its natural orifice There probably always will be some controversy regarding the relative advantage of irrigating this sinus by way of the middle or inferior meatus It will remain, however, for the individual rhinologist, by virtue of training, understanding, and experience, to decide the technique he wishes to follow in irrigating the maxillary sinus A few visits to the anatomy laboratory will convince the most skeptical that irrigation through the middle meatus can be performed in a high percentage of cases Although the more generally accepted method of irrigating the maxillary sinus is by way of the inferior meatus, using a needle or trocar, the number of otolaryngologists who are using the natural orifice and middle meatus is increasing Many rarely resort to puncture through the inferior meatus It has also been noted that it is easier to enter the maxillary sinus by way of the middle meatus in children than in adults

In order to appreciate the middle meatus approach one should have an understanding of the structures involved, and their relationships At about the tenth week of fetal life the mucous membrane of the primitive middle meatus of the nose begins to pouch laterally This evagination indicates the beginning of the maxillary sinus and is the location of the future maxillary ostium The maxillary ostium is situated in the posterior portion of the ethmoidal infundibulum where the posterior part of the bulla tapers away on the upper side, and the dorsal end of the uncinate process does the same on the

I had suggested some lateral views of the normal nose, showing the sinus openings and the opening of the naso-lacrimal duct In other words, to my mind the picture could be improved and parts of it needed re-editing I have some film showing air currents through the nose and ciliary action in the presence of an acute cold, which I think would enhance its value, however, I just received the movie from New York about ten days ago, and I have not had time to add these sections I am only sorry that Dr Kobrak is not here when it is being shown in its original form

SOUTH CAROLINA SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

The next joint annual meeting of the North Carolina Eye, Ear, Nose, and Throat Society and the South Carolina Society of Ophthalmology and Otolaryngology will be held in Asheville, N C, on September 14-17, 1958, at Grove Park Inn An excellent program is in the making The following guest ophthalmologists will be present Dr James A C Wadsworth, New York, N Y, Dr Arthur Gerard DeVoe, New York, N Y, and Dr Frank B Costenbader, Washington, D C The following guest otolaryngologists will be present Dr F W Davidson, Danville, Pa, and Dr Tom Rambo, New York, N Y A third otolaryngologist will be announced in the near future A good attendance is anticipated

For further information write directly to Dr George Noel, c/o Cabarrus Bank Bldg, Kannapolis, N C, or Dr Roderick Macdonald, 330 East Main St, Rock Hill, S C

portion of the infundibulum immediately below the level of the orbital floor and, therefore, just below the lowermost portion of the lamina papyracea of the ethmoid bone (see Figs 1, 2) The orifice is usually so placed in the infundibulum beneath the middle turbinate as to be readily approached and entered in a large majority of cases At times it is buried deeply and may be inaccessible When the ostium is deeply placed, it is rarely hidden by the bulla, it is inaccessible in such cases because of the high obstructing uncinate process which governs the depth of the infundibulum Of importance also is the distance between the uncinate and bulla, the space commonly known as the hiatus semi-lunaris This space may be obliterated by contact of the bulla and uncinate, or it may be as wide as 3 mm When greatly narrowed it presents an obstacle to the ready passage of a canula

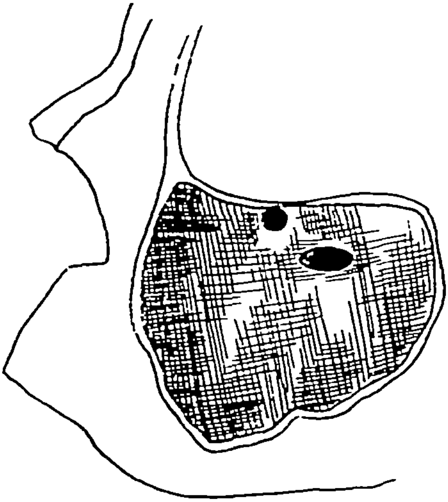

Fig 2 Semi-diagrammatic showing nasal wall of maxillary sinus and the usual location of the ostium an accessory orifice is located posteriorly and below

The size of the maxillary ostium varies from a diameter of 1 mm to a measurement of 17x11 mm Quite frequently the ostium occupies the entire infundibular region or most of it, lower side All of these structures, which vary in their size, contour and relationship, lie under cover of the middle turbinate The membranous portion of the middle meatus lies between the dorsal extremity of the uncinate process and the perpendicular plate of the palate bone, and between the dorsal extremity of the uncinate process and the ethmoidal bulla This has been called the undefended C-shaped region by

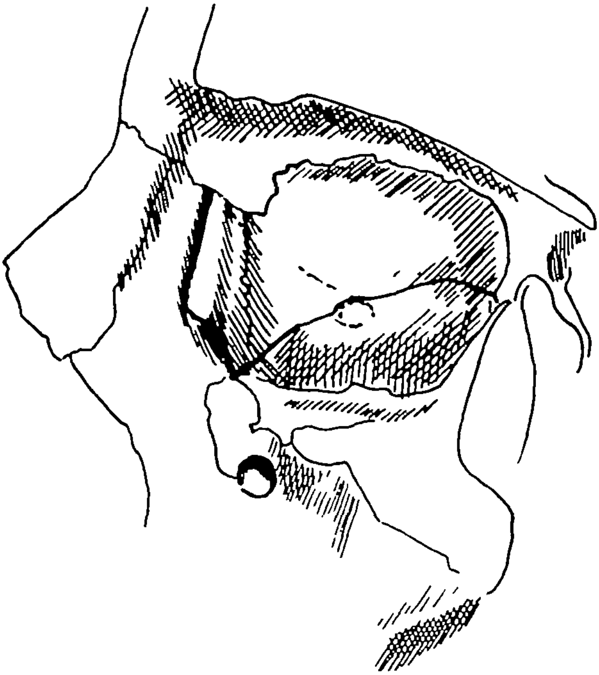

Fig 1 Semi-diagrammatic showing the relation of the infundibulum and maxillary ostium to the lamina papyracea orbital plate and surrounding structures

Schaeffer It is in this area that the accessory ostia are found

For success in the manipulation and introduction of a canula into the orifice of the maxillary sinus, it is important to have a knowledge of the maxillary opening and its accessory ostia, in addition to their relationship to the structures mentioned above

The orifice of the maxillary sinus is located in the posterior

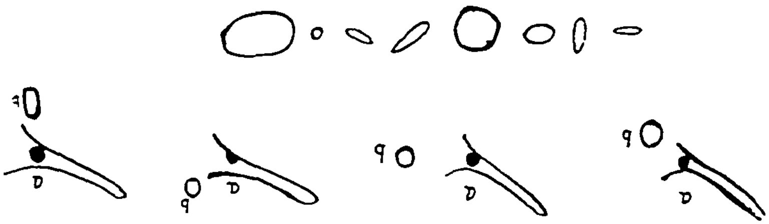

Fig 4 Semi-diagrammatic showing variety of sizes shapes and relative positions of the accessory ostium

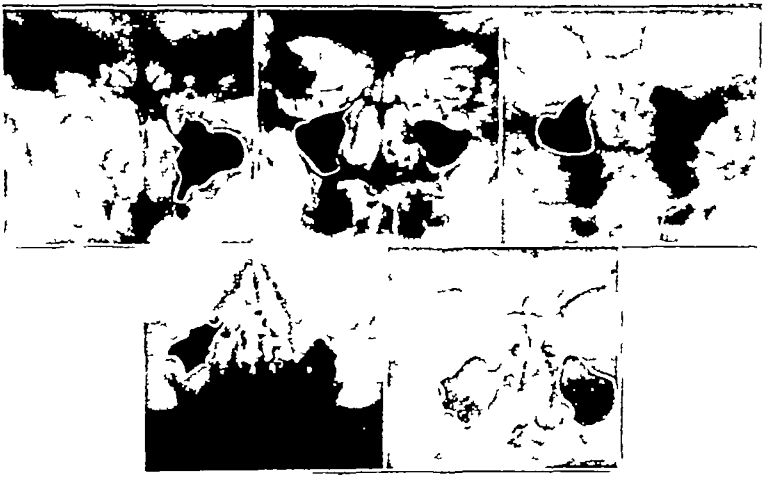

Fig 5 Roentgenographic studies made with iodized oil showing variety passageways into maxillary sinus

This paper is based upon a series of 500 consecutive patients in whom an attempt was made to irrigate the maxillary sinus through its natural orifice In those cases in which the ostium could not be entered, the membraneous portion of the middle meatus was deliberately punctured with the same blunt canula employed for entering the ostium The natural orifice was entered in 399, or 79 8 per cent, of this series of 500 cases, in 48, or 9 6 per cent, the membraneous portion was punctured with the same blunt-ended irrigation canula The total number irrigated through the middle meatus was 447, or 89 4 per cent, of the 500 subjects

In order to introduce a canula through the natural opening

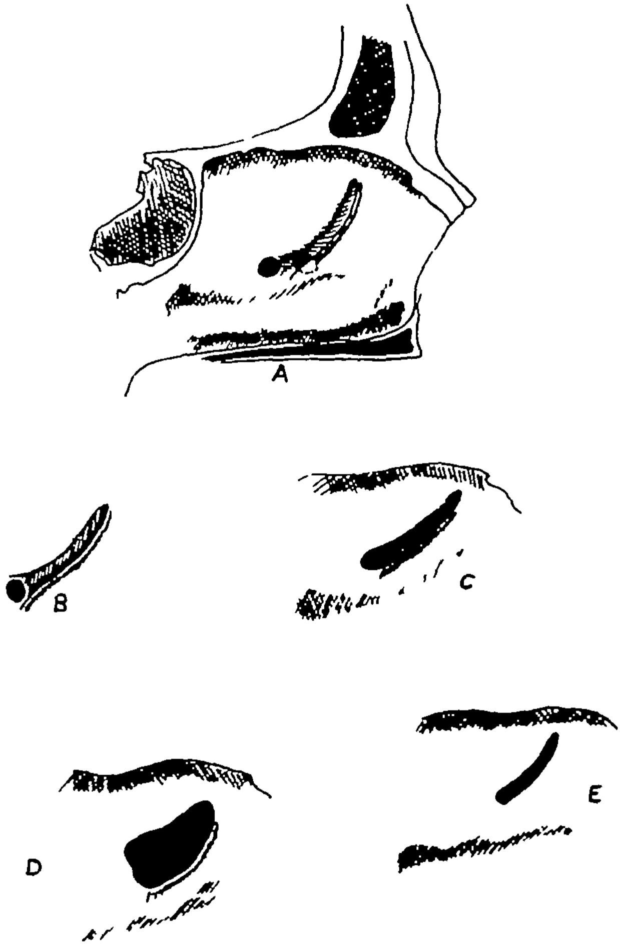

Fig 3 Semi-diagrammatic showing variety of maxillary ostia

so that a canula can be inserted with ease The size of the accessory orifice varies from a pinhead to 10 5x6 5 mm (see Figs 3, 4)

It is important to know that the position of the maxillary ostium may be vertical, horizontal or oblique When positioned horizontally or obliquely, it indicates the beginning of a canal or passage which terminates in a vertically placed orifice in the medial wall of the maxillary sinus (see Fig 5) These passageways have been stressed by Larroude, Simon, Van Alyea, and the author (see Fig 6) Simon claimed that a canal exists in 90 per cent or more of maxillary sinuses

With few exceptions, the tampon can be inserted into the region of the infundibulum, after three to five minutes it is removed and a fine cotton tipped applicator, saturated with the same cocaine solution, is placed in the same location The cotton-wound applicator can be bent so that its distal end can be properly placed When the middle meatus is anesthetized, an attempt is made to introduce the canula

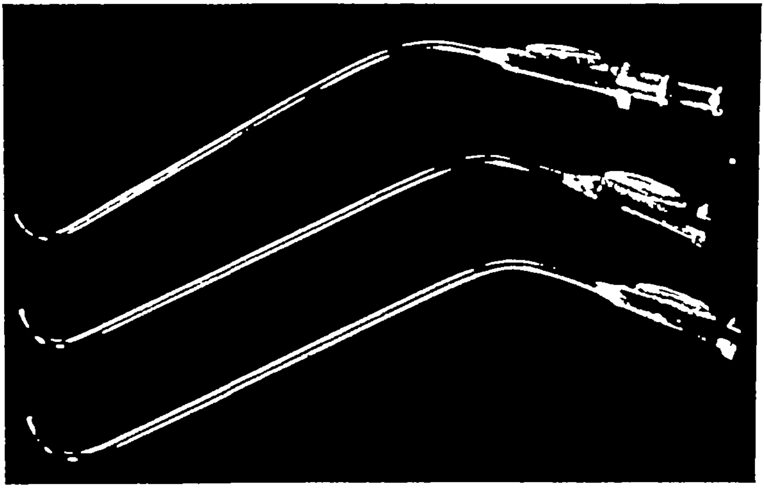

Fig 7 Author s canulae three sizes

The smallest possible canula should be used when the first attempt is made to enter the ostium The canula is introduced a few millimeters behind the anterior end of the middle turbinate with its distal end pointing upward When the middle meatus is reached, the tip of the instrument is directed laterally, if a vertically placed ostium exists, the canula will fall readily into it (see Fig 7) If the canula strikes the lateral wall it is withdrawn and introduced in an inverted position In this position the distal end will fall into a horizontally or obliquely placed orifice One can tell that the canula is in the ostium by the depth of penetration of the instrument and by the excursion of its distal end, which is controlled by the diameter of the orifice If an ostium cannot be found the membraneous portion of the middle meatus

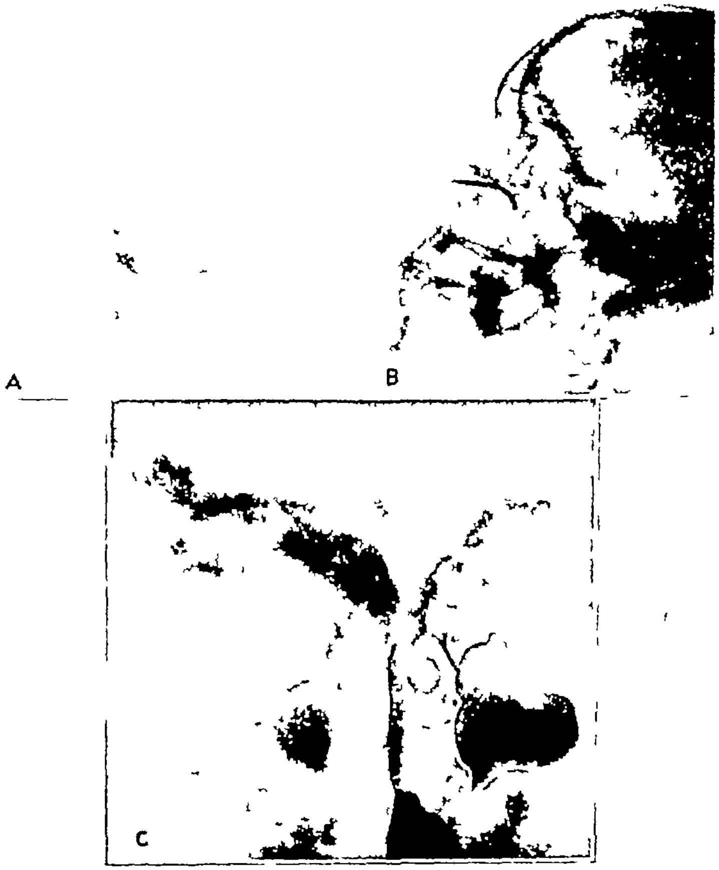

Fig 6 Roentgenographic studies showing (A and B) canula in oblique passageway (C) passageway after instillation of iodized oil

of the maxillary sinus, the middle meatus and the structures traversed by the instrument must be anesthetized To accomplish this a small flat tampon is inserted under the middle turbinate just beyond its anterior end It is advantageous to tie a piece of cotton thread to the tampon, the distal end of which is cut off at the nostril When anesthesia is complete, the tampon is removed by pulling on the thread This eliminates the necessity of using an instrument in the middle meatus, which sometimes bruises the tissues because of the narrowness of the passage or the depth of the position of the tampon, also, at times, the tampon is difficult to recover because of the extremely thick exudate which was expelled with difficulty, after inferior meatal puncture Acutely involved sinuses are never irrigated, but the exudate in cases of subacute or even chronic infections may be quite thick This, together with the presence of a small ostium, may cause slow emptying of the sinus cavity and, at times, some pain, but the irrigating fluid will usually be returned without incident That the ostium is rarely occluded has been proven by anatomic studies In a study of 600 lateral nasal walls, Zuckerkandl found the smallest ostium to be 3 mm in diameter, while the largest was 19x5 mm In 200 sections, Oppikofer found the smallest to be 2 mm in diameter and the largest 17x11 mm Schaeffer and the author found the smallest to be 1 mm in diameter

The number of otolaryngologists interested in natural orifice irrigation has increased with the years This is because they have found the procedure simpler and safer in a majority of cases Schaeffer states the reason as follows "One must bear in mind that instruments of precision, and a more highly refined technique, have come into being of late years, making successful treatment of an infected maxillary sinus by way of its natural aperture seemingly feasible in a relatively large percentage of cases" Many have stressed the advantages of irrigation through the natural orifice or through the membranous portion of the middle meatus

Those who object to irrigation through the natural opening claim there is difficulty in locating the ostium in a large percentage of cases They assert that the sinus cannot be properly irrigated when the return flow is partly blocked by the canula, and that instrumentation of the ostium injures and inflames its membranous lining If the anatomy is understood and the instruments properly manipulated, these objections are not valid

The objections to inferior meatal puncture have been known for a long time

The procedure is frequently painful, there is usually some bleeding, there is failure to penetrate with a needle or trocar because of thickened bone is perforated by the canula. Penetration through the membrane imparts a definite impulse which is readily recognized. In some cases there is a streak of blood, in most, there is none, while in others there may be no evidence of trauma. The condition of the membrane and its thickness, as well as the amount of trauma, influence the presence or absence of blood. When difficulty is encountered in the passage of the tube, one may bruise the middle meatal structures so that slight bleeding will occur for a few hours, or for as much as two or three days. The latter is exceptional and should not occur if the rhinologist is careful. When the canula is successfully introduced, there should be no injury to the tissues, nor should there be bleeding when the canula is withdrawn.

The presence of pus or mucopus in the returned irrigating fluid is evidence that the canula is in the antrum. The patient feels the fluid in his sinus, especially when the pressure of the fluid is increased. The sound heard when air is introduced into the antrum after irrigation, is distinctive.

In this series of 500 cases, the middle turbinate was impacted against the lateral wall so that the middle meatus could not be entered in 14 instances. When the space between the lateral aspect of the middle turbinate and the lateral nasal wall is so restricted, it is better to refrain from attempting to pass the canula, one should resort to puncture through the inferior meatus. At times a fine canula can be passed in an inverted position between the anterior end of the turbinate and the lateral wall, instead of beneath the anterior end of the middle turbinate, as is usually done. In five cases the middle turbinate could not be visualized because of a badly deviated, or convex septum.

It was found that patients who had nasal polyps protruding from the middle meatus presented an enlarged natural opening, so that a canula could be passed with relative ease. One is also impressed with the large number of orifices of increased diameter among the cases of chronic suppuration of the maxillary sinus.

Occlusion of the ostium during irrigation is more theoretical than real. Occlusion of the ostium occurred once in this series

ZUCKERKANDL, E "Normale und Pathologische Anatomie der Nasenhohle' 2nd Ed p 291 Wilhelm Branmuller Leipzig 1893

The needle or trocar can fall into or beneath thick necrotic or polypoid membrane and cause air embolism or infiltration and emphysema of the cheek and eyelids

Phlegmon of the soft parts of the face can occur, fluid can be injected into the pterygomaxillary fossa

Air embolism is a well-established accident of inferior meatal puncture Many deaths have been recorded

An attempt was made to enter the natural opening of the maxillary sinus in 500 consecutive cases The ostium was successfully entered in 399, or 79 8 per cent, in 48, or 9 6 per cent, the membranous portion of the middle meatus was punctured with the same canula used for entering the ostium A total of 477, or 89 4 per cent, therefore, were successfully treated through the middle meatal approach

Irrigation of the maxillary sinus through the middle meatus, either by way of the natural opening or by puncture of the membranous portion of the middle meatus, is a safe and simple procedure On the basis of my experience it should be recommended as the method of choice

DIRECTORY OF OTOLARYNGOLOGIC SOCIETIES

(Secretaries of the various societies are requested to keep this information up to date)

AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Erling W Hansen, 90 So Ninth St, Minneapolis, Minn
Executive Secretary Dr William L Benedict, Mayo Clinic Rochester, Minn
Meeting Palmer House Chicago, Ill

AMERICAN BOARD OF OTOLARYNGOLOGY

Meeting Palmer House, Chicago Ill

AMERICAN BRONCHO ESOPHAGOLOGICAL ASSOCIATION

President Dr Francis W Davison Geisinger Memorial Hospital Danville Pa
Vice-President Dr George S McReynolds 615 N Boulevard Galveston Tex
Secretary Dr F Johnson Putney, 1712 Locust St. Philadelphia 3 Pa.
Treasurer Dr Verling K Hart 106 W 7th St Charlotte N C
Meeting The Homestead Hot Springs Va March 10 11, 1959

AMERICAN LARYNGOLOGICAL ASSOCIATION

President Dr Fred W Dixon Cleveland Ohio
Secretary Dr James H Maxwell Ann Arbor Mich
Treasurer Dr Francis E LeJeune New Orleans, La
Editor, Historian, and Librarian Dr Edwin N Broyles, Baltimore Md
Meeting The Homestead Hot Springs Va March 8 9 1959

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, INC

President Dr Gordon Hoople, 1100 E Genesee St Syracuse 10 N Y
President Elect Dr Theo E Walsh 640 So Kingshighway, St. Louis 10 Mo
Secretary Dr C Stewart Nash 700 Medical Arts Bldg Rochester 7, N Y
Place The Homstead, Hot Springs Va. March, 1959

AMERICAN MEDICAL ASSOCIATION, SECTION ON LARYNGOLOGY, OTOLOGY AND RHINOLOGY

Chairman Dr Victor R Alfaro Washington D C
Vice-Chairman Dr Harold F Schuknecht Detroit, Mich
Secretary Dr Walter E Heck San Francisco Calif
Representative to Scientific Exhibit Dr Walter H Maloney, Cleveland, Ohio
Section Delegate Dr Gordon F Harkness Davenport, Ia
Alternate Delegate Dr Dean M Lierle Iowa City, Ia
Meeting Atlantic City, June 8 12, 1959

AMERICAN RHINOLOGIC SOCIETY
ANNUAL MEETING

The American Rhinologic Society will hold its fourth annual meeting in the Palmer House, Chicago, October 17-18, 1958

Among the topics to be discussed will be pulmonary and nasal physiology, laboratory and clinical aspects of bone transplants, hump removal, roof repair, and nasal process corrections

The preliminary program includes the following papers "Maxillary and Premaxillary Approach to Septal Surgery," Dr Ralph H Riggs, Shreveport, La , "Olfactory Factors in Experimental Neurosis in Animals," Dr Jules H Masserman, Chicago, "Second Golden Decade of Rhinologic Surgery—The Advances of the Past 10 Years," Dr Harvey C Gunderson, Toledo, "Physiology of Respiration," Dr David Cugell, Chicago, "Concepts of Nasal Physiology as Related to Corrective Nasal Surgery," Dr Maurice H Cottle, Chicago, "Bone Transplants, Experimental and Clinical Aspects," Dr Robert Ray, Chicago, and "Nasal Physiology," Dr Irving Cramer, Cleveland "Hump Removal, Roof Repair, Nasal Process Corrections," will be the subject of a panel, Dr Walter Loch of Baltimore will be the moderator The participants will be Drs Lewis Morrison of Indianapolis, Richard Hadley of Rye, N Y , Charles Tucker of Hartford, and Joseph West of St Louis

Dr Russell I Williams of Cheyenne, president of the Society, will preside Dr Guy L Boyden, professor of otolaryngology, University of Oregon Medical School, Portland, will be the guest of honor

The profession is cordially invited to attend as guests There will be no registration fee

For further information write to Dr Robert M Hansen, secretary of the society, *1735 North Wheeler Avenue, Portland 17, Ore*

ASOCIACION DE OTO RINO LARINGOLOGIA DE BARCELONA, SPAIN

Presidente Dr J Abello
Vice-Presidente Dr Luis Suñe Medan
Secretario Dr Jorge Perellò, 319 Provenza, Barcelona.
Vice-Secretario Dr A Pinart.
Vocal Dr J M Ferrando

BALTIMORE NOSE AND THROAT SOCIETY

Chairman Dr Walter E Loch, 1039 No Calvert St., Baltimore, Maryland
Secretary Treasurer Dr Theodore A. Schwartz

BUENOS AIRES CLUB OTOLARINGOLOGICO

Presidente Dr K Segre
Vice-Presidente Dr A. P Belou.
Secretario Dr S A Aranz
Pro Secretario Dr J M Tato
Tesorero Dr F Games
Pro Tesorero Dr J A Bello

CANADIAN OTOLARYNGOLOGICAL SOCIETY
SOCIETE CANADIENNE D'OTOLARYNGOLOGIE

President Dr Robert T Hayes, 42 Cobourg St. St. John N B
Secretary Dr Donald M McRae, 324 Spring Garden Rd , Halifax, N S

CENTRAL ILLINOIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr G C Otrich Belleville Ill
President Elect Dr Phil R. McGrath, Peoria, Ill.
Secretary Treasurer Dr Alfred G Schultz, Jacksonville Ill.

CHICAGO LARYNGOLOGICAL AND OTOLOGICAL SOCIETY

President Dr Stanton A. Friedberg 122 So Michigan Ave , Chicago 3 Ill
Vice-President Dr Maurice Snitman 408 So 5th Ave Maywood Ill.
Secretary Treasurer Dr Fletcher Austin, 700 No Michigan Ave , Chicago 11, Ill
Meeting First Monday of each Month October through May

CHILEAN SOCIETY OF OTOLARYNGOLOGY

President Dr Enrique Grünwald S
Vice-President Dr Agustin Estartus
Secretary Dr Marcos Chaimovich S
Treasurer Dr Benjamin Kaplan K.
Director Dr Alberto Basterrica A.

DALLAS ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Ludwig A. Michael 3707 Gaston Ave , Dallas, Tex.
Vice-President Dr Hal W Maxwell
Secretary Treasurer Dr Edward A. Newell 1511 No Beckley, Dallas 8 Tex.

AMERICAN OTOLOGICAL SOCIETY, INC

President Dr Moses Lurie, Boston, Mass
President Elect Dr R. C Martin
Secretary Dr Lawrence R Boles, University Hospitals, Minneapolis 14, Minn
Place The Homestead, Hot Springs, Va, 1959

AMERICAN OTORHINOLOGIC SOCIETY FOR THE ADVANCEMENT OF PLASTIC AND RECONSTRUCTIVE SURGERY

President Dr Joseph Gilbert, 111 E 61st St, New York, N Y
Vice President Dr Kenneth Hinderer, 402 Medical Arts Bldg, Pittsburgh, Pa.
Secretary Dr Louis Joel Feit, 66 Park Ave, New York 16, N Y
Treasurer Dr Arnold L Caron, 36 Pleasant St, Worchester, Mass

AMERICAN RHINOLOGIC SOCIETY

President Dr Russell I Williams, 408 Hynds Bldg, Cheyenne, Wyo
Secretary Dr Robert M Hansen, 1735 No Wheeler Ave, Portland, Ore
Annual Clinical Session Illinois Masonic Hospital, Chicago, Ill, October, 1958
Annual Meeting October, 1958, Chicago, Ill (Definite time and place to be announced later)

AMERICAN SOCIETY OF FACIAL PLASTIC SURGERY

President Dr Trent W Smith, 327 East State St, Columbus 15, Ohio
Vice-President Dr Oscar J Becker, Chicago, Ill
Secretary Dr Samuel M Bloom, 123 East 83 St, New York 28, N Y
Meeting November 12, 1958 in conjunction with the Section on Laryngology, Rhinology and Otology of the Medical Society of the County of Kings and Academy of Medicine of Brooklyn 1313 Bedford Ave, Brooklyn N Y

AMERICAN SOCIETY OF OPHTHALMOLOGIC AND OTOLARYNGOLOGIC ALLERGY

President Dr Joseph W Hampsey, Grant Bldg, Pittsburgh 19, Pa
Secretary Treasurer Dr Daniel S DeStio, 121 S Highland Ave, Pittsburgh 6, Pa.
Annual Meeting Palmer House, Chicago, Ill, October 16 17, 1958

ASSOCIACAO MEDICA DO INSTITUTO PENIDO BURNIER—CAMPINAS

President Dr Antonio Augusto de Almeida
First Secretary Dr Alberto Galo
Second Secretary Dr Alfredo Porto
Librarian Treasurer Dr L de Souza Queiroz
Editors for the Archives of the Society Dr J Penido Burnier, Dr Guedes de Melo Filho and Dr Roberto Franco do Amaral
Meetings Twice every month, first and third Thursday, 8 30 P M

ASOCIACION DE OTORRINOLARINGOLOGIA Y BRONCOESOFAGOLOGIA DE GUATEMALA

Presidente Dr Julio Quevedo, 15 Calle Oriente No 5
First Vice-Presidente Dr Héctor Cruz, 3a Avenida Sur No 72
Second Vice-Presidente Dr José Luis Escamilla, 5a Calle Poniente No 48
Secretario-Tesorero Dr Horace Polanco 13 Calle Poniente No 9 D

LOS ANGELES SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Max E Pohlman
Secretary Treasurer Dr Wendell C Irvine
Chairman of Ophthalmology Section Dr Carroll A McCoy
Secretary of Ophthalmology Section Dr Philip D Shanedling
Chairman of Otolaryngology Section Dr Robert W Godwin
Secretary of Otolaryngology Section Dr Francis O'N Morris
Place Los Angeles County Medical Association Bldg 1925 Wilshire Blvd , Los Angeles, Calif
Time 6 30 P M last Monday of each month from September to June, inclusive—Otolaryngology Section 6 30, first Thursday of each month from September to June inclusive—Ophthalmology Section

LOUISIANA MISSISSIPPI OPHTHALMOLOGICAL AND OTOLARYNGOLOGICAL SOCIETY

President Dr Fred D Hollowell, Lamar Life Bldg , Jackson, Miss
Secretary Dr Edley H Jones, 1301 Washington St., Vicksburg, Miss
Meeting Edgewater Gulf Hotel Edgewater Park Miss May 15 16, 1959

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

Chairman Members serve as chairmen in alphabetical order monthly
Secretary Treasurer Dr Roland H Myers, 1720 Exchange Bldg , Memphis, Tenn.
Assistant Secretary Treasurer Dr William F Murrah, Jr , Exchange Bldg , Memphis Tenn.
Meeting Second Tuesday in each month at 8 00 p.m at Memphis Eye Nose and Throat Hospital.

MEXICAN ASSOCIATION OF PLASTIC SURGEONS

President Dr Cesar LaBolde Mexico, D F
Vice-President Dr M Gonzales Ulloa, Mexico, D F
Secretary Dr Juan De Dios Peza, Mexico D F

MISSISSIPPI VALLEY MEDICAL SOCIETY

President Dr Arthur S Bristow Princeton, Mo
Secretary Treasurer Dr Harold Swanberg Quincy, Ill.
Assistant Secretary Treasurer Dr Jacob E Reisch Springfield Ill

NETHERLANDS SOCIETY OF OTO RHINO LARYNGOLOGY

(Nederlandsche Keel Neus-Oorheelkundige Vereeniging)

President Dr H Navis Sonsbeekweg 6 Arnhem
Secretary Dr W H Struben J J Viottastraat 1 Amsterdam
Treasurer Mrs F Velleman Pinto Jac Obrechtstr 66 Amsterdam

NORTH CAROLINA EYE, EAR, NOSE AND THROAT SOCIETY

President Dr J C Peele, Kinston Clinic, Kinston, N C
Vice-President Dr George E Bradord Winston Salem N C
Secretary Treasurer Dr J D Stratton, 1012 Kings Drive, Charlotte 7 N C
Meeting

FEDERACION ARGENTINA, DE SOCIEDADES DE OTORRINOLARINGOLOGIA

Secretary of the Interior Prof Dr Atilio Viale del Carril
Secretary of Exterior Dr Aldo G Remorino
Secretary Treasury Prof. Dr Antonio Carrascosa
Pro Secretary of the Interior Prof Dr Carlos P Mercandino
Pro Secretary of the Exterior Prof Dr Jaime A. del Sel
Pro Secretary of the Treasury Dr Jorge Zubizarreta

FIRST CENTRAL AMERICAN CONGRESS OF OTORHINOLARYNGOLOGY

President Dr Victor M Noubleau, San Salavador
Secretary-Treasurer Dr Hector R. Silva, Calle Arce No 84, San Salvador, El Salvador, Central America

FLORIDA SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Chas C Grace, 145 King St, St. Augustine, Fla ,
President Elect Dr Jos W Taylor, 706 Franklin St., Tampa, Fla
Secretary-Treasurer Dr Carl S McLemore, 1217 Kuhl Ave, Orlando, Fla.

FOURTH LATIN AMERICAN CONGRESS OF OTORINOLARINGOLOGIA

President Dr Dario
Secretary
Meeting

GREATER MIAMI EYE, EAR, NOSE AND THROAT SOCIETY

President Dr William B Steinman
President-Elect Dr James H Mendel, Jr
Secretary-Treasurer Dr H Carlton Howard
Meeting quarterly (March, May, October and December) on the second Thursday of the month 6 30 P M at Urmey Hotel, Miami

INTERNATIONAL BRONCHOESOPHAGOLOGICAL SOCIETY

President Dr Jo Ono, Tokyo, Japan
Secretary Dr Chevalier L Jackson 3401 N Broad St, Philadephia 40 Pa, U S A
Meeting Seventh International Congress of Bronchoesophagology Kyoto Japan, September, 1958

KANSAS CITY SOCIETY OF OTOLARYNGOLOGY AND OPHTHALMOLOGY

President Dr Clarence H. Steele
President-Elect Dr Dick H Underwood
Secretary Dr James T Robison, 4620 J C Nichols Parkway Kansas City, Mo
Meeting Third Thursday of November January February and April

LOS ANGELES SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Max E Pohlman
Secretary Treasurer Dr Wendell C Irvine
Chairman of Ophthalmology Section Dr Carroll A. McCoy
Secretary of Ophthalmology Section Dr Philip D Shanedling
Chairman of Otolaryngology Section Dr Robert W Godwin
Secretary of Otolaryngology Section Dr Francis O N Morris
Place Los Angeles County Medical Association Bldg, 1925 Wilshire Blvd, Los Angeles Calif
Time 6 30 P M last Monday of each month from September to June, inclusive—Otolaryngology Section 6 30, first Thursday of each month from September to June, inclusive—Ophthalmology Section

LOUISIANA MISSISSIPPI OPHTHALMOLOGICAL AND OTOLARYNGOLOGICAL SOCIETY

President Dr Fred D Hollowell, Lamar Life Bldg, Jackson, Miss
Secretary Dr Edley H Jones, 1301 Washington St. Vicksburg, Miss
Meeting Edgewater Gulf Hotel Edgewater Park Miss May 15 16 1959

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

Chairman Members serve as chairmen in alphabetical order monthly
Secretary-Treasurer Dr Roland H Myers, 1720 Exchange Bldg, Memphis, Tenn.
Assistant Secretary Treasurer Dr William F Murrah, Jr, Exchange Bldg, Memphis, Tenn
Meeting Second Tuesday in each month at 8 00 p m. at Memphis Eye, Nose and Throat Hospital

MEXICAN ASSOCIATION OF PLASTIC SURGEONS

President Dr Cesar LaBoide, Mexico, D F
Vice-President Dr M Gonzales Ulloa, Mexico, D F
Secretary Dr Juan De Dios Peza, Mexico D F

MISSISSIPPI VALLEY MEDICAL SOCIETY

President Dr Arthur S Bristow Princeton, Mo
Secretary Treasurer Dr Harold Swanberg Quincy Ill
Assistant Secretary Treasurer Dr Jacob E Reisch Springfield Ill

NETHERLANDS SOCIETY OF OTO RHINO LARYNGOLOGY

(Nederlandsche Keel Neus-Oorheelkundige Vereeniging)

President Dr H. Navis Sonsbeekweg 6 Arnhem
Secretary Dr W H. Struben J J Viottastraat 1 Amsterdam.
Treasurer Mrs F Velleman Pinto, Jac Obrechtstr 66 Amsterdam.

NORTH CAROLINA EYE, EAR, NOSE AND THROAT SOCIETY

President Dr J C Peele Kinston Clinic Kinston, N C
Vice-President Dr George E Bradord Winston Salem N C
Secretary Treasurer Dr J D Stratton, 1012 Kings Drive, Charlotte 7 N C
Meeting

NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY

President Mr G L Thompson, 16 Ramshill Road, Scarborough, Yorkshire
Vice-President Mr J H Otty, Frizley Old Hall, Frizinghall Road, Bradford, Yorkshire
Secretary and Treasurer Mr R Thomas, 27 High Petergate, York, Yorkshire

OREGON ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr David D DeWeese, 1216 S W Yamhill St., Portland 5, Ore
Secretary Treasurer Dr Paul B Myers, 223 Medical Dental Bldg, Portland 5, Ore
Meeting Fourth Tuesday of each month from September through May, Henry Thiele Restaurant 23rd and W Burnside, Portland, Ore

OTOSCLEROSIS STUDY GROUP

President Dr L R Boies, University Hospital, Minneapolis, Minn
Secretary Treasurer Dr Arthur L Juers, 611 Brown Bldg, Louisville, Ky
Meeting Palmer House, Chicago, Ill

PACIFIC COAST OTO-OPHTHALMOLOGICAL SOCIETY

President H Leroy Goss, M D, 620 Cobb Bldg, Seattle 1, Washington.
Secretary-Treasurer Homer E Smith, M D, 508 East South Temple, Salt Lake City, Utah.
Meeting

PAN AMERICAN ASSOCIATION OF OTO RHINO-LARYNGOLOGY AND BRONCHO-ESOPHAGOLOGY

President Dr Jose Gros, Havana, Cuba
Executive Secretary Dr Chevalier L Jackson, 3401 N Broad St., Philadelphia 40, Pa., U S A.
Meeting Sixth Pan American Congress of Oto Rhino-Laryngology and Broncho-Esophagology
Time and Place Brazil, 1958

PHILADELPHIA LARYNGOLOGICAL SOCIETY

President Dr Chevalier L. Jackson
Vice-President Dr John J O'Keefe
Treasurer Dr Joseph P Atkins
Secretary Dr Louis E Silcox
Historian Dr Herman B Cohen
Executive Committee Dr Harry P Schenck, Dr , Benjamin H Shuster, Dr William A Lell, Dr , William J Hitschler

PITTSBURGH OTOLOGICAL SOCIETY

President Dr Bernard L Silverblatt, 3500 Fifth Avenue, Pittsburgh Pa
Vice-President Dr Emory A. Rittenhouse, 203 Masonic Bldg McKeesport, Pa.
Secretary Treasurer Dr John T Dickinson Mercy Hospital, Pittsburgh 19, Pa.

PORTUGUESE OTORHINOLARYNGOLICAL SOCIETY

President Dr Albert Luis de Mendonca
Secretary Dr Antonio da Costa Quinta, Avenida, de Liberdale 65 1° Lisbon

PUGET SOUND ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Clifton E Benson, Bremerton, Wash.
President Elect Dr Carl D F Jensen Seattle Wash
Secretary Dr Willard F Goff, 1215 Fourth Ave Seattle, Wash

COMMENTS ON A FOURTH YEAR OF TRAINING FOR CERTIFICATION IN OTOLARYNGOLOGY

GORDON D. HOOPLE, M.D.,
Syracuse, N.Y.

BACKGROUND

Just ten years ago, the American Board of Otolaryngology, following a review of the status of otolaryngology during and following World War II, decided the training of otolaryngologists needed strengthening. It ruled that all applicants for certification by the Board would be required to have three years of residency in otolaryngology if they began their training after July 1, 1950. At the time, there were not a few who expressed concern about this increase in the length of training. Today, however, there is no thought of a return to the former two years. There is universal acknowledgment that this move has been productive of great benefits to otolaryngology.

Ten years have passed since the announcement of this ruling. During these years, a more systematic and thorough system of appraising the residencies in otolaryngology in this country has been established. The appraisal body is known as the Residency Review Committee for Otolaryngology. It has succeeded the former Review Committee of the American Board, which, when it was in existence, passed judgment on residency training programs independent of the inspections of the American Medical Association and the American College of Surgeons. When this system was in vogue, there was

---

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication Aug. 11, 1958.

confusion and inefficiency, and the settlement of any differences between official inspections of the three bodies (and there were some) often took one to two years to iron out. The present Residency Review Committee, then, has three cooperative sponsoring organizations: the American Medical Association, the American College of Surgeons, and the American Board. There is equal representation on the committee, four otolaryngologists from each of the three parent bodies. Each of the parent bodies has agreed to accept the judgment of these twelve men on any given residency. This means that approval or disapproval of a residency program, once it has been decided by the Residency Review Committee, has the simultaneous sanction of the American Medical Association, the American College of Surgeons, and the American Board. Order has come out of the confusion. The Residency Review Committee is more efficient, and its judgments are much more accurate and reliable. These judgments are the result of studied and often lengthy deliberations of twelve serious and dedicated men.

Over the past five years, the Residency Review Committee has processed an intense amount of data on otolaryngologic residency programs in the United States. The Committee meets twice a year, giving two days to each session. No other matters are considered save material pertaining to residency training programs in otolaryngolgy.

Good thinking and sound judgment have been used. As a result of these five years of deliberation, during which time the approval of more than a few residencies has been withdrawn (including, unfortunately, some university programs), a feeling has arisen amongst the members of this Committee that the 1948 action of the American Board of Otolaryngology, *good as it was, was not enough. It has been felt that additional* requirements were necessary to bolster the training of otolaryngologists. This feeling has not been crystallized by the Residency Review Committee, for this is not its function. (Approximately 50 per cent of the membership of the Residency Review Committee is made up of otolaryngologists who are not directors of the American Board of Otolaryngology.) A formalization into a regulation can properly come only from the American Board of Otolaryngology Such action has been taken by the Board, but it should be noted that this action did not arise out of thin air, nor was it the result of pressures by individuals or groups outside of otolaryngology It was as a result of the combined opinions of the men who are in the best position to know the strengths and the weaknesses of Otolaryngologic Residencies throughout the country, *e g* , the members of the Residency Review Committee, and the men who see these same strengths and weaknesses manifest in the examination of candidates, *e g* the members of the Board

THE ACTION TAKEN

At a meeting of the American Board of Otolaryngology held in October, 1957, in Chicago, the Board voted to add an additional year of training to the three-year training period in otolaryngology The Board made public announcement that the additional year was to be devoted to straight surgical training

At a subsequent meeting held in San Francisco in May 1958, the previous action was modified At this meeting the American Board of Otolaryngology reaffirmed the requirement of a four-year approved residency training program, at least three years of which shall be in otolaryngology The Board modified the requirement of one year of general surgery The additional year of training may be devoted to otolaryngology or to other fields, such as surgery, medicine, pathology, basic sciences, or research

SOME SPECIFIC REASONS FOR THE ACTION TAKEN

1 During the early part of this Century, some of the rightful functions of otolaryngology were lost by default Occupied with infections of the sinuses and ears, the otolaryngologists of the country neglected to keep pace with advances made in the field of nasal and facial fractures, nasal deformities, and regional plastic surgery, also, with a few notable exceptions, the major surgery for malignancies of the sinuses, the larynx, tongue and in the neck, was not included in the training of otolaryngologists All of this requires excellent surgical technique and sound surgical judgment, in addition to a knowledge of the physiology and function of the structures involved and an understanding of the general nutritional problems encountered

2 In the past five years too many of the residency programs in otolaryngology have graduated men whose surgical record was deficient (It is a requirement of the Residency Review Committee that a program under review must submit to the committee a list of the operations performed in that residency by the staff and by the residents) The paucity of procedures in several programs has been notable In a majority of such instances, otolaryngology has been but a division of the Department of Surgery, and these procedures were not available to the residents in otolaryngology About 60 per cent of all the residency programs in otolaryngology are under control of the Department of Surgery in their institutions In a goodly proportion of these, budgets are insufficient, an adequate number of hospital beds is not available, and little or no research is in progress

3 The tempo of residency training has slowed Many residents are married, and the end of a day's work is often 5 o'clock, and not 11 or 12 o'clock at night, as it was in former days There is now more to teach and less time in which to do it

4 During the past ten years, there has been an increasing number of so-called oncologic surgeons trained These surgeons are supposedly trained to handle, surgically, malignancies in any location in the body In the knowledge of yesteryear, this new specialist might be a boon to medicine, but in the light of modern medicine, with the necessity for knowing much about function, as well as anatomy, and with the availability of diagnostic methods and armamentaria which are best employed by specialists in their use, oncologic examination, surgery and follow-up are not equal to that which can be performed by well-trained specialists in local areas Otolaryngologic residents must have adequate training in this field

5 Another important reason is the action taken by the

National Institute of Health A number of years ago this body felt that ophthalmology needed bolstering and spent some of its energies and monies for better training in ophthalmology, and the teaching of ophthalmology has improved The National Institute of Health now feels that the teaching of otolaryngology needs strengthening, in fact, it is a specialty needing help more than most others It is planning to spend thousands of dollars over the next ten to twenty years for the training of teachers and research men in the field of otolaryngology This is the opinion of a group outside of otolaryngology This is significant

6 The most important reason for an additional year of training in otolaryngology is the recent broadening of the field Better training is needed so that future trainees will have a working knowledge of the many facets of modern otolaryngology The scope of otolaryngologic surgery now includes procedures which are as complicated and demanding as any in the field of surgical endeavor (Rehabilitation service for some of these patients demands a thorough knowledge of many techniques), but there is also in this broad field the most delicate surgery of all—microscopic surgery of the ear A very large portion of all allergy falls within the scope of otolaryngology A modern otolaryngologist must know much about audiology He cannot practice intelligently without this knowledge, yet, this science itself has grown to the point where studies at the doctorate level are required to encompass its broad reaches A practical working knowledge of endocrinology is needed by the modern otolaryngologic specialist Research in all these areas is expanding significantly From what was thought to be a narrowing specialty in the mid-forties, otolaryngology has grown to become one of the broadest and most inclusive specialties of all This is demonstrated when medical students are adequately exposed to it Their response is usually one of amazement at the scope of the specialty and the opinion that they develop is at least one of respect, and often this is followed by an active interest

HOW WILL IT WORK?

The May, 1958, action of the Board of Otolaryngology purposely made the extra year of training flexible Surgically oriented residents may spend one year of the four in straight surgery and yet receive credit for the year Likewise, medically oriented residents may spend a year in medicine

It may be asked, "Why should any surgery be included in the training of one who wishes to confine his practice to the medical aspects of otolaryngology?" The answer to this is that the very best internists are those who attend the surgery performed on their patients and know what is done, so they can intelligently treat them in the future Medical otolaryngologists (they exist, and the good ones should be respected and admired) will be better specialists if they have had some surgical experience

Various other combinations are approved It is conceivable, for instance, that a resident may take two years of ear, nose and throat training, spend a year in otolaryngologic research, and then take a fourth year in otolaryngology He should make a most valuable senior resident

If the choice is a year of surgery, this year should be oriented to the needs of the otolaryngologic resident During the *year of general surgery, the individual should receive training* in patient care, which would include study of fluid and electrolyte balance, wound repair, shock, flaps, grafts, and dietary deficiencies of tube fed patients Operating room experience in the areas of interest to the otolaryngologist, namely, neck surgery, chest surgery, neurological surgery, etc, should be included In general, it would appear advisable to place this year of surgery between the first and third years of the otolaryngologic residency, which will be after the resident has some knowledge of what should be gleaned from this extra year This surgical experience can be obtained in the same hospital in which the sponsoring otolaryngological department functions or in a neighboring institution if it appears that better values can be realized It is only necessary that a qualified surgeon be in charge of the approved surgical service which is to train the otolaryngologic resident

Probably, many of the otolaryngologic residencies of the country will make this program a straight four years in otolaryngology. Where the facilities of a department are such that the material, the teachers, and the armamentaria are available and of good standing, this will be the sensible arrangement.

A LOOK TO THE FUTURE

The American Board of Otolaryngology has realized it must make moves which will strengthen the teaching of otolaryngology. With a long look into the future it has made the present ruling, *i. e.*, an extra year of training. Otolaryngology has expanded. There is no denying this. Almost surely, it will expand further. (The bio-acoustics of space travel, for instance.) The extra year of training has been added to prepare residents properly for the very broad field now emerging. In the future, not everyone will practice the entire field, but everyone should have training in all ramifications, so proper diagnoses, referrals, and follow-ups will be made. Only complete training will accomplish this.

Apparently, there is a need for more otolaryngologists in the United States today. One school of thought may argue for lower standards, so more practitioners will be produced. The time to increase standards is when there is a need for additional workers and when expansions in scope demand additional training. This is the situation today and is one of the reasons why the change has been made. It is believed that the response of future medical students will be adequate and rewarding.

This proposed year of additional training has seemed startling to some and to others, unnecessary. This is probably so, because not everyone is familiar with all this background material which has been available to the members of the Board. What everyone should remember is that this move has been made in view of the facts above outlined. It has been done in order to strengthen otolaryngologists and thus, to strengthen otolaryngology itself; all other reasons are subservient to this.

POSTMORTEM CHANGES AND ARTIFACTS IN HUMAN TEMPORAL BONES [*][†]

CESAR FERNÁNDEZ, M D ,

Chicago, Ill

I INTRODUCTION

The recognition of autolytic changes in human specimens is particularly important because, as a rule, the temporal bones are removed and fixed some hours after death, when autolysis is well under way This process may have developed to the point where pathologic change is masked or its recognition impeded, furthermore, autolysis and pathologic change often are intermingled with artifacts, so that a differentiation between one and the others remains uncertain To minimize these complications, the technique of injecting a fixative into the middle ear soon after death was developed The rationale was that the round window and probably the oval window are the main pathways of the fixative Then, if this was injected into the middle ear soon after death there was a good chance to eliminate or minimize the autolytic process Another procedure based on the same reasoning was removal of stapes before immersion

The purpose of the investigation to be described here was to compare the results in human temporal bones treated by three procedures—removal of stapes before immersion, immersion, and early fixation by injecting formalin into the middle ear soon after death The investigation was concerned with the preservation of the inner ear structures, study of patterns of postmortem changes and artifacts in human temporal bones, and comparison with those observed in guinea pigs [1]

II MATERIAL

The study included 53 human temporal bones taken from 28 cadavers which were kept under refrigeration (between -1 1° and 4 4° C) until autopsy The technique for removing human temporal bones as described elsewhere[2] was used

Removal of the stapes before immersion in fixative was done in two specimens Helly's fluid was used as the fixative and nitric acid as the decalcifier The immersion procedure, which consisted of removal of temporal bones and then immersion in fixative, was employed in 25 specimens In this group Helly's fluid, Zenker's solution, or Heidenhain-Susa were used as fixatives, and nitric acid, trichloroacetic acid, or formic acid plus sodium formate, as decalcifiers The technique for injecting fixative into the middle ear, as developed in the Department of Otolaryngology of the University of Chicago Clinics, was as follows One injection (10 cc) of 10 or 20 per cent formalin through the tympanic membrane, as soon as possible after death, removal of temporal bones at autopsy and immersion in fixative This group included 26 specimens Fixatives and decalcifiers as in immersion procedure were employed

The temporal bones were sectioned at 20 microns, and one of every ten or twenty sections stained as described elsewhere[3] with hematoxylin-eosin or Mallory's azan The preparations were studied under regular light microscopy

III DEFINITIONS

There are two types of artifact which should be differentiated one is primary, and is the result of interaction between reagents and membranes, fluids and cell constituents In the guinea pig this result was called the normal microscopic cytoarchitecture of the inner ear[1] when fixation by intravital perfusion of Heidenhain-Susa and staining with hematoxylin-eosin were used

The normal microscopic cytoarchitecture of the human inner ear must be defined in terms of the best result obtained by any procedure Examination of these specimens showed a homogeneous rather than a granular-like cytoplasm, in almost all cell populations of non-nervous tissue Undoubtedly this, together with some precipitates and globular formation, are signs of postmortem changes Golgi's apparatus, centriole and mitochondria were absent, as they were in animal specimens In the nucleus, the granular-like formation was also absent, and the karyosomes barely differentiated The plasmosome stained more prominently than any other cell constituent The cell bodies of Corti's ganglion presented swelling and homogenization, while Scarpa's ganglion was better preserved Size, shape and position of cells and membranes were, in general, comparable to those found in animals Any change

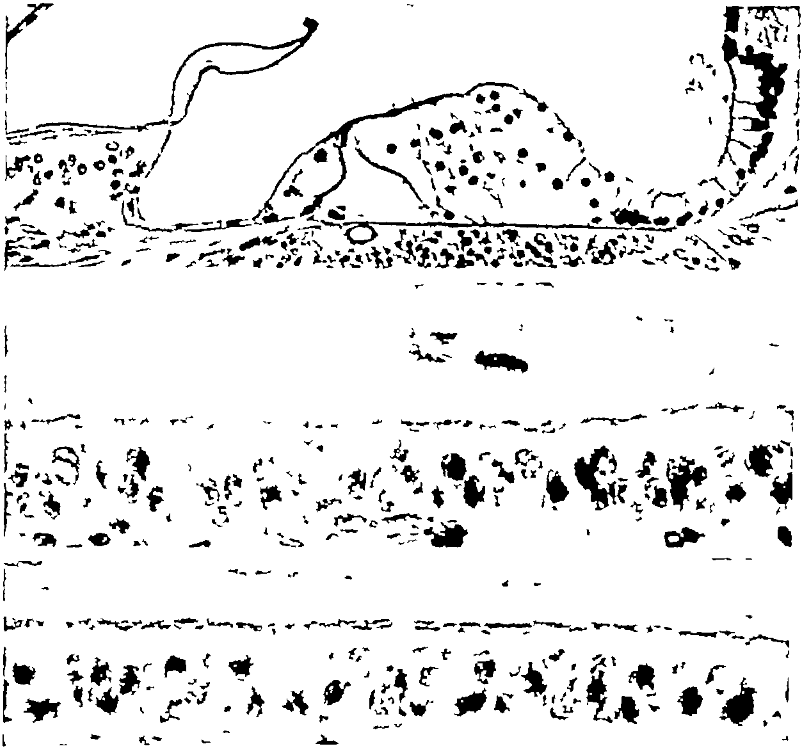

Fig 1 Good preservation of structures with minimum postmortem changes From top to bottom Organ of Corti (H-E X255) macula saccularis (H-E X625) and macula utricularis (H-E X625) Fine details of cell constituents can be identified

in this picture, other than pathologic or autolytic processes, was called secondary artifact For convenience, the term artifact has been used here to mean, unless otherwise specified, the secondary artifact

In the series of 53 human temporal bones a wide variation in degree of preservation was found The results were defined in terms of the efficiency of the methods in preserving the inner ear structures from postmortem changes and artifacts Using this criterion, the specimens were divided into four categories *1* Good, postmortem changes and artifacts were at a minimum These specimens were considered to demonstrate the normal microscopic cytoarchitecture of the inner ear and they were the ones to which all others were compared In Figs 1 and 2 the best samples of structures ideally preserved are presented The degree of preservation for individual specimens, in general varied from one structure

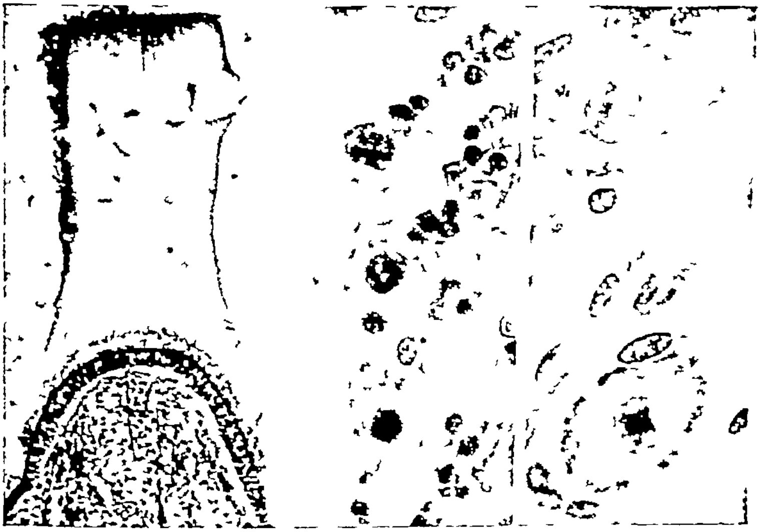

Fig 2 Good preservation of structures Left crista and cupula of a semicircular canal (H-E X105) in which there is some precipitate around the cupula and also over the surface of sensory epithelium Center cell bodies of Corti's ganglion (H-E X700) showing edema and hemogenization but in general nuclei are well preserved Right cell bodies of Scarpa's ganglion (H-E X700) in which the fine details of cell constituents are preserved

homogeneous rather than a granular-like cytoplasm, in almost all cell populations of non-nervous tissue. Undoubtedly this, together with some precipitates and globular formation, are signs of postmortem changes. Golgi's apparatus, centriole and mitochondria were absent, as they were in animal specimens. In the nucleus, the granular-like formation was also absent,

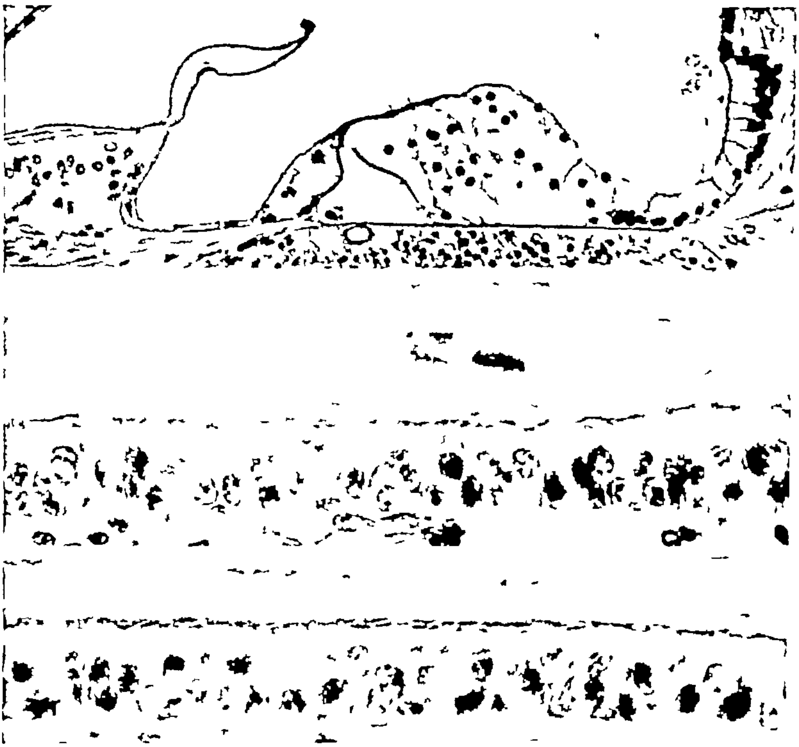

Fig. 1. Good preservation of structures with minimum postmortem changes. From top to bottom Organ of Corti (H-E ×255) macula saccularis (H-E ×625) and macula utricularis (H-E ×625). Fine details of cell constituents can be identified.

and the karyosomes barely differentiated. The plasmosome stained more prominently than any other cell constituent. The cell bodies of Corti's ganglion presented swelling and homogenization, while Scarpa's ganglion was better preserved. Size, shape and position of cells and membranes were, in general, comparable to those *found in animals. Any change* in this picture, other than pathologic or autolytic processes, was called secondary artifact For convenience, the term artifact has been used here to mean, unless otherwise specified, the secondary artifact

In the series of 53 human temporal bones a wide variation in degree of preservation was found The results were defined in terms of the efficiency of the methods in preserving the inner ear structures from postmortem changes and artifacts Using this criterion, the specimens were divided into four categories *1* Good, postmortem changes and artifacts were at a minimum These specimens were considered to demonstrate the normal microscopic cytoarchitecture of the inner ear and they were the ones to which all others were compared In Figs 1 and 2 the best samples of structures ideally preserved are presented The degree of preservation for individual specimens, in general varied from one structure

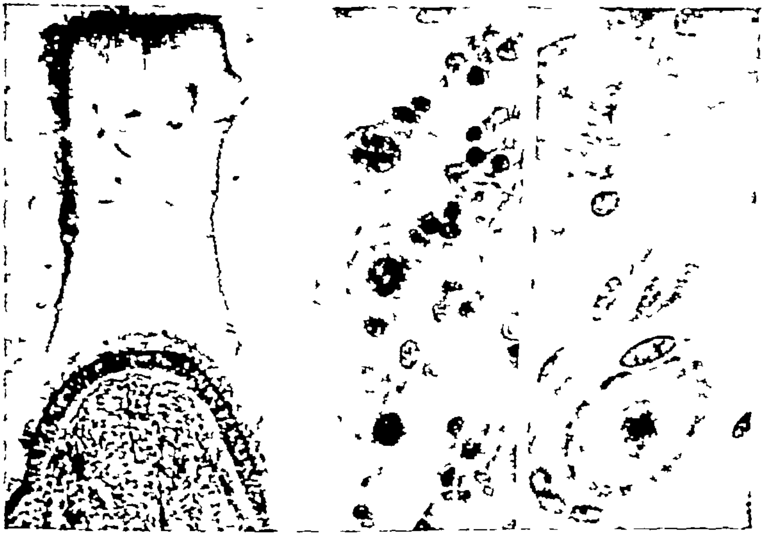

Fig 2 Good preservation of structures Left crista and cupula of a semicircular canal (H-E X105) in which there is some precipitate around the cupula and also over the surface of sensory epithelium Center cell bodies of *Corti s ganglion* (H-E X700) showing edema and hemogenization but in general nuclei are well preserved Right cell bodies of Scarpa s ganglion (H-E X700) in which the fine details of cell constituents are preserved

to another, the variation consisted mostly in more or less advanced postmortem changes *2* Fair, still more advanced postmortem changes and/or artifacts Precipitates and distortion of cells by swelling and homogenization were the most prominent features, however, cell membranes, nucleus and general cytoarchitecture were preserved, and consequently the specimens were useful for histologic studies *3* Poor, the cells were so distorted by postmortem changes and artifacts that usefulness of these specimens for histologic studies was questionable The distortion affected the organ of Corti more than structures of vestibular receptors Finally *4* unsatisfactory, useless for histologic studies of fine details

It must be clearly understood that this grouping of results into four categories was based only on the efficiency of the procedure for preserving the inner ear Any specimen, no matter how distorted it is by advanced autolytic process or artifacts, can be used for histologic studies of gross pathologic changes In cases of tumor, hemorrhage, atrophy of cochlear and vestibular nerve, infection, and other conditions the lesion can be identified, even though the fine details may be completely lost In other cases, such as acoustic trauma, intoxication and degenerative processes, the preservation of fine details is critical Our grouping was made with this latter type of pathologic change in mind

For convenience, the following definitions are given Injection time was defined as the time between death and injection of formalin into the middle ear Pre-refrigeration time meant the time between death and transfer of cadaver to the Pathology Department, as was found in the medical record We were informed that all cadavers are put in the refrigerator as soon as received In a few cases the pre-refrigeration time was questionable because it was too short Refrigeration was defined as the time the cadaver remained in the refrigerator, and immersion time as the time interval between death and immersion of the specimen in fixative

IV PRESERVATION AFTER REMOVING THE STAPES

In one cadaver the pre-refrigeration time, refrigeration and immersion time were three, eight and 13 hours respectively The stapes was removed in both ears, just before immersion The preservation of both temporal bones was classified as fair The Organ of Corti presented edema and homogenization of cells, precipitates, and globular formation In one specimen Reissner's membrane collapsed over the Organ of Corti without compressing it, in the other, Reissner's membrane was straight The sensory epithelium of vestibular receptors showed the same pattern of postmortem changes and similarly, the vestibular walls collapsed in one specimen without compressing the receptors In Fig 3 the Organ of Corti and a region of macula saccularis are illustrated The ganglion of Corti showed swelling and homogenization of cell bodies but no pyknosis In Scarpa's ganglion the granular-

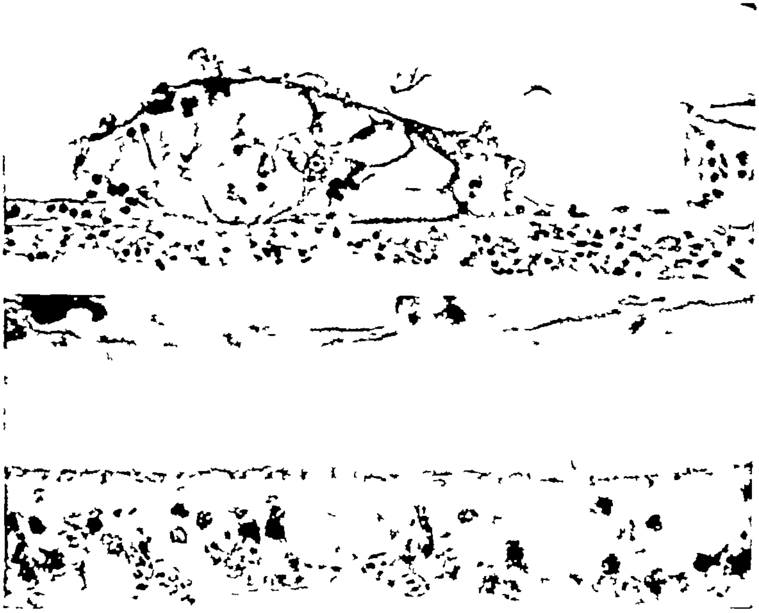

Fig 3 Fair results obtained by removing the stapes before immersion of the specimen in fixative H H 58 years cancer of the lung The Organ of Corti (H-E X255) presents edema of cells precipitates and globules but cells can still be identified The macula saccularis (H-E X625) shows edema of some sensory cells precipitates and globules between otoconia and sensory epithelium

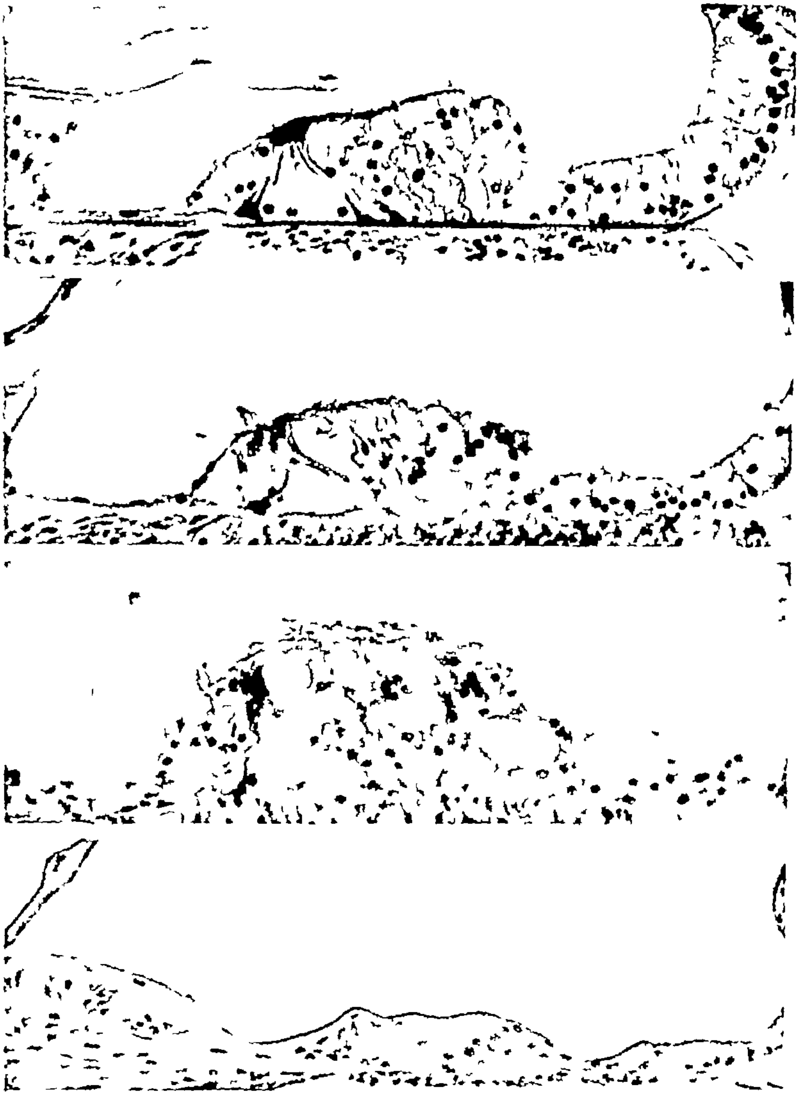

Fig 4 Type of results in the Organ of Corti obtained with the immersion procedure From top to bottom good (Mallory's azan stain ×255) fair (H-E ×255) poor (Mallory's azan stain ×255) unsatisfactory (H-E ×255) Fair and poor results were caused mainly by postmortem changes while the unsatisfactory was due to compression of the Organ of Corti

like cytoplasm and constitutents of the nucleus were differentiated

The procedure gave results which were no better than those of other methods It had the disadvantage that structures of middle ear may be largely destroyed during removal of stapes, and consequently, the procedure is not suitable for these particular studies Investigations with guinea pigs[1] showed that preservation of cochlear structures was as good by immersion procedure alone as it was by removal of the stapes With the latter, vestibular structures were better preserved, but there was a tendency to produce collapse of the membranous labyrinthine walls

Recapitulating, the investigation in animals and the study of two human temporal bones indicates that the removal of the stapes had more disadvantages than simple immersion

V PRESERVATION AFTER IMMERSION PROCEDURE

The histologic picture of the cochlea, vestibule and nervous elements will be described and discussed separately

Cochlear Receptors The results were as follows Good in seven, fair in two, poor in five, and unsatisfactory in eleven The four types of preservation are illustrated in Fig 4 Fair and poor results were brought about mainly by postmortem changes, while preparations were judged to be unsatisfactory primarily because of artifacts

Different degrees of swelling and homogenization with or without pyknosis characterized the picture of postmortem changes In poor results, large and numerous space formations in the Organ of Corti were seen, but we could not decide whether this represented edema of cells or intercellular spaces Precipitates and globular formation over surfaces, in Organ of Corti and/or cochlear spaces were consistently observed Comparison of these findings with those of experimental animals showed that the characteristic sequence of autolysis as a function of time was not seen in human as clearly as in animal specimens Fig 5 shows that the progress of autolysis was delayed in human preparations The immersion time in

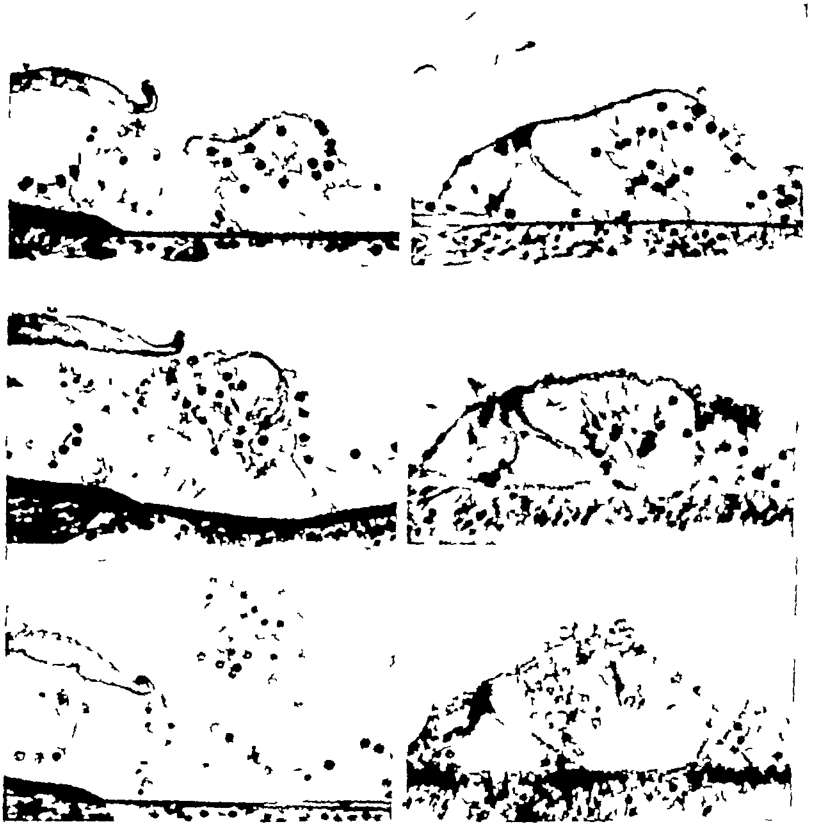

Fig 5 Comparison of autolytic changes in the Organ of Corti as function of time in guinea pig and human specimens Immersion procedure was used in all these cases The photomicrographs in the left column belong to guinea pig specimens immersed in fixative 6 10 and 20 hours after death (from top to bottom) In the right column are the corresponding samples of human specimens immersed 6 11 and 18 hours after death The figure illustrates that the autolytic process was faster in animal than human specimens The difference may be due primarily to refrigeration of human cadavers Mallory s azan stain was used in these sections except the middle one in the right column which was stained with H-E All photomicrographs X255

the 25 specimens varied between four and 20 hours In general, the degree of postmortem change increased as this time was prolonged Occasionally a specimen fixed a few hours after death presented more advanced autolysis than another which had been put into fixative many hours later Disintegration of cochlear structures, as seen in later stages of the autolytic process in animals, was found only in the stria vascularis of one specimen This was a child of 15 months

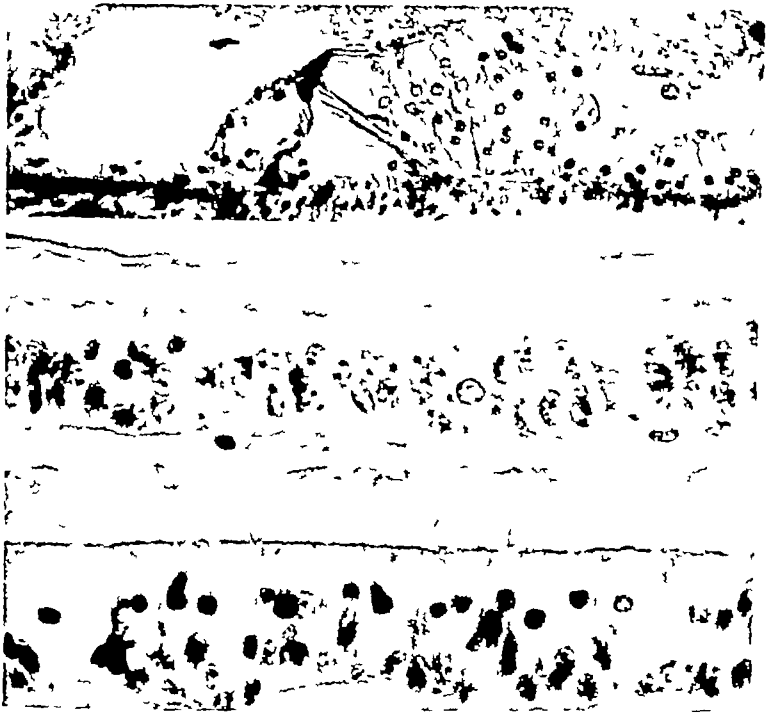

Fig 6 Good preservation of structures in a specimen in which the cochlea was broken during dissection of temporal bones By mistake the specimen remained in decalcifier for about four months From top to bottom Organ of Corti (Mallory's azan stain ×255) which presents precipitates over the surface macula saccularis (H-E ×625) where no postmortem changes are detectable and macula utricularis (H-E ×625) in which some sensory cells present edema and pyknosis The good preservation of structures might be attributed to facilitation of penetration of fixative through the broken cochlea however in the opposite ear where the cochlea was not broken the same results were obtained Refrigeration of cadaver seems to be the main factor in preserving this specimen from progress of autolysis

with a fracture of the base of the skull Immersion time of these temporal bones was 12 hours Disintegration of the stria vascularis was similar to that found in animal specimens immersed ten hours after death

The reason for the difference in the trend of postmortem changes in human and animal preparations was not clear We did not find evidence which could be related to terminal temperature of the patient, fixatives, decalcifiers or other steps in the histologic technique Difference in species and

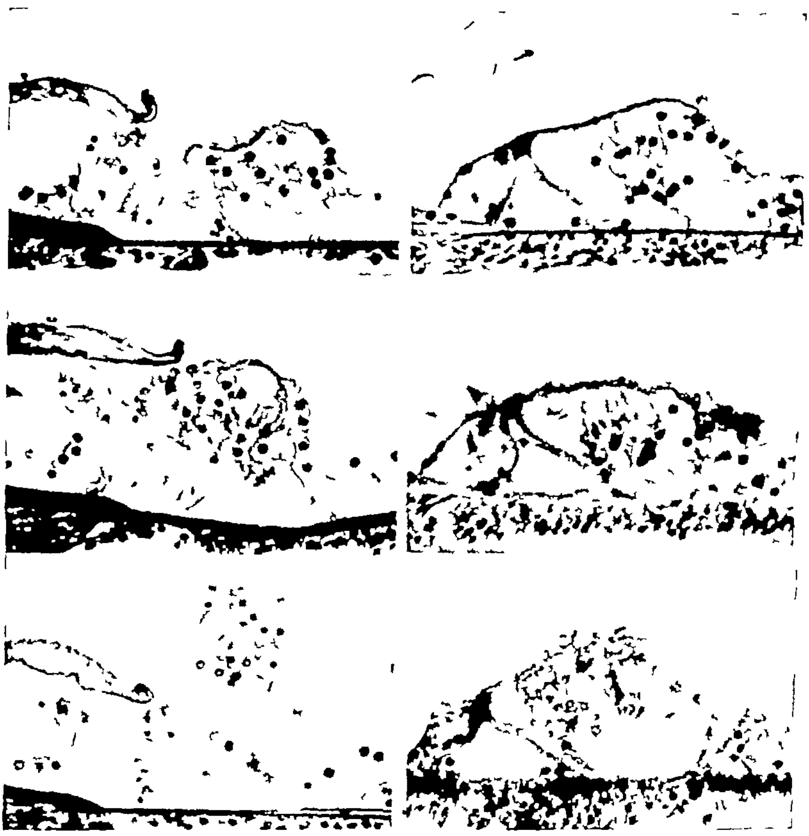

Fig 5 Comparison of autolytic changes in the Organ of Corti as function of time in guinea pig and human specimens Immersion procedure was used in all these cases The photomicrographs in the left column belong to guinea pig specimens immersed in fixative 6 10 and 20 hours after death (from top to bottom) In the right column are the corresponding samples of human specimens immersed 6 11 and 18 hours after death The figure illustrates that the autolytic process was faster in animal than human specimens The difference may be due primarily to refrigeration of human cadavers Mallory's azan stain was used in these sections except the middle one in the right column which was stained with H-E All photomicrographs ×255

the 25 specimens varied between four and 20 hours In general, the degree of postmortem change increased as this time was prolonged Occasionally a specimen fixed a few hours after death presented more advanced autolysis than another which had been put into fixative many hours later Disintegration of cochlear structures, as seen in later stages of the autolytic process in animals, was found only in the stria vascularis of one specimen This was a child of 15 months

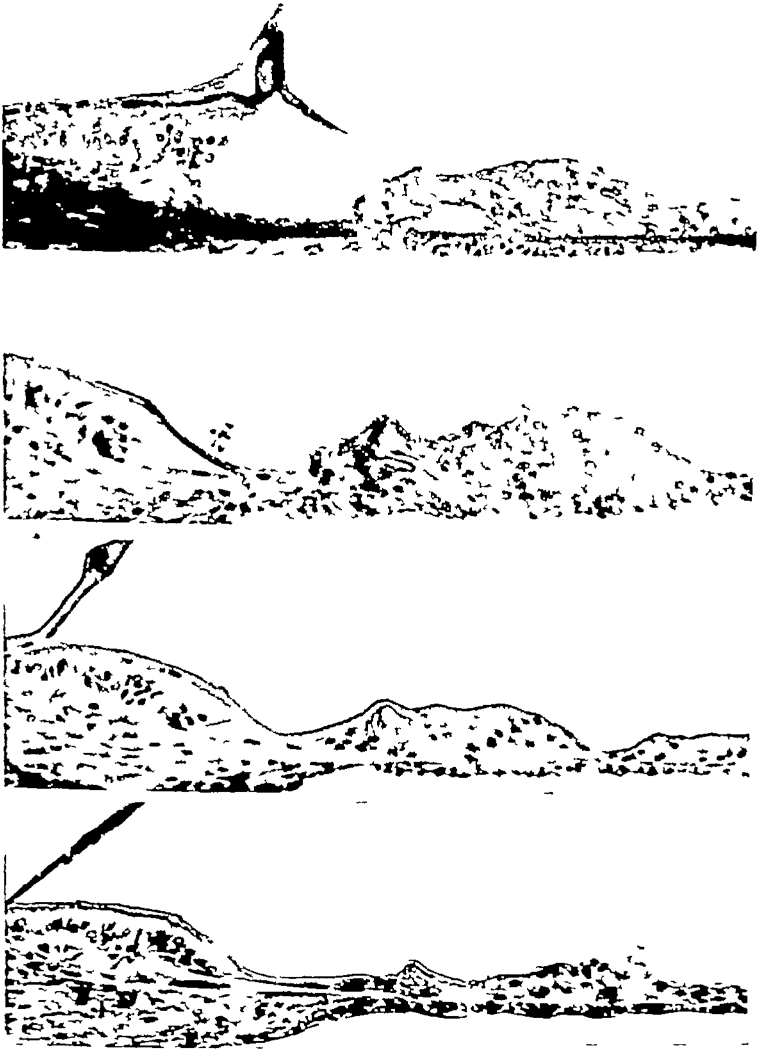

Fig 7 Several degrees of compression of the Organ of Corti from slight distortion to complete flattening In all cases the tectorial membrane is reduced to a thin lamina which generally appears collapsed over internal sulcus cells and Organ of Corti The degree of compression is reflected also in the limbus which in extreme cases may be flattened over the internal sulcus as the photomicrograph at the bottom of the figure illustrates In all cases the mesothelial cells appear agglutinated to the basilar membrane The section at the bottom of figure was stained with H-E the others with Mallory s azan stain All photomicrographs X255

conservation of cadavers in refrigeration until autopsy seem to be the most probable factors. Although refrigeration delays the autolytic process, the pre-refrigeration time must be considered, because the cadavers were exposed to room temperature (about 25.5° C) and consequently autolysis progressed steadily. This time varied from 30 to 170 minutes. As expected, the best results were found in specimens with the shortest pre-refrigeration time, but even among these there were unsatisfactory preparations. An example which may illustrate the importance of early refrigeration is given in Fig. 6. This was removed from a cadaver refrigerated 30 minutes after death and the temporal bones immersed in fixative 14 hours later. The photomicrograph shown in Fig. 6 is of the ear in which the cochlea was broken during dissection. This temporal bone was misplaced during decalcification, where it remained for about four months. The good results might have been attributed to facilitation in penetration of fixative, however, the opposite ear, where the cochlea was not broken, and the temporal bone not misplaced, showed as good results. This suggested that early refrigeration of cadavers is very likely of considerable importance in preventing or impeding postmortem change in temporal bones.

Detachment of tectorial membrane from the Organ of Corti was a consistent finding, but the membrane did not shrink as much as in experimental animals. This may be a matter of difference in size of this structure in the two specimens. Detachment of this membrane from the limbus was also observed in cases with advanced postmortem changes. The position of Reissner's membrane varied from straight to complete collapse (see Table I). Artifacts, such as detachment of Hensen's from Deiter's cells, space formation in internal and/or external sulcus cells, were almost absent.

Compression of the Organ of Corti accounted for almost all the unsatisfactory results. This phenomenon was characterized by collapse of the structures to such an extent that cells frequently could not be identified. The cytoplasm was dense, the nuclei were pyknotic and cell borders diffuse. The pillars of Corti and cuticular lamina collapsed so that the tunnel of Corti and Nuels' spaces disappeared. As a rule the tectorial

other cases it may be collapsed over the Organ of Corti In all the cases mesothelial cells were agglutinated to the basilar membrane Compression was also visible in the vestibular system where the otoconia agglutinated over the maculae and sometimes the cupulae over the cristae In these structures the height of sensory epithelium seems to be diminished As in the cochlea, the vestibular labyrinth did not present precipitates and globular formation

The cause of the compression phenomenon has been the center of several theories and debates According to Witmaack[4,5] perilymph is produced by a process of filtration, while endolymph is formed by a secretory process which takes place in the stria vascularis, Organ of Corti, cristae, maculae and its marginal epithelium Wittmaack claimed that endolymphatic pressure must be higher than perilymphatic, otherwise the architecture of the cochlear duct could not be maintained Under some circumstances the endolymphatic pressure may be diminished or the perilymphatic pressure may be increased In either case, Reissner's membrane collapses over the Organ of Corti, which will be affected in varying degree, from mild distortion to complete flattening This picture was called "hypotonic degeneration" by Wittmaack who claimed it is essentially a vital process Mygind[6] stated that perilymph is a filtration product mainly of the vestibular region of spiral ligament while endolymph is secreted mainly by the stria vescularis Normally both mechanisms are in balance Mygind found the picture described as hypotonic degeneration by Wittmaack only in animals fixed by intravital perfusion He assumed that because of some caprice of nervous mechanism, filtration predominated over secretion during perfusion of saline Consequently, Reissner's membrane collapsed over the Organ of Corti, causing several degrees of compression He called this picture "endolymphatic compression" and, like Wittmaack claimed it is a vital process Mygind[6] also stated that in human temporal bones the process of autolytic dissolution may induce collapse of the Organ of Corti so that it may be confused with the true compression as previously described

In either theory the factor which brings about the com-

membrane was flattened to a thin lamina, which either collapsed over internal sulcus cells and Organ of Corti (most of the cases), or it was detached from it and agglutinated to Reissner's membrane or the limbus Several degrees of compression were found, from moderate distortion to flattened structures A few examples are illustrated in Fig 7 As this figure shows, the limbus also presented several degrees of

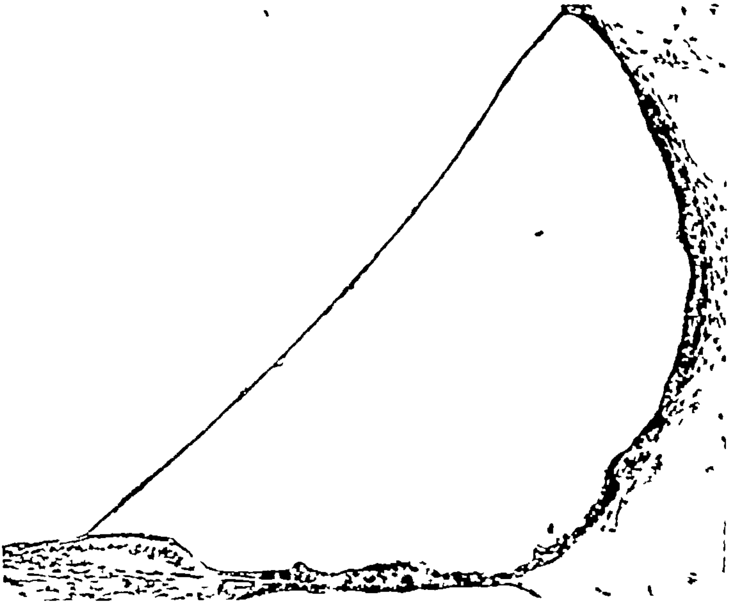

Fig 8 This photomicrograph of the scala media illustrates the neatness of the section in a case of compression of the Organ of Corti Notice the clear cut border of epithelium surfaces and absence of precipitates and/or globules H-E X120

flattening The absence of precipitates and globular formation was characteristic, and gave to the sections an aspect of neatness (see Fig 8) not found even in the best preserved specimens, however, using Mallory's azan stain and observing at high magnification, sometimes a thin layer of agglutinated precipitates could be seen over the Organ of Corti and stria vascularis Surface of the stria vascularis was unusually clear-cut and its flattened epithelium presented many pyknotic nuclei Reissner's membrane occasionally was broken, in

other cases it may be collapsed over the Organ of Corti In all the cases mesothelial cells were agglutinated to the basilar membrane Compression was also visible in the vestibular system where the otoconia agglutinated over the maculae and sometimes the cupulae over the cristae In these structures the height of sensory epithelium seems to be diminished As in the cochlea, the vestibular labyrinth did not present precipitates and globular formation

The cause of the compression phenomenon has been the center of several theories and debates According to Witmaack[4, 5] perilymph is produced by a process of filtration, while endolymph is formed by a secretory process which takes place in the stria vascularis, Organ of Corti, cristae, maculae and its marginal epithelium Wittmaack claimed that endolymphatic pressure must be higher than perilymphatic, otherwise the architecture of the cochlear duct could not be maintained Under some circumstances the endolymphatic pressure may be diminished or the perilymphatic pressure may be increased In either case, Reissner's membrane collapses over the Organ of Corti, which will be affected in varying degree, from mild distortion to complete flattening This picture was called "hypotonic degeneration" by Wittmaack, who claimed it is essentially a vital process Mygind[6] stated that perilymph is a filtration product mainly of the vestibular region of spiral ligament while endolymph is secreted mainly by the stria vescularis Normally both mechanisms are in balance Mygind found the picture described as hypotonic degeneration by Wittmaack only in animals fixed by intra-vital perfusion He assumed that because of some caprice of nervous mechanism, filtration predominated over secretion during perfusion of saline Consequently, Reissner's membrane collapsed over the Organ of Corti, causing several degrees of compression He called this picture "endolymphatic compression" and, like Wittmaack claimed it is a vital process Mygind[6] also stated that in human temporal bones the process of autolytic dissolution may induce collapse of the Organ of Corti so that it may be confused with the true compression as previously described

In either theory the factor which brings about the com-

membrane was flattened to a thin lamina, which either collapsed over internal sulcus cells and Organ of Corti (most of the cases), or it was detached from it and agglutinated to Reissner's membrane or the limbus Several degrees of compression were found, from moderate distortion to flattened structures A few examples are illustrated in Fig 7 As this figure shows, the limbus also presented several degrees of flattening The absence of precipitates and globular formation was characteristic, and gave to the sections an aspect of neatness (see Fig 8) not found even in the best preserved specimens, however, using Mallory's azan stain and observing at high magnification, sometimes a thin layer of agglutinated precipitates could be seen over the Organ of Corti and stria vascularis Surface of the stria vascularis was unusually clear-cut and its flattened epithelium presented many pyknotic nuclei Reissner's membrane occasionally was broken, in

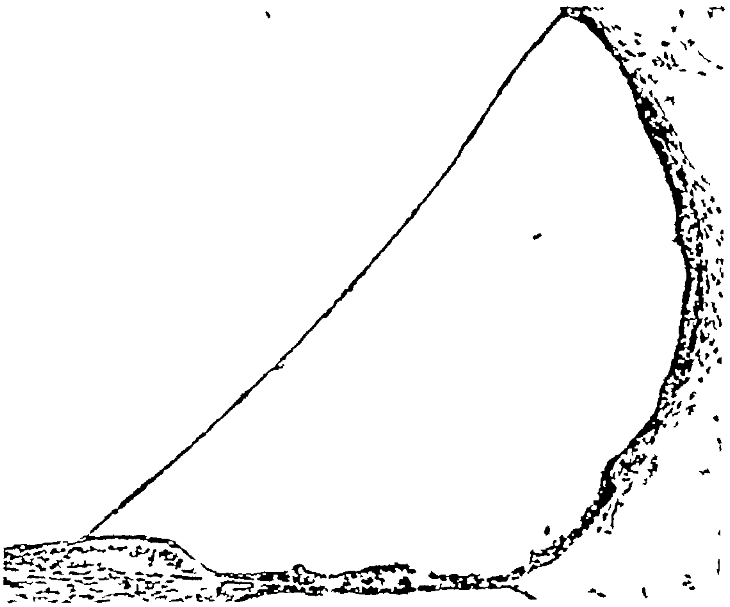

Fig 8 This photomicrograph of the scala media illustrates the neatness of the section in a case of compression of the Organ of Corti Notice the clear cut border of epithelium surfaces and absence of precipitates and/or globules H-E X120

other cases it may be collapsed over the Organ of Corti In all the cases mesothelial cells were agglutinated to the basilar membrane Compression was also visible in the vestibular system where the otoconia agglutinated over the maculae and sometimes the cupulae over the cristae In these structures the height of sensory epithelium seems to be diminished As in the cochlea, the vestibular labyrinth did not present precipitates and globular formation

The cause of the compression phenomenon has been the center of several theories and debates According to Wittmaack[4,5] perilymph is produced by a process of filtration, while endolymph is formed by a secretory process which takes place in the stria vascularis, Organ of Corti, cristae, maculae and its marginal epithelium Wittmaack claimed that endolymphatic pressure must be higher than perilymphatic, otherwise the architecture of the cochlear duct could not be maintained Under some circumstances the endolymphatic pressure may be diminished or the perilymphatic pressure may be increased In either case, Reissner's membrane collapses over the Organ of Corti, which will be affected in varying degree, from mild distortion to complete flattening This picture was called "hypotonic degeneration" by Wittmaack, who claimed it is essentially a vital process Mygind[6] stated that perilymph is a filtration product mainly of the vestibular region of spiral ligament while endolymph is secreted mainly by the stria vesicularis Normally both mechanisms are in balance Mygind found the picture described as hypotonic degeneration by Wittmaack only in animals fixed by intravital perfusion He assumed that because of some caprice of nervous mechanism, filtration predominated over secretion during perfusion of saline Consequently, Reissner's membrane collapsed over the Organ of Corti, causing several degrees of compression He called this picture "endolymphatic compression" and, like Wittmaack claimed it is a vital process Mygind[6] also stated that in human temporal bones the process of autolytic dissolution may induce collapse of the Organ of Corti so that it may be confused with the true compression as previously described

In either theory the factor which brings about the com-

pression phenomenon in human or animal specimens seems to be mainly the pressure applied over the Organ of Corti We think, as has been maintained in the past,[7] that the phenomenon of compression is an artifact The arguments which lead to this conclusion were as follows

1 Békésy[8] demonstrated that the tectorial membrane and reticular membrane are stiff plates, furthermore, Katsuki and Covell[9] also demonstrated that the reticular membrane with attached pillar cells is particularly resistant to being broken They stated, "The rather firm anchorage of the upper ends of the internal and external hair cells in the reticular membrane and the obviously rigid support of the phalangeal cells and pillar cells tend to produce a unit that is compact and not readily broken up" These observations suggested that a high pressure, which is not likely to be produced in the living state, would be necessary to compress the Organ of Corti It may be argued that a loss in turgescence of cells, as put forward by Wittmaack,[10] might facilitate the collapse of the unit But Katsuki and Covell[9] also found that the body of hair cells can be teased out of the Organ of Corti, leaving their cuticular border with the hairs and reticular membrane intact Schuknecht[11] illustrated in a cat with presbycusis that the frame formed by internal pillar cells and reticular membrane remained in its normal position, even though the external pillar cells and hair cells were absent These observations have shown that large changes in sensory and supporting structures of the Organ of Corti can take place without much altering the frame work formed by reticular membrane and pillar cells This argument supported the theory that the compression phenomenon seems to be related to changes which take place during the histological treatment of temporal bones

2 To explain collapse of the limbus (see Fig 7) by a vital process is still more difficult The limbus is a compact structure made of thick fibers, connective tissue cells and ground substance and it is widely attached to the spiral lamina Studies on presbycusis[11] and acoustic trauma[12] have shown that the connective tissue cells may disappear, but the frame formed by the fibrous tissue remained as in the normal animals These investigations showed that the limbus is particularly resistant to distortion even in the presence of degenerative processes Explanation of the collapse of this structure, as seen in human specimens, by pressure, degeneration, or another mechanism except artifact, is unsatisfactory

3 The absence of precipitates and/or globular formation is very difficult to attribute to any part of a vital process In the best preserved human specimen, and in the best animal sections prepared by intravital perfusion,[1] some debris always was found over the epithelial surfaces or in the scalae The amount of debris increased as autolysis progressed or when pathologic changes were present For these reasons and because the preparations with compression of the organ of Corti are too neat, we doubt this feature of the phenomenon can be produced by a mechanism other than artifact

4 Although the mechanism of dilatation of cochlear duct in Ménière's disease remains unexplained, we may assume that an overpressure probably was developed, but the evidence seemed to indicate that this overpressure is not enough to produce collapse of the Organ of Corti, tectorial membrane and limbus

The reports on histopathology of Meniere's disease,[13] where dilatation of cochlear duct was demonstrated, showed degeneration of the Organ of Corti, but not the features of compression Day and Lindsay[14] reported a case of Ménière's disease of the right ear in which electrocoagulation of the vestibule was done The histologic study of the temporal bone demonstrated dilatation of cochlear duct and a flat Organ of Corti showing some features in common with the compression phenomenon, as Fig 9 illustrates

These changes, which seemed to be degenerative, are incompatible with function, as shown by the audiogram, and the question was raised whether they represented an artifact or a pathologic change Fig 10 illustrates a case taken from our series, in which there was dilatation of cochlear duct without compression of the Organ of Corti and hearing loss as the audiogram indicates

Fig 9 Organ of Corti of a case of Meniere's disease which was treated by electrocoagulation of the vestibule Dilatation of cochlear duct was found throughout The changes in Organ of Corti are incompatible with auditory function The picture presents the features of compression and the question was raised whether the changes are artifacts or pathologic changes H-E ×115 (Courtesy Dr J R Lindsay)

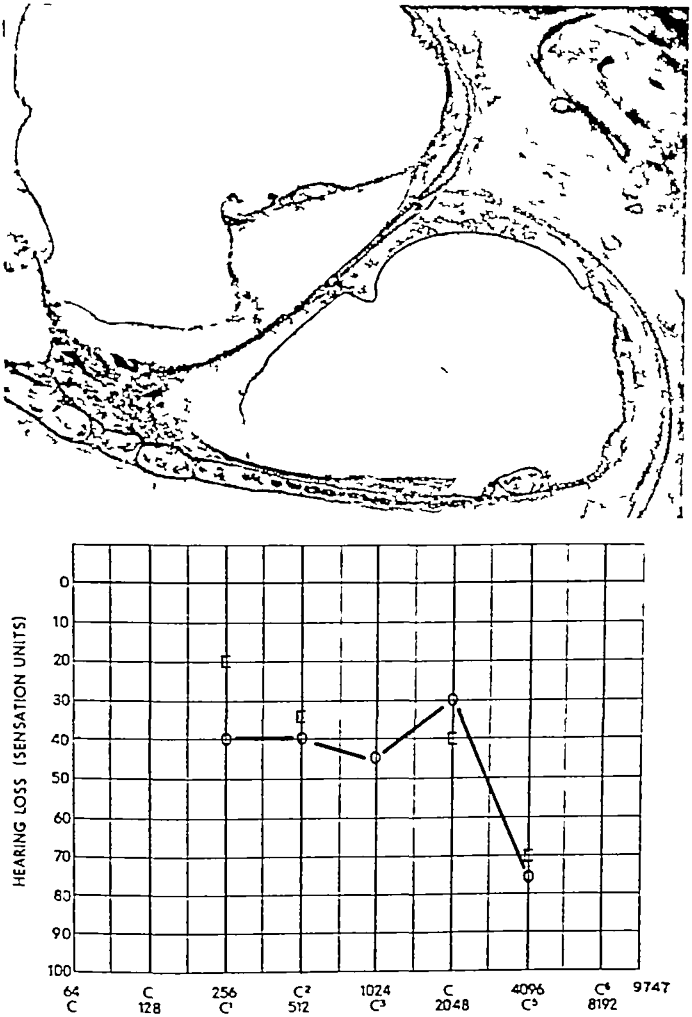

Fig 10 Dilatation of cochlear duct without compression of the Organ of Corti O H 66 years ruptured aortic aneurysm The photomicrograph shows the apical turns (Mallory s azan stain X38) Throughout the cochlea no signs of compression were found in spite of pronounced dilatation of cochlear duct. Notice that tectorial membrane limbus and Organ of Corti retain their shape and also that precipitates and globular formation are present The audiogram was taken 20 days before death

5 If the overproduction of perilymphatic fluid or diminution of endolymphatic fluid brings about the compression, then Reissner's membrane should be found collapsed over the Organ of Corti In Table I the position of the membrane for the 53 specimens is presented Included in Column 1 were all the cases in which the membrane was straight or deviated in one way or the other In Column 2 were those in which the collapse reached only the limbus, in Column 3, all the cases where Reissner's membrane touched the Organ of Corti In most of these cases, the collapse was restricted in extent mainly to the second turn Included in Column 4 were cases in which dilatation of cochlear duct or major distortion of the cochlea by artifacts made it impossible to include them in the other categories In cases with compression of the Organ of Corti (unsatisfactory results) the tendency of Reissner's membrane was to collapse, but the same picture also was found in cases without compression, furthermore, some specimens with compression presented a straight membrane Evidently, collapse of Reissner's membrane can not be used as an indication of overproduction of perilymph or diminution of endolymph The theory of Mygind[6] about the position of Reissner's membrane and endolymphatic compression is not applicable to human temporal bones because only postmortem immersion is used Since the compression, as seen in human material, was similar to that reported by Mygind in animals fixed by intravital perfusion, the theory that it was brought about by perfusion is questionable

TABLE I POSITION OF REISSNER'S MEMBRANE

		1	2	3	4
Results	No Cases	Normal	Collapsed over Limbus	Collapsed over Organ of Corti	Not Classified

Fair	7	2	1	4	
Poor	6	2	2	2	
Unsatisfactory	22	4	2	13	3

6 If compression is related to pathology or other disturbances of the inner ear, then comparison of the histologic pic-

ture and hearing tests may give some basis for that relationship Audiograms were available for 29 ears In some, the testing was done a few days before death, in others at varying intervals during the year preceding expiration In Table II the results are summarized

Seven of 15 patients with normal hearing, (see Column 1) as determined by the averaging method, presented compression Because these results were not correlative to function (see Fig 11), we believe the compression phenomenon is an artifact It is probable that some diseases of the inner ear present some features of compression, but the relationship of the disease to the histologic findings still must be demonstrated On the other hand, we believe that several times in the past the compression phenomenon has not been identified, or has been confused with pathologic changes For instance, Bunch and Wolff[15] reported three cases of degeneration of the Organ of Corti incompatible with function As far as we can judge from the reproductions, the Organ of Corti presented the features of the compression phenomenon Similarly, Ozaki[16] illustrated a case of streptomycin ototoxicity which had all the characteristics of compression Reissner's membrane appeared to be absent, probably it was broken and agglutinated over surfaces of the cochlear duct Organ of Corti and tectorial membrane were collapsed and the limbus presented a moderate flattening No precipitates nor globular formation could be detected

7 The suggestion of Mygind[6] that postmortem changes may induce endolymphatic compression in human specimens is questionable, since the trend of autolytic process is just the

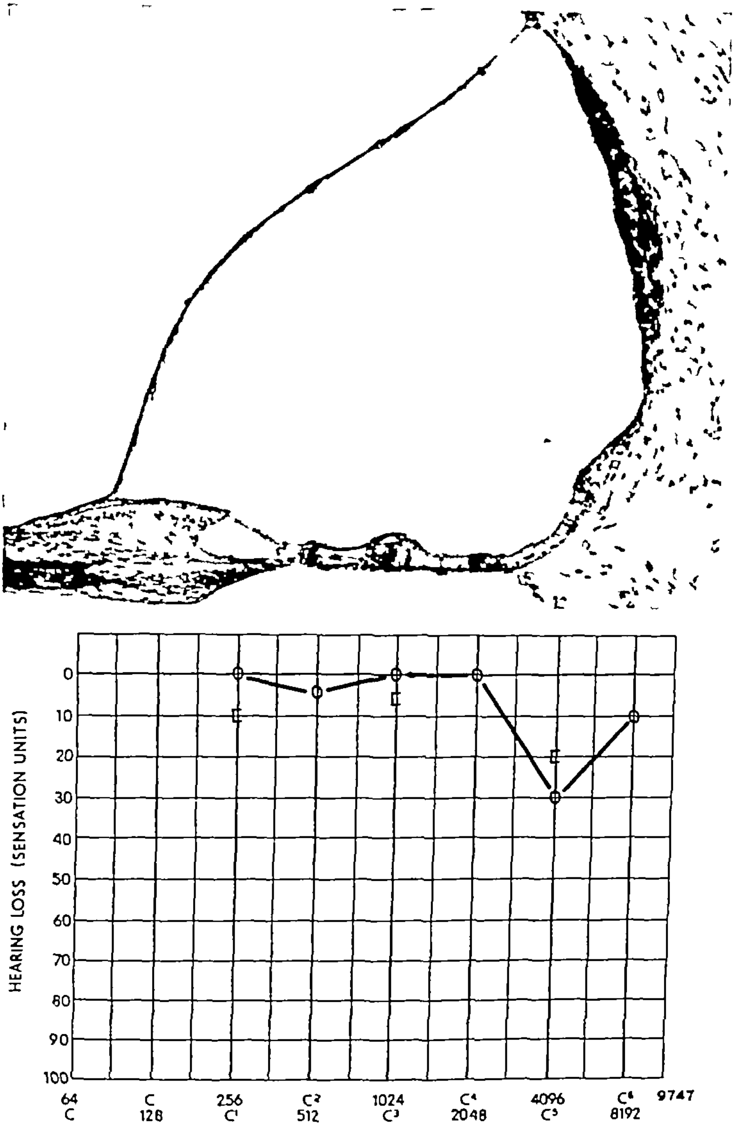

Fig 11 The figure illustrates a case of compression of the Organ of Corti in which the changes are incompatible with auditory function E G 47 years cancer of the tongue The photomicrograph (Mallory s stain X110) shows all the features of compression The audiogram was taken four months before death

opposite, *i e* to produce precipitates, globular formation and disintegration of cells

8 If compression is a vital process, then we would expect to find it in both temporal bones rather than on one side only Of the 25 subjects in which both temporal bones were saved, compression was found to be unilateral in 13 and bilateral in four, furthermore, unilateral compression was accompanied in many cases (8 subjects) by good results in the opposite ear, as Fig 13 illustrates (see legend)

9 The agglutination of mesothelial cells to the basilar membrane, found only in cases of compression, indicates that the phenomenon also took place in scala tympani This finding, and the fact that round window membrane did not show signs of pressure, suggested *that the agglutination of mesothelial* cells to basilar membrane is related more to histologic treatment than to pressure or a vital phenomenon

All these considerations suggested that compression phenomenon is not related to a vital process, as Wittmaack[4,5] and Mygind[6] contended The evidence pointed more to artifacts In the long process of histologic preparations many errors in the technique may be committed, or the interaction between reagents and delicate structures may be different from those expected, and thus marked changes in the cytoarchitecture can be produced In this series, there was no evidence of what kind of error may be committed and no indication as to where in the histologic technique an error may be critical

The arguments supported the theory that compression is an artifact Any effort to prove or disprove this theory is to be desired, because it is of considerable consequence to know whether the phenomenon is an artifact or a vital process

Vestibular Receptors Postmortem changes in the vestibular receptors paralleled those in the cochlea Swelling and pyknosis of sensory cells were the most prominent features In many cases, sensory and supporting cells of margins of maculae were better preserved than the center This may be due to penetrating characteristics of fixatives Precipitates and globular formation were usually found between otoconia and maculae, and also between cupulae and cristae Advanced postmortem changes, as seen in later stages of autolytic process in animals were rare As previously described, compression phenomenon was also detected in the vestibule, however, due to the simplicity of the cytoarchitecture of vestibular receptors, the distortion was moderate relative to that seen in the Organ of Corti

Neural Elements Ganglion of Scarpa was better preserved than the ganglion of Corti, as had been anticipated[1] The degree of postmortem change was not as might have been expected, however In animals the neural elements were the first among all structures of the inner ear to show signs of autolysis Swelling, homogenization, pyknosis, and finally disintegration, was the characteristic pattern In human specimens the picture was different The cell bodies of ganglion of Corti presented swelling and homogenization, pyknosis in a few cases, but no disintegration This probably was due to the fact that autolysis was delayed by refrigeration of cadavers In the ganglion of Scarpa the degree of preservation as a function of time was such that not much difference was seen from one specimen to another Fig 12 illustrates the state of both ganglions as a function of time Two main factors seemed to be involved in the good preservation of the ganglion of Scarpa, one was refrigeration, the other, anatomical arrangement Scarpa's ganglion is in the inner meatus and consequently, readily exposed to fixative

VI PRESERVATION AFTER INJECTION OF FIXATIVE IN THE MIDDLE EAR

This group included 26 specimens In 14 cases the injection time was 15 to 45 minutes, and in 12 cases was 70 to 120 minutes Pre-refrigeration, refrigeration and immersion times were about the same as in immersion procedure The results were classified as 11 good, three fair, one poor and 11 unsatisfactory

Cochlear Receptors The four types of preservation in the Organ of Corti are illustrated in Fig 13 Comparison with the result of immersion procedure showed that for either one

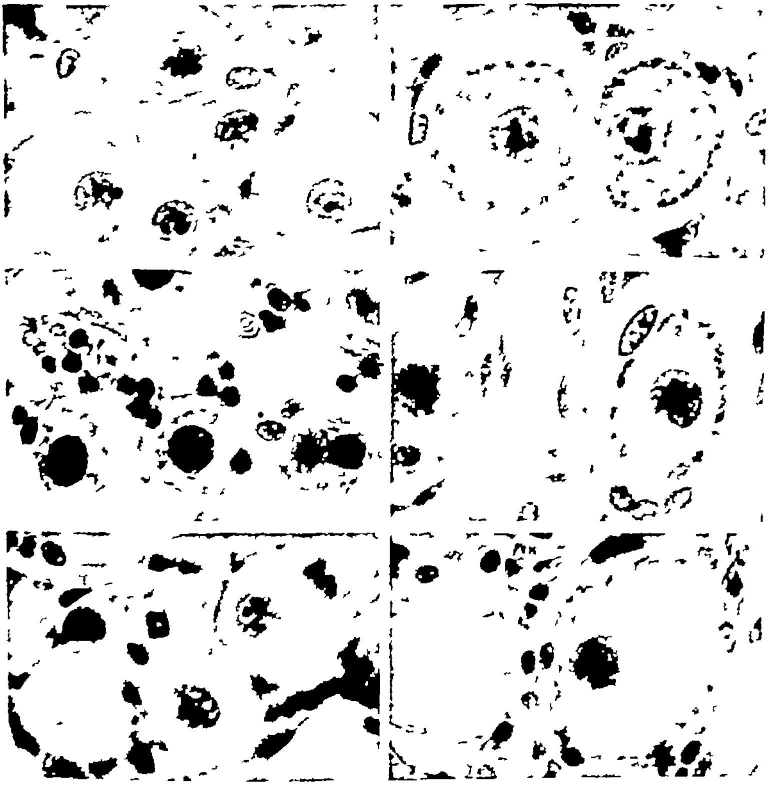

Fig 12 Autolytic changes in ganglions of Corti and Scarpa as function of time found in specimens fixed by immersion procedure From top to bottom on the left, cell bodies of Corti s ganglion of specimens immersed in fixative 7 (X700) 10 (X700) and 20 hours (X625) edema and homogenization are the most prominent features the nuclei are preserved although some may be pyknotic On the right are the corresponding cell bodies of Scarpa s ganglion (X625 X700 and X500 respectively) in which the cell constituents are better preserved than in Corti s ganglion All the sections from which the photomicrographs were taken were stained with H-E

the degree of preservation was similar (see Fig 4) From this point of view there was no advantage of one procedure or the other, however, injection of fixative into the middle ear soon after death gave a higher proportion of well-preserved specimens than was obtained by immersion alone Early fixation helped in preserving the inner ear structures from postmortem changes, but refrigeration still seemed to be the main factor Three observations supported this assumption one, the best results from immersion and injection

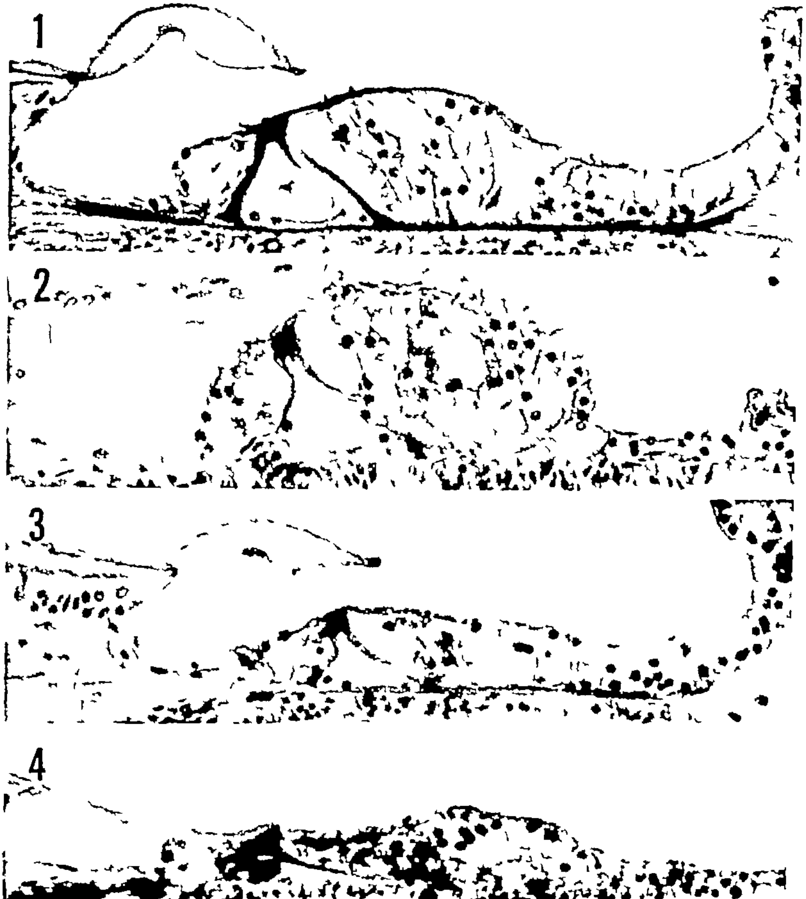

Fig 13 Preservation of the Organ of Corti after early fixation by injecting formalin into the middle ear soon after death 1 Good there is edema in internal sulcus cells and precipitates 2 Fair notice collapse of Reissner s membrane over Organ of Corti without compression 3 Poor edema of cells and intercellular spaces which give a picture of degenerative changes however they are incompatible with auditory function which was within normal range 4 Unsatisfactory compression of the Organ of Corti 1 and 4 belong to the same subject and the audiograms taken 12 days before death gave the same high tone hearing loss on both sides Consequently compression shown in 4 was considered an artifact

procedures are comparable, two, results were as good when injection time was 70 to 120 minutes as when it was 15 to 20 minutes, three, the ganglion of Scarpa, which can not be reached by fixative injected in the middle ear, was as well preserved in this group as it was in the group fixed by immersion only

Postmortem changes, swelling and homogenization of cells, precipitates and globular formation, were as described in immersion procedure

Nine of 11 cases of unsatisfactory results were caused by the compression phenomenon The features were as previously described This observation is in apparent disagreement with the theory that compression is an artifact, because, if early fixation was accomplished by injection, then the inner ear structures should not be affected by subsequent treatment The question is whether one injection of formalin into the middle ear was enough to fix the inner ear structures From basic principles of cytology,[17] a piece of soft tissue of no more than 3 mm in thickness requires 16 to 24 hours to be fixed providing it is completely surrounded by the fluid According to this, fixation of inner ear structures by injecting a fixative into the middle ear must be incomplete, the amount of formalin was small (10 cc), the time of fixation too short

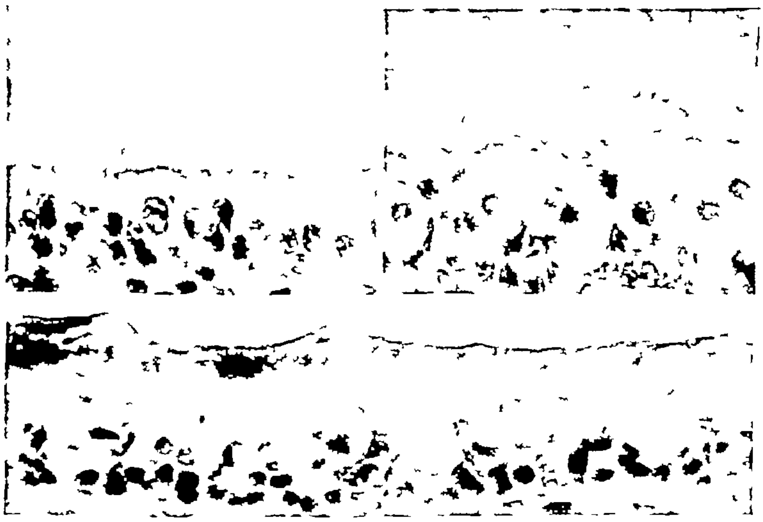

Fig 14 Preservation of macula saccularis after early fixation by injecting formalin into the middle ear soon after death Top left, good right fair bottom unsatisfactory result The latter is due to compression in which the epithelium appears flattened the cells pyknotic and otoconia agglutinated over the macula H-E ×625

(3 to 14 hours) and the structures not completely surrounded by the fixative (round window is the main if not the only pathway) Thus, the conditions under which subsequent treatment of temporal bones was carried out might induce the compression phenomenon

Vestibular Receptors The degree of postmortem changes and the effect of compression upon vestibular structures were of the same order as in immersion procedure In Fig 14 several stages of preservation of macula saccularis are illustrated Notice the effect of compression, the macula was somewhat flattened, and all cells were pyknotic, while otoconia and precipitates were agglutinated over the epithelium Occasionally cell detachment and the first stages of disintegration of the receptors were observed

TABLE III PRESERVATION OF INNER EAR STRUCTURES

As given by removal of the stapes before immersion routine immersion and early fixation by injecting formalin into the middle ear soon after death

Procedure	No	Good	Fair	Poor	Unsatisfactory
Stapes removed	2		2		
Immersion	25	7	2	5	11
Early fixation	26	11	3	1	11
Total	53	18	7	6	22

Neural Elements As in immersion procedure, the elements of cell bodies in Scarpa's ganglion were differentiated, and signs of postmortem changes were minimal in most of the cases Corti's ganglion presented the same pattern of preservation in this group as in specimens fixed by immersion procedure

VII FINAL OBSERVATIONS

In Table III the results of the series are summarized The necessity of improving on histological technique is evident, since about 40 per cent of the specimens were unsatisfactory for studies of fine details, largely because of artifacts

Both procedures, early fixation by injecting formalin into the middle ear and routine immersion, can be improved One injection of formalin, or other fixatives, seems to be insufficient, because a large amount of fluid must be taken up by the tissue of middle ear, and probably some runs out through the Eustachian tube Injections repeated at intervals may be profitable Cadavers should be refrigerated as soon as possible after death, and the temporal bones removed immediately after the cadaver is taken out of the refrigerator

The conditions under which subsequent fixation was actually carried out may increase the progress of postmortem changes first, the wave front of the fixative seems to take hours to penetrate through tympanic membrane, Eustachian tube, oval and round window, and other narrow pathways before reaching the inner ear structures, second, the fixative fluids were used at room temperature (about 25 5° C), and when the specimens were immersed in it heat probably reached the inner ear ahead of the fixative The end result was, most probably, an increase in the progress of autolysis Consequently, subsequent fixation at low temperature (4° C) is a possibility which we are now investigating

From the results obtained in guinea pigs[1] with postmortem perfusion, it was apparent that better fixation would be possible if this method were employed to preserve human specimens Since cadavers can not be perfused, a technique is now being developed to perfuse the temporal bones through the internal auditory artery as soon as the specimens are removed

SUMMARY

The purpose of this investigation was to study the preservation of human temporal bones from postmortem changes and artifacts A study of 53 specimens was made Three histologic techniques were compared removal of stapes before immersion (two ears), routine immersion (25 ears) and injection of fixative into the middle ear soon after death (26 ears) The results were classified as good, fair, poor or unsatisfactory, according to the efficiency of the technique in preserving fine cellular details

Removal of the stapes proved to be no more advantageous

than the other techniques, furthermore, it is not suitable for middle ear studies

Early fixation by injecting formalin into the middle ear soon after death gave a higher proportion of good results than was given by immersion procedure Fair and poor results were mainly due to postmortem changes, while unsatisfactory results were due to artifacts

Several degrees of swelling, homogenization and pyknosis of cells, precipitates, and globular formation were characteristic of autolytic process Disintegration, as seen in experimental animals, was not found even in specimens immersed in fixatives as long as 20 hours after death

Unsatisfactory results due to compression phenomenon were observed in 40 per *cent of the specimens included in the series* Compression was found as frequently in early fixation by injecting formalin *into the middle ear as in the immersion* procedure

Several suggestions were made to improve the current histologic technique

TREATMENT OF FRACTURES OF THE FRONTAL AND ETHMOID SINUSES*

HOLLIE E MCHUGH, M D ,

Montreal, Canada

The traumatic disruption of the frontal and ethmoid sinuses, complicated in severe cases by dural tears, loss of brain substance and intracranial infections, presents a problem of management for both the neurosurgeon and the otolaryngologist The degree of involvement of these paranasal sinuses following blunt or penetrating injuries to the forehead, varies from simple fracture lines to gruesome disintegration of the whole frontal area of the skull and its base The success of any plan of treatment can best be assessed in terms of permanent recovery, and the prevention of complications early or late, such as cerebrospinal rhinorrhoea, intracranial aerocele, meningitis or brain abscess

PURPOSE

The purpose of this study is to review the basic principles of the neurosurgical treatment of head injuries associated with fractures of the paranasal sinuses, and to consider the aspects of the problem which are of particular interest to the otolaryngologist The closest collaboration "between those who work below and those who work above the cribriform plate" (Cairns), will best decide the ultimate fate of the patients treated for these injuries

INCIDENCE

Lewin, in 1954 reported that of 1000 consecutive cases of non-missile head injuries severe enough to be admitted to the hospital, 72 (7 2 per cent) were found by radiological examination, or at autopsy, to have a fracture of the paranasal

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication Jan 27 1958

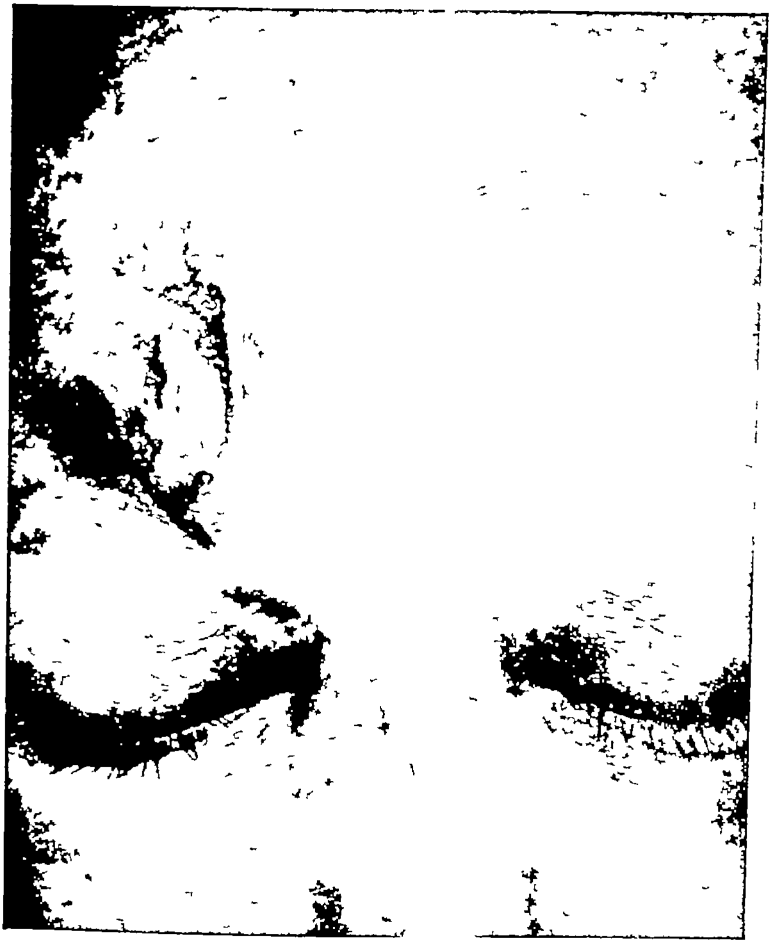

Fig 1 The superficial appearance of the forehead gives no indication of the extent or severity of the deeper damage—Case 3

sinuses It is significant that approximately 20 per cent of the 72 cases with severe frontal injuries died within 12 hours of the injury, and at autopsy the majority revealed dural tears in relation to the paranasal sinuses It is important to note, in less severe head injuries, that dural defects may occur into the paranasal sinuses with or without evidence of displacement of bone fragments, and that such defects constitute a danger which, in the absence of operative inter-

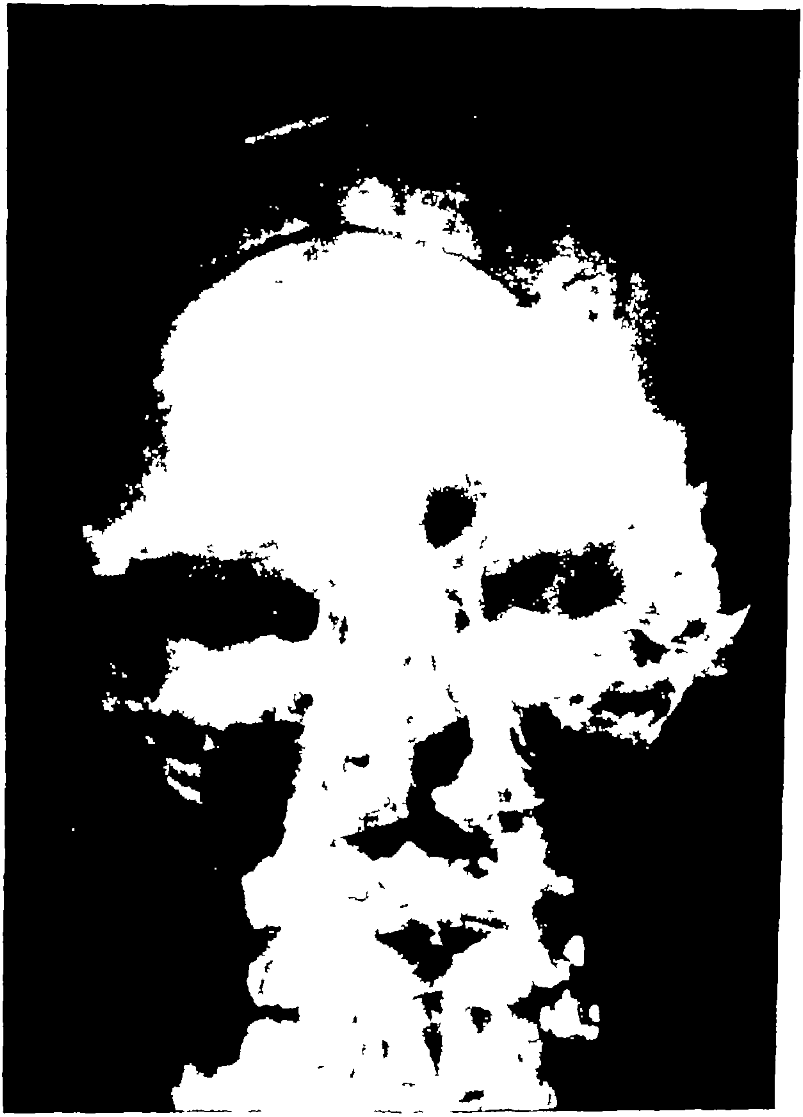

Fig 2 Multiple compound comminuted fractures of the skull with involvement of the paranasal sinuses—Case 3

ference, persist for years after the injury, if not indefinitely (Johnson and Dutt) In all head injuries, and in particular fronto-orbital fractures Cone, Schorstein and others have emphasized that the extent and severity of the deep damage is often considerably in excess of that which the external appearance would suggest (see Figs 1, 2, 3)

All of these cases, therefore, demand the most careful and thorough physical and radiological examinations The otolaryngologist can contribute valuable clinical information by meticulous examination of the ears, nasal passages, turbinates, meatuses and nasopharynx, for sources of cerebrospinal fluid loss or evidence of infection, and his surgical experience and skill can be utilized in the proper treatment of the traumatized sinuses in cooperation with the neurosurgeon

THE MECHANISM OF FRONTAL AND ETHMOID SINUS FRACTURES

The type of violence that is especially likely to produce fractures of the frontal and ethmoid sinuses is the head-on

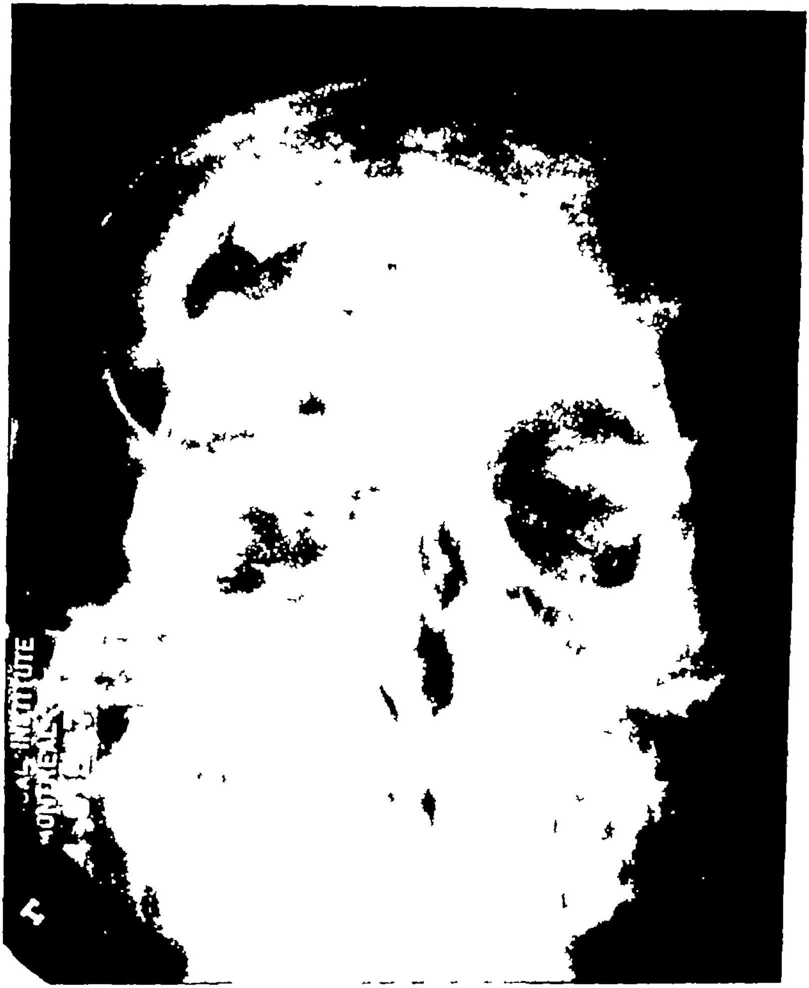

Fig 4 The X-ray appearance of the skull following operation with ablation of the right frontal sinus and exenteration of the right ethmoid sinus—Case 3

blow (Cairns) or blunt injury, in contrast to penetrating wounds The ethmoid sinuses may also be involved in cases where the force of the blow is applied mainly to the facial bones

The factors that determine the shape of the fracture must here, as elsewhere in the skull, include the size and shape of the object that inflicts the damage and the force with which

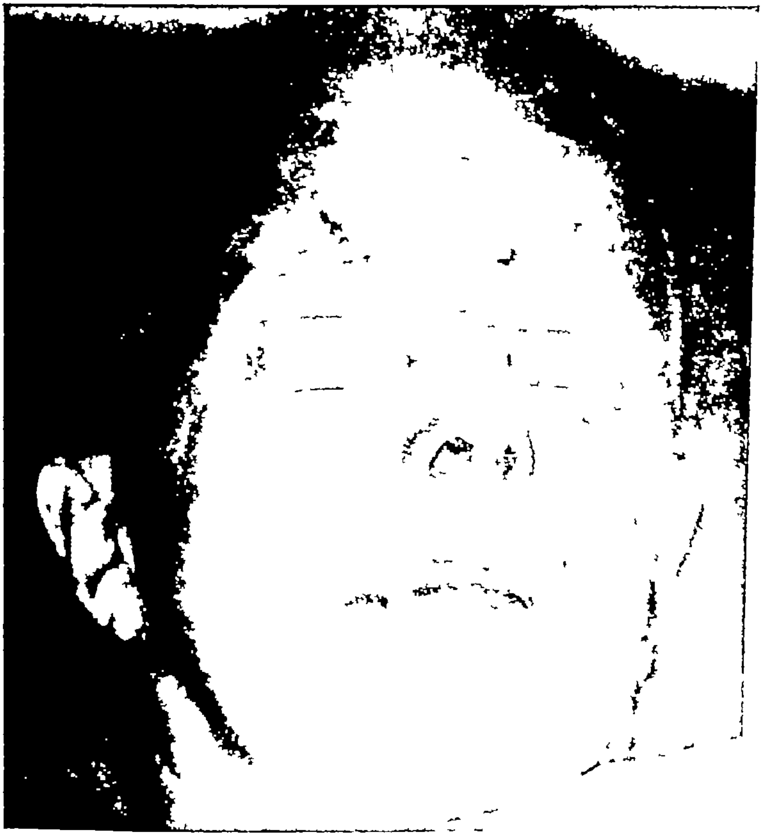

Fig 5 The appearance of the patient after treatment—Case 3

the skull is struck The extent to which the frontal bone is pneumatized must also be an important mechanical determinant (Schorstein)

Fractures involving the frontal and ethmoid sinuses may occur as the result of one or more of the following mechanisms (Schorstein)

1 A force which impinges on the supraorbital arches will, if severe enough, communicate itself to the floor of the anterior fossa and tend to shorten the orbital plate in an anteroposterior direction Should its elasticity be exceeded the bone of the anterior fossa will bend upwards and break, following its natural curvature In this type of direct injury or head-on blow, the dura is lacerated by displaced bone fragments, and defects are found both in the frontal sinuses and the ethmoids, frequently with separation, displacement or complete disappearance of the crista galli (Johnson and Dutt)

2 Fissured fractures may run either in an antero-posterior direction, down across the posterior wall of the frontal sinus and orbital roof or traverse the orbital plate from side to side They are basal bursting fractures, the result of forces striking the vault of the skull above the level of the base Their direction depends upon the direction of the injury and force, and not uncommonly they may traverse the lamina cribrosa and run into a defect in the ethmoids with an overlying dural tear

A fissured fracture will be deflected from a direction determined by the forces which produce it, by irregularities in the thickness of the bone, and will tend to run around and isolate hillocks or blisters of thicker bone (Johnson and Dutt) Fissure fractures tend to run into the nearby foramina in the roof of the cribriform plate and ethmoid

3 A third mechanism may act in conjunction with the two just mentioned the depressed anterior wall of the frontal sinus, by impinging on the brittle posterior wall, may break it over a wide area, including a portion of the anterior fossa floor

TYPES OF FRACTURES AND COMPLICATIONS

In a study of fractures of the skull involving the frontal sinus, Teachenor (1927) was impressed with "the amazing frequency of intracranial complications from this source, and likewise the pleasing success of prompt surgical drainage in the prevention of these complications" Calvert (1942) in discussing injuries of the frontal and ethmoidal sinuses stated that "fractures of the air sinuses are more often productive of grave complications than the literature on the subject would lead one to expect," Calvert emphasized that "the chief hazard in cases of frontal or ethmoidal sinus *fracture is laceration of the dural barrier and spread of infection intracranially from the nose"*

FRACTURES OF THE FRONTAL SINUSES MAY BE

1 Simple fissured or comminuted fractures of the anterior wall of the sinus with or without displacement of bone fragments Fissure fractures may involve the posterior wall without involvement of the anterior wall (Teachenor)

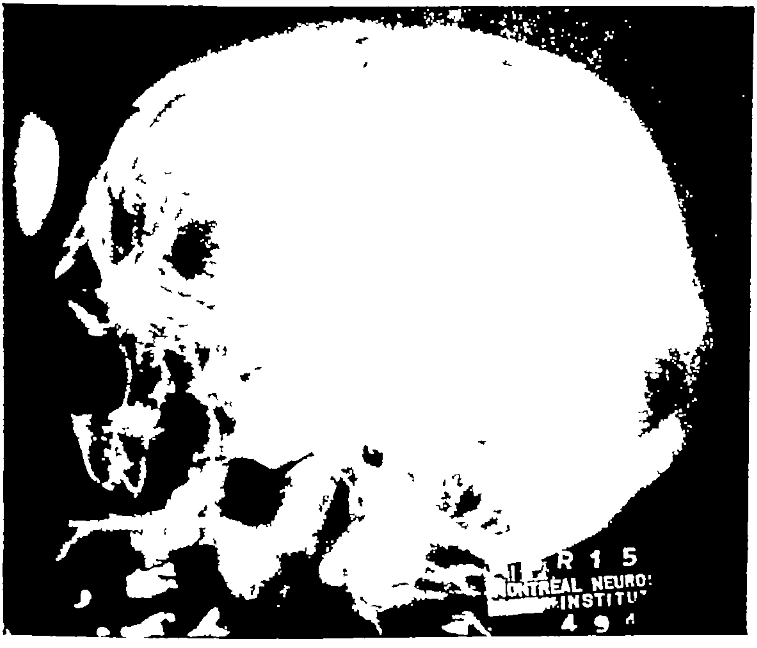

Fig 6 Compound comminuted fractures of the frontal bone with involvement of the anterior and posterior wall of the frontal sinus

2 Compound comminuted fractures of the anterior wall and floor of the frontal sinus with displacement of bone fragments into the sinus (see Fig 6)

3 Severe compound, comminuted fractures with gross bony displacement, dural tears and pulping of brain tissue

Cushing (*1927*) pointed out that mild frontal injuries may,

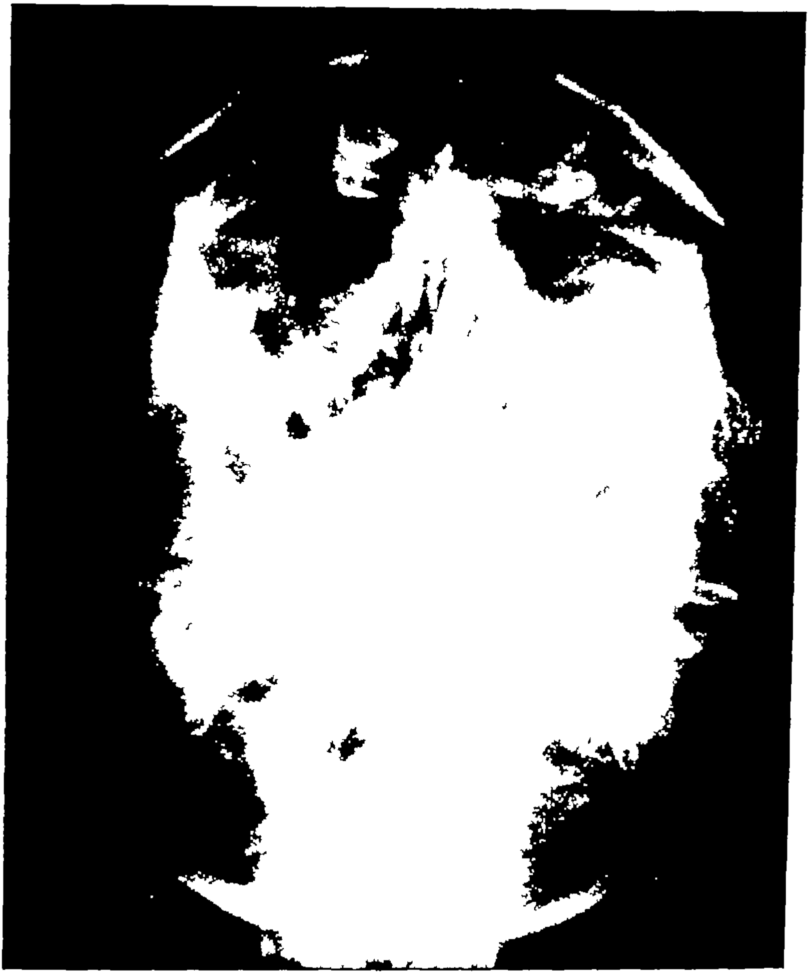

Fig 7 Radiological appearance of the skull with rubber tubes through the trephine openings into both frontal sinuses—Case 1

more often than suspected, produce a fissured fracture of the floor of the anterior fossa, or if not a fracture, a diastasis of the suture between the orbital plates of the frontal bone and the adjacent edge of the ethmoid bone roofing the ethmoid plates

In the floor of the anterior fossa, as in the depressed fractures of the vault of the skull, the dural tear may not always correspond to the fracture line, but will be determined by the sites and degree of fixation of the dura and its relative thickness As it tears, the elastic dura slides over the cortex, and a fold is occasionally entrapped in the fracture line (Johnson and Dutt) The thin adherent dura may be penetrated by displaced spicules of bone or split by distortion accompanying a fissured fracture (McKenzie)

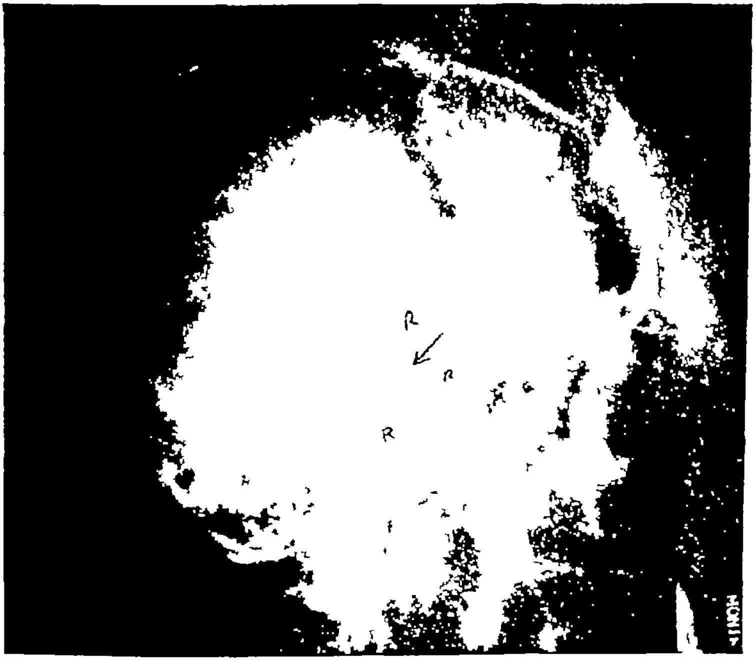

Fig 8 Multiple fractures of the vertex and base of skull with involvement of all the sinuses on the right side with subarachnoid and sub-dural air—Case 2

It is extremely rare for a fissure fracture to cross the ethmoidal roof without producing a defect in the bone and a tear in the dura (Johnson and Dutt) Because the inner periosteum of the cribriform plate is the thinnest part of the dura and, moreover, firmly anchored by its extensions through the bone along the olfactory nerves, Cairns believes that the most dangerous lesion is a fracture of the cribriform plate In such cases there is usually an escape of cerebrospinal fluid from the nose, anosmia may occur, and there is the obvious risk of intracranial infection

In fractures of the frontal sinuses alone the risk of cerebrospinal rhinorrhea and intracranial infection is, in the opinion of Cairns, not so great The dura strips more easily from the bone in this region and, even if it is torn, there is less likelihood that a cerebrospinal fluid fistula will immediately result, because the subarachnoid spaces on the frontal pole of the brain are not so large as on the inferior surface of the frontal lobe The possibility is, therefore, greater that over the frontal pole the defect will be plugged by brain tissue (Cairns)

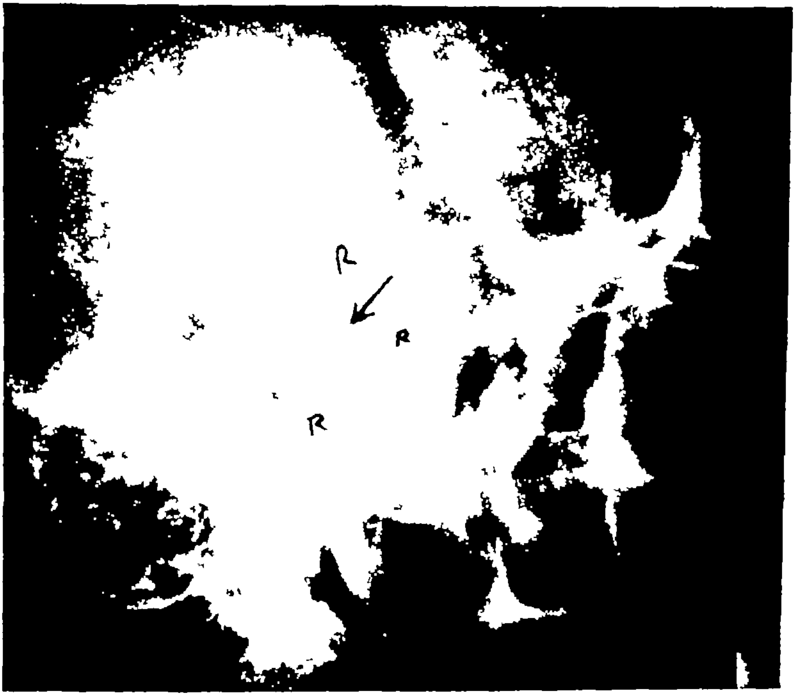

Fig 9 Detail of Fig 7 showing aeroceles and fissured fractures of floor of anterior fossa—Case 2

These opinions are in agreement with Lewis (1928), who stated that dural defects into the frontal sinus, if slight, tended to open the subdural space, but if extensive, communicated with injured brain. Fractures involving the ethmoid region are more likely to open into the large cerebrospinal fluid lakes in the basal subarachnoid space. Lewis believed, therefore, that the risk in the frontal sinus fracture was largely one of abscess or aerocele formation, while in the ethmoidal group the risk was more one of meningitis. (Johnson and Dutt, Cairns and McKenzie).

The two unequivocal signs of dural rupture are leakage of cerebrospinal fluid from the nose and the presence of an intracranial aerocele (Calvert). Cerebrospinal rhinorrhea may follow any type of fracture involving the paranasal sinuses varying from the finest crack, just visible on X-ray, to extensive comminution and depression of the whole frontal area, but not all paranasal sinus fractures are associated with cerebrospinal fluid rhinorrhea, even when the overlying dura is torn (Lewin).

Cerebrospinal rhinorrhea may occur in the acute stage, or as a delayed complication of a head injury. Streams of clear fluid may be seen coming from the middle or superior meatuses in the nose, or on the lateral or posterior wall of the nasopharynx, with the aid of the nasopharyngoscope. A sufficient quantity can usually be collected for analysis by proper positioning of the patient's head, so that the fluid flows or drips from the nose. Cerebrospinal fluid can be recognized by its clear colorless appearance, salty taste, and chemically differentiated from thin nasal secretions by the presence of sugar and the absence of mucin. This type of complication occurred in approximately two per cent of the 1,000 head injury cases reported by Lewin (1954).

Intracranial air and cerebrospinal rhinorrhea are frequently, but not always, associated complications. Air may enter the intracranial cavity through traumatized sinuses and produce an aerocele following sneezing, straining or blowing the nose. Aeroceles may be single or multiple, subdural, subarachnoid, ventricular or intracerebral, and may occur as early or late complications.

Anosmia occurred in approximately five per cent of Lewin's review of 1,000 cases of head injuries It was a symptom in 38 per cent of the cases with associated sinus fractures and in 78 per cent of the cases with cerebrospinal rhinorrhea

The extent of deep damage to the brain substance of the frontal lobes and its relationship to the dural tears, as seen at operation, varies considerably Where there is bone missing as a result of the fracture, the brain may herniate down into the defect and later become firmly adherent to the bony margins This is seen most frequently in the ethmoid region (Lewin) The fracture line may be enlarged by a gradual erosion of the thin margins of bone by the pulsating brain, similar to the changes in bone in contact with an aneurysm In this type of injury the risks of epilepsy as a late complication are of considerable importance

The presence of a nasal-intracranial connection through traumatized sinuses permits an easy pathway to the brain and meninges for infection Meningitis may be an early or late complication, and brain abscess is more frequently a late complication, especially in cases where the fractured sinuses were inadequately treated at the time of injury

GENERAL PRINCIPLES OF TREATMENT

Injuries to the frontal and ethmoid sinuses frequently come within the domain of both the neurosurgeon and the otolaryngologist, "and treatment without appreciation of this fact is not conducive to the best results" (Coleman) The use of sulphonamides and penicillin has lessened the risk of intracranial infection during the acute stages after injury, and it has also effectively lowered the incidence of post-operative infection in these cases (Lewin, 1954)

The basic principles of the neurosurgical treatment of contaminated compound fractures of the vertex of the skull, with laceration of the dura and of the brain, are now standardized and in general use The variations are those of method and timing of operative interference Cone emphasized that "fronto-orbital wounds differ not only from wounds elsewhere in the body, but also from wounds of the vertex with brain injury, because of the intracranial-intranasal connections through the damaged paranasal sinuses"

The basic principles of the rhinological treatment of severe compound comminuted fractures of the frontal and ethmoid sinuses are well established, but the treatment of the simple or apparently less serious fractures of these structures is not so well standardized The treatment of the various types of fronto-ethmoidal fractures will be considered as follows

1 Simple undisplaced fractures of this area may require no treatment (Work, 1954) It has been pointed out, however, that fissure fractures of the posterior wall of the frontal sinus may be associated with dural defects, and that such defects constitute a danger of intracranial infection that persists for years after the injury Although the treatment of simple fractures of the frontal sinuses may be conservative if no infection is present, fractures involving chronically infected sinuses demand prompt and appropriate action to prevent serious complications Cairns stated, however, that "the infrequency of overt sinusitis after injury suggests that intracranial infection can occur, indeed usually does occur through sinuses that are not inflamed" see Calvert, 1942)

Schorstein (1944) commented "at the present time a certain amount of controversy exists as to the need for radical operation in those frontal sinuses where the posterior wall has been broken without a laceration of the overlying skin" He added that some advocate immediate and radical operation, and others a watching policy

Teachenor (1927) advocated prompt surgical drainage of every case of fractured frontal sinus during the acute stage, whether there was leakage of cerebrospinal fluid or not, because "air and infection forced into the frontal sinus from the nasal cavity during sneezing or straining are important factors in the production of complications" In fissured or undisplaced comminuted fractures of the posterior wall of the frontal sinus, a simple trephine opening can be made, with a burr in the under surface of the medial end of the superior orbital ridge, through a small incision just below the eyebrow This permits inspection of the contents of the sinus and of the appearance of the mucous membrane A soft rubber catheter or polyethelene tube can be sewn into place, thus permitting daily gentle irrigation of the sinus with bacitracin or neomycin in solution The purpose of such a trephine is to prevent infection, or air, passing through the sinus into the intracranial cavity This method of frontal sinus decompression has been advocated by Cone for many years, and it has been used in selected cases of less severe fractures of the frontal sinus with success (see Cases 1 and 2) The drainage tube is left in place until the patency of the nasofrontal duct is re-esablished and the instilled solution passes freely into the nose

2 In compound comminuted fractures of the anterior wall and floor of the frontal sinus, the initial debridement may consist of removing bone fragments, providing closure of the skin can be accomplished and the patency of the nasofrontal duct can be established and maintained Patency can be accomplished satisfactorily by an external ethmoidectomy and the use of an acrylic dilator (Work, 1954)

3 If the injury is more extensive and there is comminution and compounding of both the anterior and posterior walls of the frontal sinuses and fractures of the ethmoids, ablation of the frontals and exenteration of one or both the ethmoids is the procedure of choice (Work) If there are dural lacerations and evidence of loss of brain substance the surgical treatment should be carried out completely and finally at the first operation, as early as possible after the injury, by the neurosurgeon and otolaryngologist This concept of primary treatment was strongly advocated by Cone, Stewart and Botterell

In severe compound, comminuted fractures of the fronto-orbital region, with shattering of the paranasal sinuses, tearing of the dura and laceration, contusion and pulping of the brain, Cone removes all of the frontal bone which contains frontal sinus The orbital plates are taken away, the glabella removed, and the orbital fascia is exposed back to the optic foramen and lesser wing of the sphenoid The removal of the ethmoid from above is almost complete, including the perpendicular plates, lamina cribrosa, the crista galli and the os planum The middle and superior turbinated processes come away with the inner wall of the lateral mass The removal is carried back to the sphenoid region The dura is thus exposed widely, the opening in it can be enlarged or new incisions can be made to permit debridement of the damaged brain The new vault of the nasopharynx is the dura and at the sides the orbital fascia The completely free drainage into the nasopharynx and the protection of the dura by packing until all defects are healed, are important factors in this overall method of treatment (Cone) (see Figs 10, 11, 12, 13)

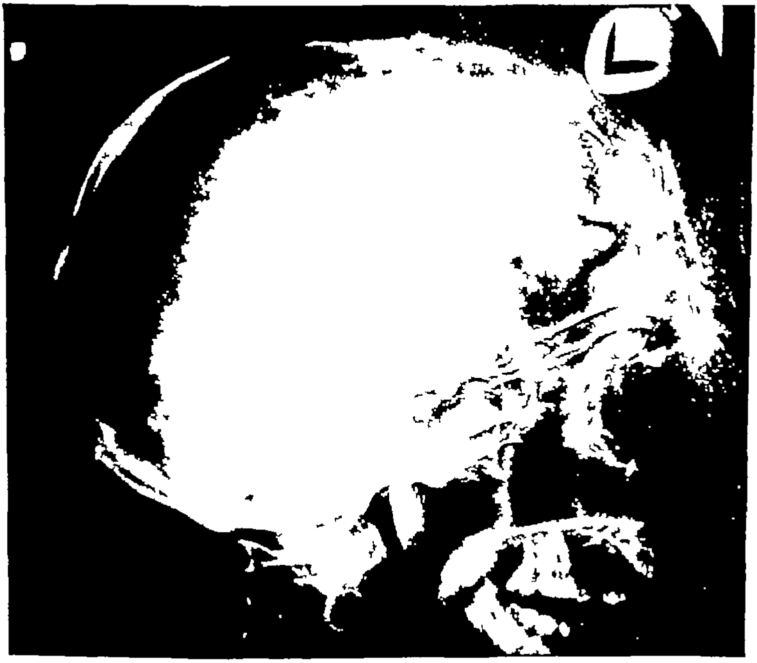

Fig 10 Note the very severe destruction of the bones of the anterior part of the skull and disorganization of the frontal and ethmoid sinuses—Case 5

A series of five cases of head injury with fracturing of the frontal and ethmoid sinuses, and in some cases all of the sinuses, is herewith presented with comments on the type and success of treatment employed

Case 1 Miss L L, age 22 This patient was admitted to Montreal Neurological Institute June 20 1942 three hours after she had fallen from her bicycle and struck her head against a cement abutment She suffered momentary unconsciousness a laceration 4 cm long above the lateral half of the left eyebrow abrasions about the left eye face and side of the neck There was bleeding from the nose but no definite cerebrospinal fluid rhinorrhea

X rays revealed fractures of the left radius and ulna and multiple fractures of the left zygoma left antrum, ethmoid, frontal and possibly

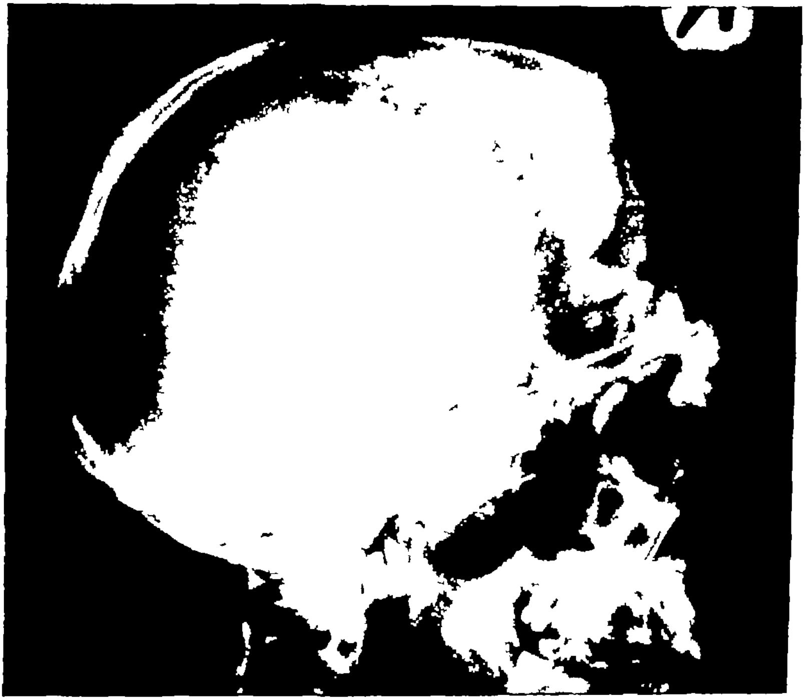

Fig 11 After surgical removal of the grossly fragmented anterior wall of the skull—Case 5

the sphenoid sinuses with no bony displacement in any of these regions There was *a fracture involving the lateral portion of the anterior wall* of the left frontal sinus and there was possible involvement of the posterior wall with no displacement Linear fissure fractures were seen in the floor and roof of the left orbit and in the lateral wall of the left antrum All of the paranasal sinuses on the left side and the right frontal and ethmoid sinuses were cloudy

Neurological Examination revealed a cerebral concussion with no other evidence of damage to the central nervous system

E N T Consultation June 21st No significant findings but in view of the X ray findings a trephine of both frontal sinuses was recommended to prevent if possible serious intracranial complications

Operation June 22 1942 Local anesthesia nupercaine 1 1500 Trephine of frontal sinuses via an incision one-half inch long in the medial end of the eyebrow A Cushing hand operated trephine bur was used to open into each frontal sinus The mucous membrane in the right frontal sinus was thickened pale and polypoidal The nasofrontal duct was blocked by one of the polyps hanging down into its orifice This was carefully removed, and the remainder of the mucosa was left untouched A firm rubber tube was inserted through the trephine opening into the sinus and held in place with dermalon sutures The lining in the left side was only slightly thickened but was ecchymotic in appearance The cavity was filled with blood clot and serous fluid but no definite cerebrospinal fluid A firm rubber drain was inserted as in the right side (see Fig 6)

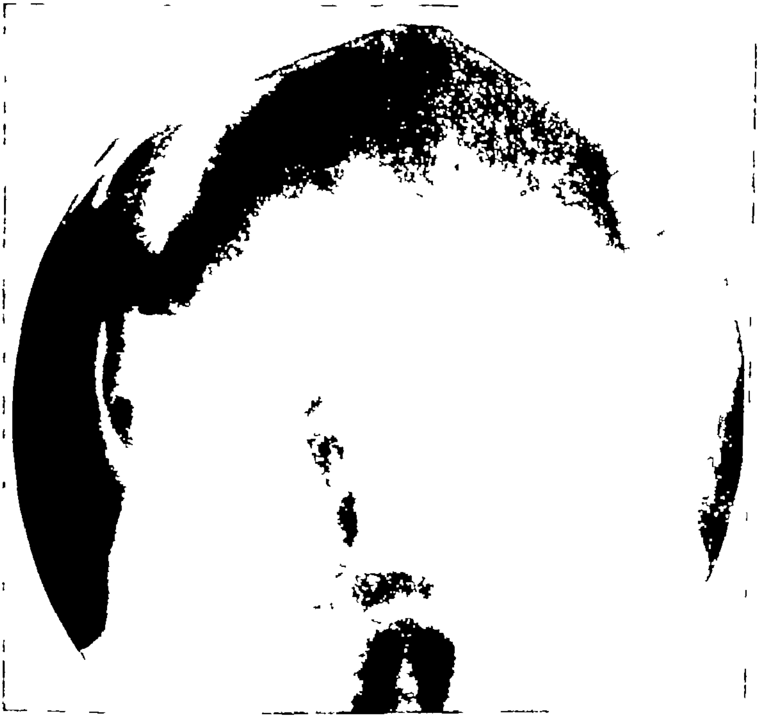

Fig 12 X-rays showing complete removal of the frontal and ethmoid sinuses (Cone s Method)—Case 5

Progress The dressings were changed daily and the frontal sinuses irrigated very gently with triple sulpha suspension On the fourth post operative day the irrigating fluid passed freely into the nose The drains were removed on the sixth post-operative day Sulphadiazine was given by mouth until July 4 Patient discharged on July 14

X rays taken on that date showed marked clearing of the sinuses

Films taken in 1951 showed no sinus involvement and the fractures had healed No complications have occurred since that time

COMMENT

This case represents a multiple uncomplicated linear fracturing of the frontal, ethmoid, maxillary and possibly sphenoid sinuses, treated conservatively with a trephine of both frontal sinuses to prevent possible complications The nasofrontal ducts were apparently blocked until the fourth postoperative day There were no intracranial complications early or late (15 years)

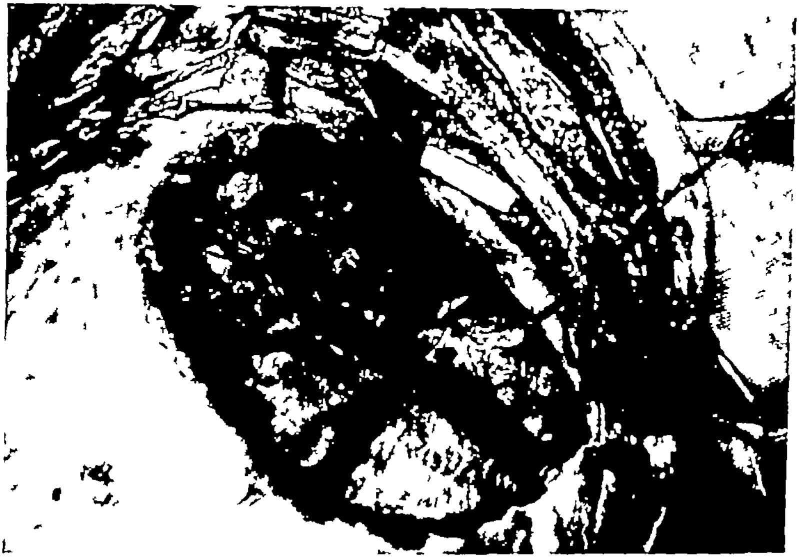

FIG 13 Seen from above All of the frontal bone which contains frontal sinus and compound comminuted bone fragments have been removed Likewise the orbital plates and ethmoid sinuses completely exenterated The dura of the frontal lobe is exposed widely The new vault of the nasopharynx is the dura above and the orbital fascia at the sides

Case 2 Mr G B age 29 This patient apparently fell 70 feet from a tower at 9 00 a m on March 19 1957 and was knocked unconscious He was flown some 1200 miles to Montreal Neurological Institute the same day There was marked swelling and ecchymosis of the eyelids temporal zygomatic and maxillary areas on the right side with a superficial brush burn over the right malar bone He was conscious but irritable and in pain There was no history of bleeding from either ear but he had vomited a large quantity of blood presumably from the back of the nose and paranasal sinuses

Neurological Examination Left abdominal and cremasteric reflexes absent Right plantar upgoing to Gordon s stimulation, no involvement of the cranial nerves

X rays, Skull and Sinuses There were multiple linear fractures of the lateral wall and floor of the right middle fossa and of the parietal and temporal bones and one of these may involve the roof of the middle ear There was air in the anterior fossa over the frontal lobes and possibly over the temporal and parietal lobes on the right side The right antrum was completely dense and both frontal sinuses were cloudy (see Figs 8 9)

E N T Consultation March 19 1967 Some swelling of the right external canal Right drum apparently intact but there appeared to be blood and/or spinal fluid in the middle ear space Nose—evidence of *recent bleeding but no definite cerebrospinal fluid visible In view of* the X ray findings a bilateral frontal trephine and an endonasal antrotomy were recommended

Operation—Bilateral Frontal Trephine and Right Endonasal Antrotomy General anesthesia The mucosa of the left frontal sinus was grossly edematous and ecchymotic in appearance A large fracture line was seen in the roof of the right orbit just posterior to the orbital edge some blood clot in both frontals Soft rubber catheters were inserted into the frontal sinuses and sewn in place with dermalon sutures A large endonasal antrotomy was then performed on the right side

Lumbar Puncture March 22 1957 Pandy trace protein 180 mg per cent, sugar 66 mgm per cent chlorides 733 mgm per cent cells 3000 polys 300 lymphs Daily lumbar punctures for one week and weekly punctures until April 15th showed gradual return to normal of protein sugar color and cell count

Bacteriology All cerebrospinal fluid cultures negative Culture of nasal swab staphylococcus pyogenes

Course in Hospital After drainage of the frontal sinuses was secured it was felt that there was no need for a radical neurosurgical procedure The sinuses were irrigated daily with bacitracin and sulpha suspension On the day of admission he developed a high fever rigidity of the neck and positive Kernig and Brudzinski signs A diagnosis of acute meningitis was made and vigorous systemic and intrathecal therapy was instituted at once This was followed by early clinical improvement and complete return of cerebrospinal fluid findings to normal He was discharged on April 17 1957 on sulphadiazine 0 5 G t i d for two weeks

COMMENTS

A case of multiple fractures of the vertex and base of the skull, with involvement of all the sinuses on the right side, with sub-arachnoid and sub-dural air, and development of purulent meningitis The frontal sinuses were gently irrigated daily until satisfactory intranasal drainage was re-established This occurred first on the left side on the sixth post-operative day and two days later on the right side

The intra-cranial air may have entered via the sphenoids, or via the right frontal and ethmoid sinuses

Case 3 Mr R S, age 50 This patient was seriously injured in an automobile accident April 12, 1950, when his wife drove into the back of a truck parked on the highway They both sustained serious injuries and were taken to the hospital This patient was apparently unconscious for three hours A piece of metal was removed from a laceration on the right side of the forehead and the wound closed He was transferred to the Montreal Neurological Institute on April 15, 1950, for further observation and treatment

Neurological Examination The patient was amnesic after the accident and for a period of about three days Speech was not affected Cranial nerves were intact There was a laceration over the right supra-orbital region, depression of the right supra-orbital ridge and right malar eminence, bilateral periorbital ecchymosis and marked right periorbital edema (see Fig 1)

X rays—Skull Multiple compound comminuted fractures of the skull with involvement of the paranasal sinuses Multiple transverse curvilinear fractures of the frontal bone mainly toward the right side multiple faciomaxillary fissure fractures involving both orbits and including the frontal ethmoid, maxillary and probably the sphenoid sinuses, especially on the right side The right frontal right ethmoid and the left antrum were completely airless there was considerable thickening of the lining of the left frontal left ethmoid and right antrum (see Fig 2)

E N T Consultation April 15, 1950 Ear drums intact and middle ear spaces clear Nasal septum obstructing on the left side, mucosa of the right middle meatus swollen and very moist possible cerebrospinal fluid leak, but no streaming seen, possible cerebrospinal fluid in the nasopharynx 'Decision re exenteration of the right frontal sinus to be made after neurosurgeon had exposed the area and repaired the dural tears"

Electroencephalogram April 15, 1950 "This E E G suggests the possibility of severe brain damage in the right frontal region to a lesser extent the left frontal region and to a considerable extent in the left anterior temporal region"

Lumbar Puncture April 15 1950 Initial pressure 80 fluid bloody

Operation April 16 1950 Bifrontal craniectomy for debridement and repair of compound depressed skull fracture right frontal, right ethmoid bilateral orbital exenteration of right frontal and ethmoid sinuses

Operation Findings Bifrontal scalp incision temporal fossa to temporal fossa reflected forwards The fracture lines were found as seen in the X rays but were much more extensively comminuted and depressed (see Fig 3) The right frontal sinus contained blood and perhaps some brain There was one large and several small tears in the dura of the orbital surface over the right frontal lobe Fracturing of the right anterior fossa involved the right ethmoid sinuses and the orbital roof as far posteriorly as the free edge of the lesser wing of the sphenoid There was no subdural hematoma but some cerebral laceration A number of free fragments of bone from the orbital roof on the left side were comminuted and had lacerated the dura

Gelfoam impregnated with penicillin, streptomycin bacitracin and sulfa crystals was used to fill the spaces between bone orbital fascia and nasal cavity, the left frontal sinus was trephined and a small rubber catheter inserted into the sinus through a stab incision in the eyebrow

Postoperative Course—X rays April 21st The orbital roofs the cribriform plate and the right lamina prapacea of the ethmoid bone were removed and the fragments of bone around the right frontal region adjusted until they are now in quite good position (see Figs 4 5)

May 23 1950 Patient had a remarkably good recovery (five weeks) There was some periorbital swelling on the right side three weeks post operatively associated with some infection (staphylococcus pyogenes) in and about the right sphenoid sinus and in the nose The new roof of the nasopharynx is clean and covered with mucous membrane

E E G May 15th Shows residual severe damage maximum over the right anterior frontal region

COMMENT

This procedure was carried out as an emergency operation four days following extensive compound comminuted skull fracture Its chief purpose was to close the dural defects and prevent intradural septic complications This was accomplished in this case with less radical removal and less deformity than usual

Case 4 Mr M R age 26 This patient was struck by a car and knocked unconscious on August 1 1942 He was semi conscious when admitted to the Neurosurgical Service one hour later He had a contused area above the root of the nose ecchymosis with marked swelling of both eye-lids and superficial lacerations and abrasions of the face body and extremities He was bleeding extensively from the nose and mouth with vomiting of blood at times

Neurological Examination Cranial nerves intact reflexes normal cerebral concussion fracture of base of skull and facial bones

X rays—Skull and Sinuses Aug 1 1942 Multiple fractures involving the frontal bone ethmoid and nasal bones and both maxillae The fracture lines were roughly stellate in the frontal region with the point of convergence in the outer table immediately overlying the left frontal sinus with definite involvement of the frontal sinuses on both sides The major fracture line in the left frontal bone showed no depression There was however quite marked depression of a circular area involving the frontal sinuses nasal bones and ethmoid bones The right antrum was diffusely dense the left antrum relatively clear the sphenoids were clear the lower orbital margins and the roofs of the antra were involved on both sides

E N T Consultation Ears normal nose some deformity and swelling over the bridge and both sides filled with blood and blood clots Blood clots in the nasopharynx throat clear except for postnasal bleeding

Operation, August 1 1942 Through an incision in the left and right eyebrows the anterior and posterior walls of the left frontal sinus were found to be extensively comminuted Loose fragments were present in the posterior wall of both frontal sinuses Both sinuses were filled with blood and clots The mucous membrane was removed from both frontal sinuses The fracture lines were followed back to the posterior ethmoid cells and fragments of bone were removed from this whole area At only one point was the dura opened this was to the left of the crista galli Only a slight amount of cerebrospinal fluid was seen When the debridement was completed a large rubber tube was passed from above down through the nose The cavity left after removal of the frontal sinuses and ethmoid air cells was packed with gauze soaked in sulfona mide and elphamel ointment mixture, a Penrose drain was passed out through a seperate stab wound the incision was then closed carefully

On Aug 14th and 24th the original incision was reopened, the cavity inspected, irrigated and re-packed as in the original operation The hard rubber drain was removed on Aug 14, and replaced by a Penrose drain healthy granulations covered the exposed dura, the visible deformity over the forehead was minimal

On Sept 11, 1942, the patient had a generalized seizure

Encephalogram, Sept 12 1942—Showed a marked general dilatation of both lateral ventricles, also the third ventricle The appearance suggested at least partial obliteration of the subarachnoid space over the surface of the two hemispheres The patient has had no further complications since discharge from hospital Sept 29, 1942

Case 5 Mr M C age 23 On Nov 25 1949, this patient was struck on the forehead by a falling log in a lumber camp He was admitted to hospital in an unconscious state with a compound comminuted fracture of the frontal bones and sinuses Brain tissue was found extruding from the lacerations At operation a frontal skin flap was turned the dura over the left frontal was found torn and the wound filled with bone fragments The dura was apparently not sutured, drains were inserted and the skin closed On penicillin and streptomycin the patient did fairly well until he developed an obvious wound infection He was transferred to the Montreal Neurological Institute on Dec 13, 1949 in a state of stuporous confusion with a purulent discharge from the frontal laceration

X rays—Skull, Dec 13, 1949 A large approximately round fragment of bone containing the upper portions of both frontal sinuses was seen lying in the middle of a large frontal bone defect It was bulging outwards about one cm signifying considerable increase in intracranial pressure There was extreme comminution of the central portion of the floors of both anterior fossa The cribriform plate was markedly comminuted with the medial halves of the orbital plates of the frontal bone There were multiple fractures of the laminae papyracea of the ethmoid of the lesser wings of the sphenoid of the inferior orbital margins, and of the left side of the skull All of the paranasal sinuses were dense

Electroencephalogram Dec 13 1949 'These findings suggest a diffuse destructive brain process in both frontal lobes ' This patient had infected frontal fractures with brain abscess and osteomyelitis

Operation, Dec 13 1949 Pansinusectomy and debridement of the frontal lobe The frontal and ethmoid sinuses were completely removed, *i e* the roof and medial wall of the orbits, the supraorbital ridges the cribriform plate and crista galli (which was floating in pus) the superior and middle turbinates The ostea of the antra were enlarged and the mucous membrane of the antra removed The sphenoid sinuses were entered anteriorly and the mucous membrane removed, all through this intracranial approach The damaged and infected brain and dura was then debrided complete dural closure was found to be impossible The wound was irrigated with sulfa crystals and bacitracin repeatedly The nasal cavity was closed off with gauze packs soaked in the same solution and the frontal cavity packed with gelfoam soaked in the same solution and powdered with bacitracin, the skin was closed with 00000 nylon sutures

Course in Hospital Despite this extensive infection of the bone sinuses and brain this patient did remarkably well, his temperature was 104 on admission and with the aid of penicillin and streptomycin was 99 in two days and it remained down thereafter The nasal packs were removed in two weeks and by the end of six weeks all of the crusts and apparently all of the gelfoam had come away there was no discharge from the nose after three weeks from the time of operation

Eleven months after the accident the patient had a generalized convulsion In the following 18 months he had eight to ten attacks and on March 17 1952 he was admitted to the Neurosurgical Service for treatment Bilateral meningo cortical scars were removed, patient discharged improved

CONCLUSIONS

The incidence, mechanisms and types of fractures of the frontal and ethmoid sinuses occurring in head injuries, and the various complications, have been reviewed and discussed The basic principles of the rhinological and neurosurgical treatment of this particular group of clinical problems have been considered, and comments have been made on the cases presented to illustrate these principles From all this data certain aspects of the problems involved, which are of particular interest to the otolaryngologist, have become apparent

1 The frequency of complications following even simple fissured or comminuted fractures of the frontal and ethmoid sinuses demands recognition

2 The external appearance of the injured area gives no indication of the extent nor of the severity of damage to the underlying bones, sinuses, dura and brain substance

3 Because serious intracranial complications may occur after not only a severe but apparently a minor head injury, when associated with fractures of the paranasal sinuses, all of these cases deserve the most complete and thorough physical and radiological examinations

4 These cases should be examined, evaluated and treated as soon as possible after the injury

5 If there is definite evidence of dural lacerations and damage to the brain substance, it is logical that the surgical treatment should be carried out completely and finally at the first operation, by the neurosurgeon and otolaryngologist working in close cooperation The collaboration of these two specialties will best decide the ultimate fate of the patients treated for these serious injuries

ACKNOWLEDGMENT

The author expresses his sincere appreciation and gratitude to Dr W J Cone, Neurosurgeon-in-Chief at the Montreal Neurological Institute, for his encouragement and assistance in preparing this paper, for the use of his photographs and for his patient instruction and guidance in this type of surgery in the past 18 years

PROBLEMS IN THE DIAGNOSIS OF PHARYNGEAL PARESIS*

JOHN A. KIRCHNER, M.D.,

New Haven, Conn.

Within the narrow confines of the hypopharynx, an area comprising the pyriform sinuses and postcricoid area, one may encounter a surprisingly large variety of disorders producing symptoms. Mechanical obstruction by neoplasm or stricture may produce dysphagia, aspiration, and cough. Narrowing of the lumen by mucosal atrophy in Plummer-Vinson syndrome or encroachment on the lumen by cervical exostoses may interfere with swallowing. Pulsion diverticulum may produce dysphagia, regurgitation, and cough. Increase in the tonus in the cricopharyngeus muscle may cause vague sensations of tightness and choking.

These conditions can usually be diagnosed by a careful history and a combination of physical, neurological, radiological and endoscopic examinations. The exception to this general rule is a disorder which may present a perplexing problem in diagnosis even after thorough investigation with all available techniques, namely, isolated pharyngeal paresis. This condition is usually due to a lesion in the upper portion of the vagus nerve trunk and may be the result of injury by chemical or bacterial toxins, by trauma, tumor, certain degenerative disorders or by localized vascular accidents in the region of the nucleus ambiguus. Supranuclear lesions may also produce dysphagia and voice changes if they involve the corticobulbar tracts of both sides.[1-10]

Pharyngeal paresis may exist in the absence of other neurological disturbances or may precede them and may closely simulate neoplasm of the hypopharynx both by mirror examination and by roentgenogram. Of approximately 15 cases

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication Jan. 27, 1958.

of nonpoliomyelitic pharyngeal paresis admitted to this hospital during the past three years, five were sent in with an admission diagnosis of carcinoma of the hypopharnx or upper esophagus because of various combinations of dysphagia, "exudate" in one pyriform sinus, "edema" and fullness of one side of the larynx, and other suggestive findings

Curiously enough, the failure to find tumor by endoscopy may still leave the diagnosis in doubt, a fact dramatically illustrated during my internship, in an elderly woman admitted with dysphagia of several months' duration Barium studies were interpreted as showing a space-occupying lesion of the hypopharynx The "filling defect" on X-ray was so strongly suggestive of neoplasm that after esophagoscopy failed to reveal tumor, surgical exploration of the neck was carried out on the assumption that an extrinsic mass was present and was making pressure on the hypopharynx In retrospect, it is obvious that the asymmetry in the barium-filled hypopharynx was due to inadequate emptying by the atonic musculature on one side, particularly since a diagnosis of neurological disease was made before the patient left the hospital

There are certain remarkable similarities between pharyngeal paresis and carcinoma of the hypopharynx in the history, physical and endoscopic examination, and by radiological studies

HISTORY

A Dysphagia This may be present in either condition In carcinoma of the hypopharynx, it results from mechanical obstruction at the esophageal inlet, tends to come on rather slowly, and is noticed first for solids, then for liquids

In pharyngeal paresis, dysphagia results from involvement of the constrictor muscalature of both sides Although complete unilateral paralysis has been shown to be compatible with normal deglutition,[9, 10] many patients with dysphagia present a predominantly unilateral atony of the pharynx on radiological examination with barium It is probable that both sides have been involved in the neurological disorder, but that the weakness is greater on one side This is particularly apt to occur in patients with a previous mild cerebral vascular accident

B Hoarseness A postcricoid carcinoma, which involves the anterior wall of the hypopharynx, may infiltrate the cricoarytenoideus posticus muscle, the strong abductor of the cords This produces a limitation of motion and resultant changes in voice[11] A postcricoid or pyriform sinus tumor may also produce hoarseness by infiltrating laterally and inferiorly to involve the recurrent laryngeal nerve

Vagus nerve lesions located between the nucleus ambiguus and the ganglion nodosum cause paralysis of the cord, usually in a para-median position[5 10]

C Cough and Choking In carcinoma of the hypopharynx, local irritation may produce cough In both tumor and paresis, inadequate emptying of the pharyngeal recesses allows aspiration of the excess secretions with resultant cough

PHYSICAL FINDINGS

A Mirror Examination Indirect examination of the larynx and hypopharynx may be very uninformative Unless a tumor has outgrown the depths of the pyriform sinus or postcricoid space, there may be no view of the neoplasm itself A motionless vocal cord may be present in either condition (see above) Saliva or food lodged in the pyriform sinus on the paralyzed side may look like exudate and may simulate a keratinizing neoplasm

What looks like edema may actually be relaxation and bulging of the atonic musculature of the ventricular band or of the lateral pharyngeal wall This may simulate a tumor deep in the pyriform sinus

B Palpation of the Trachea Palpation of the trachea may reveal forward displacement in either condition In postcricoid tumor by pressure from behind the cricoid, in pharyngeal paresis by relaxation of the cricopharyngeus muscle which usually supports the cricoid tightly against the cervical vertebrae[12] What is more remarkable, the trachea may deviof nonpoliomyelitic pharyngeal paresis admitted to this hospital during the past three years, five were sent in with an admission diagnosis of carcinoma of the hypopharnx or upper esophagus because of various combinations of dysphagia, "exudate" in one pyriform sinus, "edema" and fullness of one side of the larynx, and other suggestive findings

Curiously enough, the failure to find tumor by endoscopy may still leave the diagnosis in doubt, a fact dramatically illustrated during my internship, in an elderly woman admitted with dysphagia of several months' duration Barium studies were interpreted as showing a space-occupying lesion of the hypopharynx The "filling defect" on X-ray was so strongly suggestive of neoplasm that after esophagoscopy failed to reveal tumor, surgical exploration of the neck was carried out on the assumption that an extrinsic mass was present and was making pressure on the hypopharynx In retrospect, it is obvious that the asymmetry in the barium-filled hypopharynx was due to inadequate emptying by the atonic musculature on one side, particularly since a diagnosis of neurological disease was made before the patient left the hospital

There are certain remarkable similarities between pharyngeal paresis and carcinoma of the hypopharynx in the history, physical and endoscopic examination, and by radiological studies

HISTORY

A Dysphagia This may be present in either condition In carcinoma of the hypopharynx, it results from mechanical obstruction at the esophageal inlet, tends to come on rather slowly, and is noticed first for solids, then for liquids

In pharyngeal paresis, dysphagia results from involvement of the constrictor muscalature of both sides Although complete unilateral paralysis has been shown to be compatible with normal deglutition,[5 10] many patients with dysphagia present a predominantly unilateral atony of the pharynx on radiological examination with barium It is probable that both sides have been involved in the neurological disorder, but that the weakness is greater on one side This is particularly apt to occur in patients with a previous mild cerebral vascular accident

B Hoarseness A postcricoid carcinoma, which involves the anterior wall of the hypopharynx, may infiltrate the cricoarytenoideus posticus muscle, the strong abductor of the cords This produces a limitation of motion and resultant changes in voice[11] A postcricoid or pyriform sinus tumor may also produce hoarseness by infiltrating laterally and inferiorly to involve the recurrent laryngeal nerve

Vagus nerve lesions located between the nucleus ambiguus and the ganglion nodosum cause paralysis of the cord, usually in a para-median position[5 10]

C Cough and Choking In carcinoma of the hypopharynx, local irritation may produce cough In both tumor and paresis, inadequate emptying of the pharyngeal recesses allows aspiration of the excess secretions with resultant cough

PHYSICAL FINDINGS

A Mirror Examination Indirect examination of the larynx and hypopharynx may be very uninformative Unless a tumor has outgrown the depths of the pyriform sinus or postcricoid space, there may be no view of the neoplasm itself A motionless vocal cord may be present in either condition (see above) Saliva or food lodged in the pyriform sinus on the paralyzed side may look like exudate and may simulate a keratinizing neoplasm

What looks like edema may actually be relaxation and bulging of the atonic musculature of the ventricular band or of the lateral pharyngeal wall This may simulate a tumor deep in the pyriform sinus

B Palpation of the Trachea Palpation of the trachea may reveal forward displacement in either condition In postcricoid tumor by pressure from behind the cricoid, in pharyngeal paresis by relaxation of the cricopharyngeus muscle which usually supports the cricoid tightly against the cervical vertebrae[12] What is more remarkable, the trachea may deviate from the mid-line position in either condition: in neoplasm, as the result of pressure from postero-laterally; in paresis, from relaxation of the supporting musculature on *one side*. Deviation of the larynx and trachea in unilateral paresis of the pharynx is rather difficult to explain, yet it has been seen in two cases. Two possible mechanisms for this deviation suggest themselves: *1*. relaxation of the middle and inferior constrictors of one side, allowing those of the active side to rotate or displace the larynx and hyoid, and *2*. lateral pressure by food retained in one pyriform sinus.[13]

NEUROLOGICAL EXAMINATION

In both pharyngeal paresis and hypopharyngeal carcinoma the patient may initially show no other sign of disease. Weakness of the other three posterior cranial nerves should be looked for, and movements of the soft palate, tongue, posterior wall of the pharynx, sternocleido mastoid and trapezius muscles observed. Certain disorders of the posterior group of cranial nerves have been described by Schmidt, Avellis, Vernet, Jackson, Tapia, and Collet-Sicard.[11] These syndromes consist of various combinations of dysphagia, hoarseness, dysarthria, nasal regurgitation, and sensory and motor disturbances of the trunk and extremities. They are usually due to obvious neurological disorders and do not present the type of problem in differential diagnosis under discussion here.

RADIOLOGICAL EXAMINATION

This usually consists of a plain antero-posterior view, lateral view of the neck, fluoroscopic study of the barium swallow and comparison of the two sides of the barium-coated hypopharynx during the Valsalva maneuver. Careful radiological examination is probably the most important single measure in the evaluation of pharyngeal paresis of any type.[15-21] Here again, however, there are certain pitfalls.

1. *Lateral Film*. The plain lateral film is one of the most useful views in distinguishing between tumor and paralysis in this area, and yet there may be a soft tissue mass behind the larynx in either condition, in tumor, because of neoplasm, in paresis, because of the anterior sagging of the atonic inferior constrictor muscle or because of spastic contraction of the muscle in supra-nuclear lesions

2 *Barium Swallow Film* "Filling defect" may be deceptive and may represent the normally emptied side of the hypopharynx after the swallow has been completed Fluoroscopic observation during swallowing will show that the radio-opaque side of the hypopharynx is paretic

Since certain individuals tend to use only one pyriform sinus in swallowing a small amount of fluid, the filling ability of both pyriform sinuses must be checked by 1 having the patient turn his head first to one side, then to the other while swallowing, so as in each case to direct the fluid into the opposite pyriform sinus, 2 having the patient swallow a large enough amount of barium to fill both pyriform sinuses at the same time It may be difficult to get the patient to swallow a large mouthful of fluid since he realizes that even small amounts will produce coughing Templeton[16, 17] states that a paretic pharynx will accommodate larger amounts of barium mixture if this is administered while the patient is in a supine position In this position, both pyriform sinuses will fill initially as is shown by Fig 7

Food particles which may have been retained in the pyriform sinus should be looked for before barium studies are done

3 *Valsalva's Maneuver* The Valsalva maneuver, a forced expiratory effort against a closed mouth and nose, may outline the superior edge of a tumor, or it may show ballooning of the atonic side in unilateral pharyngoplegia This is a most useful diagnostic test

CASE HISTORIES

Case I Dr E H 71 year-old dentist admitted with inability to swallow of four days duration

Present Illness—Four nights before admission he awoke from sleep with tightness of the throat moderate intermittent dyspnea and hoarseness on admission he could not swallow even fluids and his voice was hoarse

Mirror Examination—There is puddling of milk and saliva in the right pyriform sinus The right vocal cord is motionless in the midline The right false cord is markedly edematous and there is a grayish mass visible deep in the pyriform sinus below the arytenoid cartilage on the right side

Impression—Carcinoma of the right pyriform sinus or hypopharynx with involvement of the right recurrent laryngeal nerve

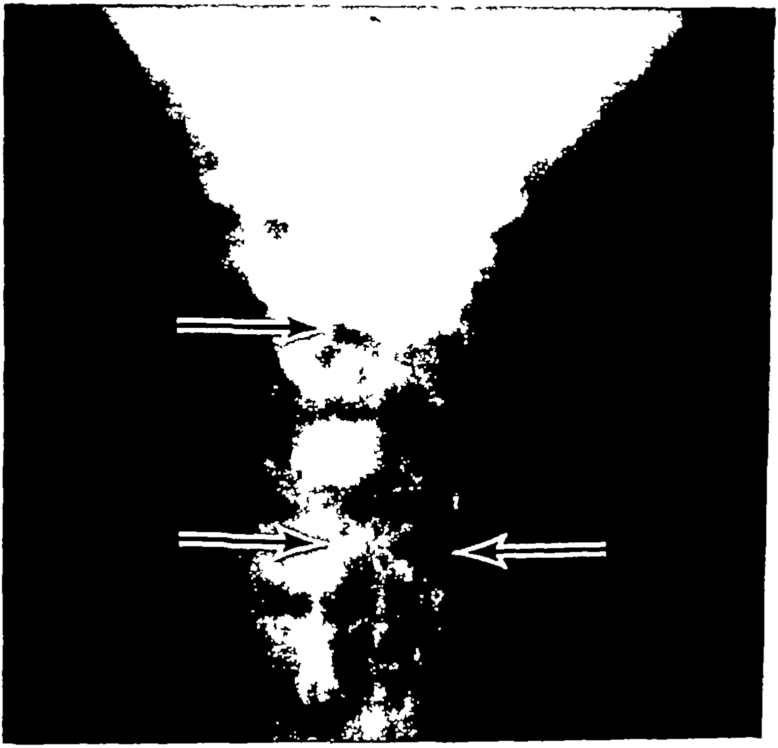

Fig 1 (E H) Irregularly outlined area of radiolucency behind the cricoid cartilage (upper arrow) with puddling of barium in the hypopharynx and valleculae chiefly in right pyriform sinus Dilatation of right pharyngeal wall and deviation of trachea to left (lower arrow) Compare this picture of pharyngeal paresis with Fig 3 retrocricoid carcinoma

X ray—There is displacement of the trachea to the left in the region of the lower cervical and upper dorsal vertebrae no well defined mass is noted In the region of C 5 and 6 there is a soft tissue swelling with an indentation on the posterior wall of the trachea in that area (see Figs 1 2)

Esophagoscopy—Swelling of the right lateral pharyngeal wall at the cricoid level Right cord motionless questionable bulging of the posterior tracheal wall Esophagoscopy negative for mucosal lesion

X ray—(two days after admission) (Thin barium) The valleculae and pyriform sinuses bilaterally show no pathology The contrast medium appears to encounter an obstruction at the level of the junction of the pharynx with the esophagus beyond which no contrast medium is noted in the esophageal passage There is a small amount of regurgitation of barium into the trachea and this is noted in the over-exposed film in the left main bronchus

X ray Diagnosis—

1 Obstruction of proximal most portion of esophagus

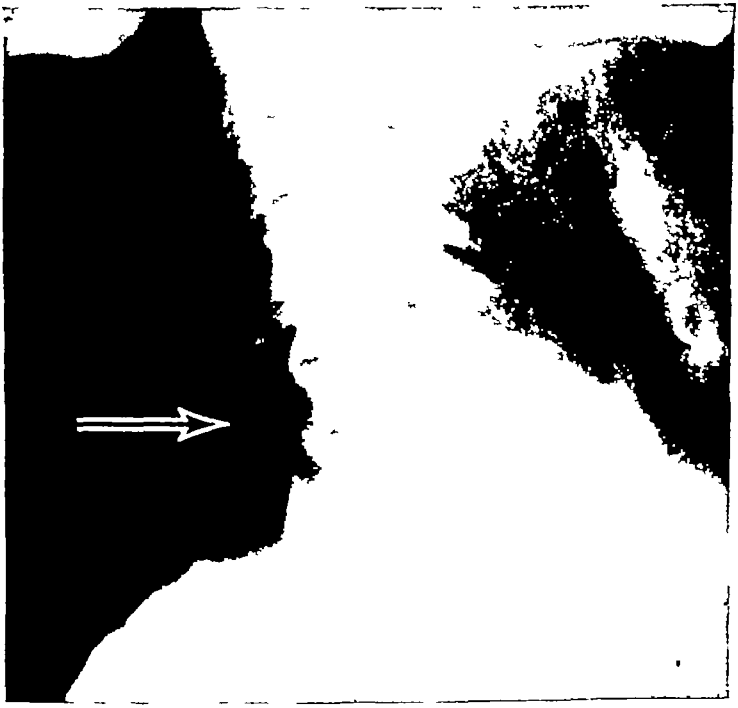

Fig 2 (E H) Soft tissue density in retrocricoid area the result of atony of the cricopharyngeus muscle Compare with Fig 4 retrocricoid carcinoma.

2 Soft tissue mass opposite C 6

3 Hypertrophic osteoarthritis of the cervical vertebrae

ENT Consultation—(Two days after admission) Mirror examination revealed right vocal cord in a para median position voice husky both vocal cords inflamed and swollen probably foreign body which has penetrated the mucosa and is causing pari-esophageal inflammation

Over the next three days the patient gradually improved and was able to swallow a little fluid There was less edema noted in mirror examination of the larynx several large grayish brown masses were coughed up by the patient

X rays—(Six days after admission) There is failure to opacify completely the left pyriform sinus, however, under fluoroscopy this pyriform sinus appeared to be well visualized and not remarkable in any respect The trachea deviates to the left in region of C 6 and 7 There is a small trickle of barium into the esophagus, no evidence of filling defect

X ray diagnosis—Incomplete obstruction of the proximal esophagus, probably due to a central nervous system lesion or secondary edema

Esophagoscopy—(Eleven days after admission), no foreign body or mucosal lesion found

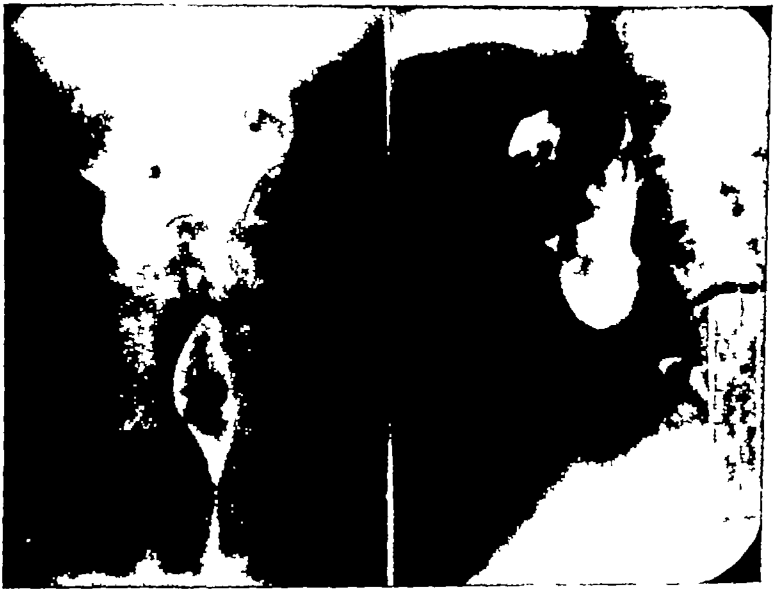

Fig 3 (V W) Valsalva maneuver showing slight dilatation of pharynx particularly of right pyriform sinus in a case of retrocricoid carcinoma Compare with Fig 1

Diagnosis—Bulbar lesion (Vascular) involving Nerves X and IX

After three weeks the swallowing had improved The patient could take a liquid diet and the final impression was that there was a vascular lesion localized in a very small area of the bulb probably an embolus As the patient's temperature was never over 99 2 rectally urinalysis and blood picture normal, it is unlikely that infection was a prominent etiological factor here

Follow up—Two years later this patient had a cerebrovascular accident with temporary paralysis of the left side from which he recovered When check up was attempted five years after original admission he had moved to Florida Voice was said by his son to be adequate but slightly weak, he eats mostly soft food

Discussion—The history, mirror examination, and the initial radiological examination in this case suggested a neoplasm of the upper esophagus or hypopharynx The trachea deviated away from the side of the paralysis and was due in this case, not to pressure from a tumor situated in the hypopharynx, but probably to relaxation of the constrictor musculature attached to the right side of the larynx The "edema" of the larynx seen on mirror and direct endoscopic examination probably represented relaxation and bulging of the atonic inferior constrictor muscle, and accounted for the soft tissue swelling behind the larynx on the lateral X-ray view The grayish mass in the pyriform sinus was identified in this case as retained food (junket), in others as saliva and epithelial debris from the mouth

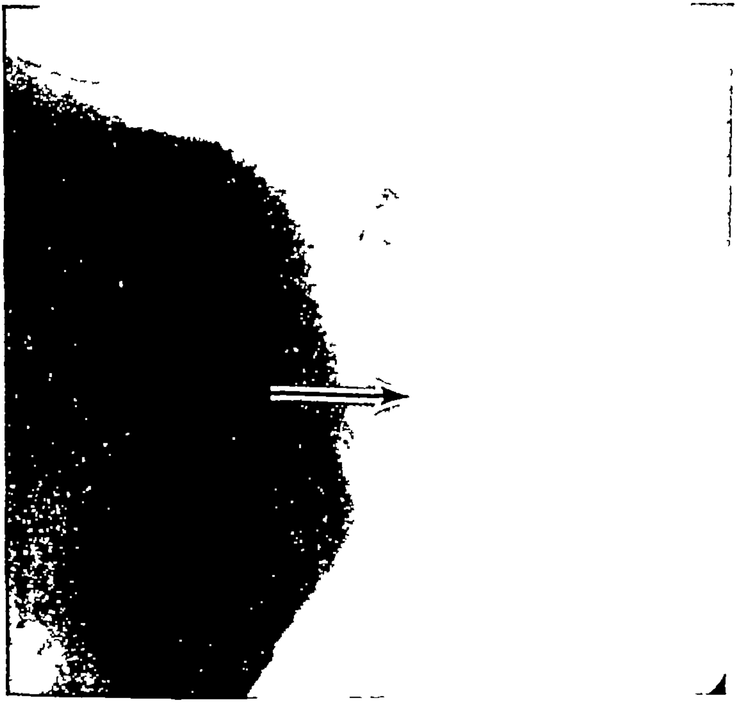

Fig 4 (Y W) Retrocricoid soft tissue density with some forward displacement of posterior wall of trachea Compare with Fig 2 postcricoid carcinoma.

Case II R C 68 year old woman, admitted with chief complaint of hoarseness and dysphagia six months

Present Illness—Six months ago the patient developed hoarseness over a period of a few days Shortly thereafter she developed progressive dysphagia so that she can now take only soft foods and liquids She has lost about 30 pounds over this period of time, has occasional regurgitation of food or liquid into the mouth, has a morning cough productive of yellow sputum

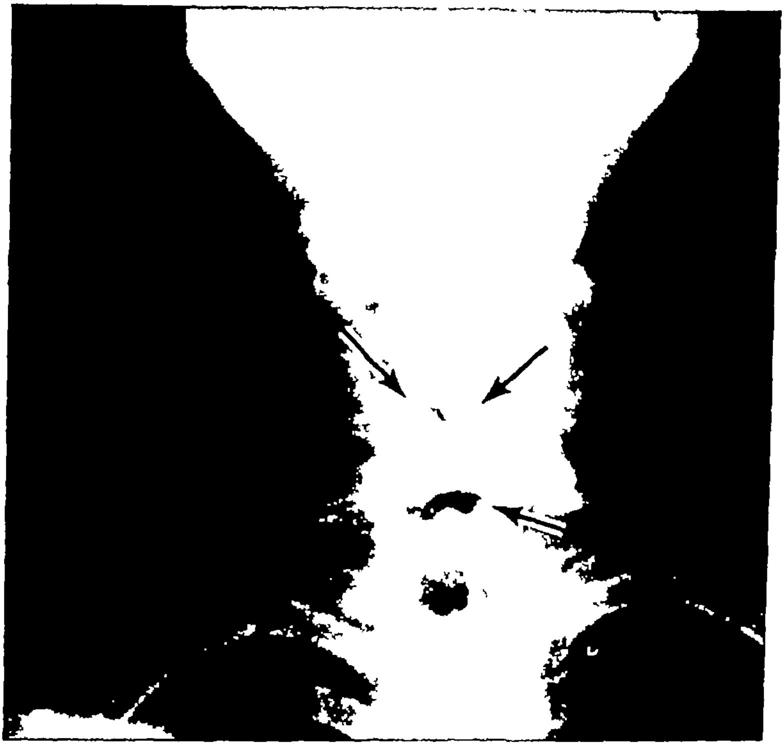

Fig 5 (R C) Irregularly outlined soft-tissue density with retention of barium in valleculae and left pyriform sinus The soft-tissue density in the right pyriform sinus area is illusory and represents the normal hypopharynx after completion of swallow The opposite side both hypopharynx and larynx are paralyzed

Past History—Seven years ago left mastectomy for a carcinoma without lymph nodes One year ago right mastectomy intraductal proliferation without malignancy

Mirror Examination—Left cord is motionless and lies in paramedian position, patient is hoarse There is a collection of saliva in the left pyriform sinus

Physical Examination—Blood pressure 175/110 There is a 0 5 cm nodule under the intact skin on the left in the scar of the mastectomy it is firm and movable Laboratory work showed no abnormalities of the blood or urine Wassermann negative There are no cervical or supra-clavicular lymph nodes palpable The left shoulder droops noticeably and is limited in motion

X ray—Metastatic involvement of dorsal spine L 3 and 4 left sacrum left ileum and left ischium Minimal fibrotic tuberculosis right apex Bilateral apical plaural thickening Poor filling of the right pyriform sinus no displacement of the barium filled esophagus

Diagnosis—Metastatic lesion involving the right pyriform sinus (see Fig 5)

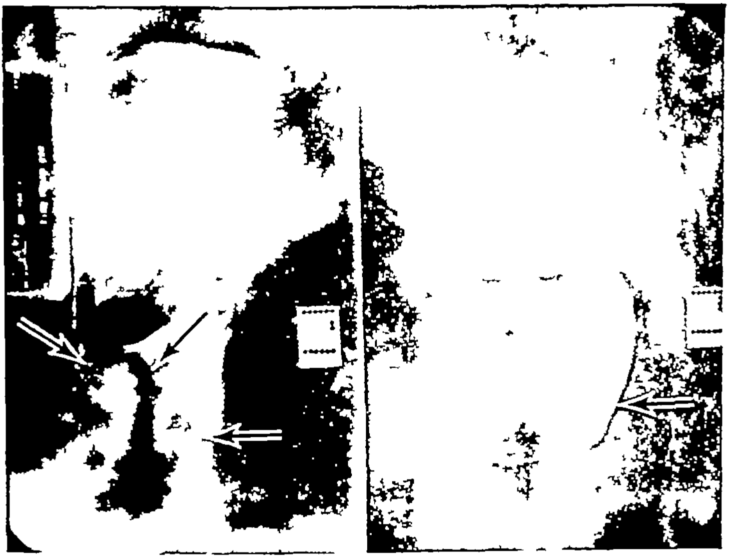

Fig 6 (H R) Film on left demonstrates the pattern which was originally interpreted as soft-tissue mass in right hypopharynx Valsalva maneuver on right half of plate shows dilatation of left pyriform sinus and strongly suggests paresis as the underlying disorder

Endoscopy—No evidence of tumor in the hypopharynx or the upper esophagus The lumen was patent and admitted an esophagoscope left vocal cord motionless

Impression—Bulbar lesion in region of nucleus ambiguus Absence of upper mediastinal mass on X ray with signs of Nerve X and XII involvement suggests central rather than peripheral lesion

Discussion—The X-rays in this case show a failure of the right pyriform sinus to fill with barium Absence of tumor in this area on endoscopic examination indicates that the right hypopharynx is the normal side and has emptied itself normally (see Fig 5) The puddled saliva and residual barium in

Case II R C, 68 year old woman, admitted with chief complaint of hoarseness and dysphagia, six months

Present Illness—Six months ago the patient developed hoarseness over a period of a few days Shortly thereafter she developed progressive dysphagia so that she can now take only soft foods and liquids She has lost about 30 pounds over this period of time, has occasional regurgitation of food or liquid into the mouth, has a morning cough productive of yellow sputum

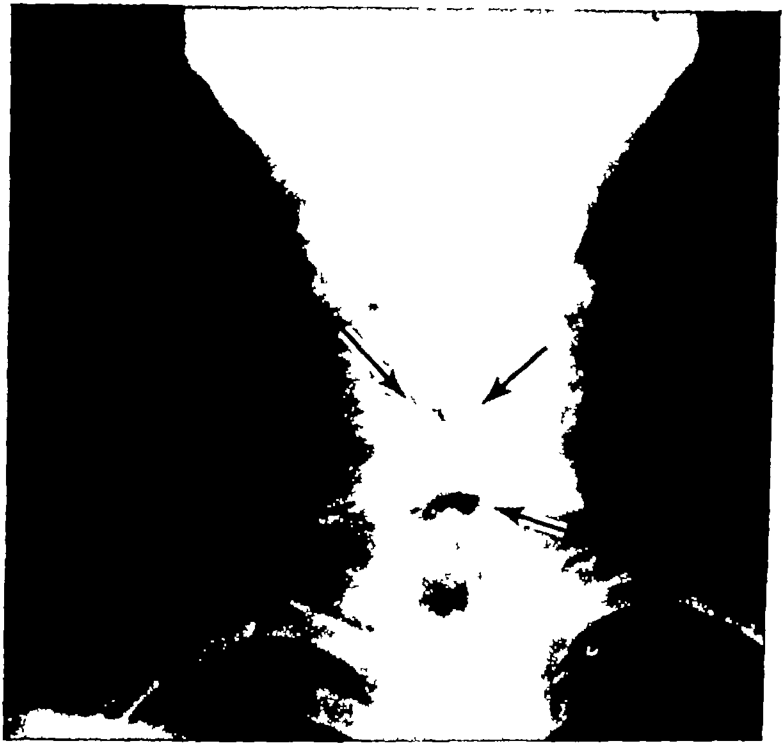

Fig 5 (R C) Irregularly outlined soft-tissue density with retention of barium in valleculae and left pyriform sinus *The soft tissue density in the right pyriform sinus area is illusory* and represents the normal hypopharynx after completion of swallow The opposite side both hypopharynx and larynx are paralyzed

Past History—Seven years ago left mastectomy for a carcinoma without lymph nodes One year ago right mastectomy intraductal proliferation without malignancy

Mirror Examination—Left cord is motionless and lies in paramedian position, patient is hoarse There is a collection of saliva in the left pyriform sinus

Physical Examination—Blood pressure 175/110 There is a 0 5 cm nodule under the intact skin on the left in the scar of the mastectomy it is firm and movable Laboratory work showed no abnormalities of

Mirror Examination—Complete paralysis of left vocal cord puddling of saliva in left pyriform sinus

X ray—Ballooning of entire pharynx Left vocal cord immobile Ballooning of pharynx probably due to involuntary Valsalva maneuver each time the patient attempts to swallow

Impression—Left sided bulbar paralysis with inability of the left pyriform sinus to contract, and immobility of the left vocal cord (see Figs 6 and 7)

During the next six weeks the patient became rapidly worse with progressive atrophy of the muscles of the neck shoulder girdle mandible and both upper and lower extremities A diagnosis of amyotrophic lateral sclerosis was made before he died although involvement of Nerves II and III was felt to be against it autopsy was not obtained

Discussion—Certain degenerative conditions involving the brain stem may be ushered in by dysphagia and hoarseness as a result of involvement of the nucleus ambiguus with resultant paresis of the constrictor muscles and vocal cords Very little else may be found initially, even though weakness and asymmetry of the soft palate and posterior pharyngeal wall are carefully looked for

CONCLUSION

Isolated pharyngeal paresis may simulate carcinoma of the hypopharynx (pyriform sinus and postcricoid area) because of similar findings on history, physical examination, mirror examination and routine roentgenograms with contrast media Endoscopic examination having ruled out an intrinsic neoplasm, pharyngeal paresis can best be demonstrated by fluoroscopic comparison of the emptying-time of the two sides of the hypopharynx during barium swallow, preferably in the supine position, and by the demonstration of ballooning and asymmetry of the muscular walls of the hypopharynx during the Valsalva maneuver

the left pyriform sinus is the result of atony of the pharyngeal musculature on that side Fluoroscopy and the Valsalva maneuver after barium swallow demonstrate this vividly

Case III H R 68 year old man, admitted with three-week history of hoarseness and dysphagia Preadmission roentgenograms had been interpreted as showing a "tumor of the hypopharynx (see Fig 6)

Endoscopy—The right vocal cord is slightly sluggish There is saliva puddled in both pyriform sinuses and no evidence of neoplasm Patient was discharged without further workup

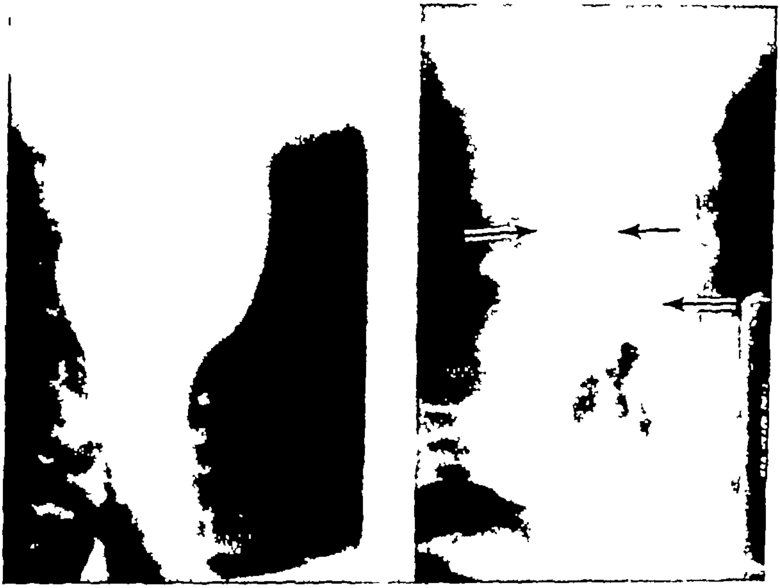

Fig 7 (H R) Barium-filled hypopharynx caught during fluoroscopy in supine position by spot-film (left) rules out a space-occupying mass in right hypopharynx as suggested by Fig 6 and by the right half of this plate The latter shows the normally emptied right side of the hypopharynx immediately after completion of swallow and further supports diagnosis of left-sided pharyngoplegia

Six weeks later he was readmitted because of occipital headache of two weeks duration Four weeks prior to admission the patient had developed weakness of the left eyelid and left arm On admission there was ptosis of the left lid and a dilated reactionless left pupil spinal fluid was negative sputum negative for acid fast bacilli WBC 12 000

Neurological—Patient has a shuffling gait There is evidence of involvement of Nerves III IX and X Vibratory sensation and heat sensation are increased on the right

Impression—Tumor of brain stem or metastases to brain stem from a primary tumor in GI tract or lung

MEDICAL AND SURGICAL TREATMENT OF BELL'S PALSY*†‡

EDMUND P. FOWLER, JR., M.D.,
New York, N. Y.

The best symptomatic descriptions of paralysis of the motor nerve of the face were those made by Sir Charles Bell before 1841,[1] yet the true causes and the best treatments for non-traumatic facial paralysis still remain controversial, and few patients seek early treatment from the few specialists in this field. In order to understand the rationale for the treatments described in this paper, it is necessary to study some of the probable causes of the sudden, usually transient, paralysis of the VIIth cranial nerve, which has come to be known as "Bell's Palsy."

In the common idiopathic form it is generally believed that there occurs an edema which squeezes the nerve trunk so as to block the passage of neural impulses. Cawthorne[2] has described an "hour-glassing" by either a fibrous band or a congenitally small bony ring at the stylomastoid foramen. He, as well as Sullivan,[3] Collier,[4] Kettel[5] and others, have confirmed the observation of Arthur Duel[6] that there is often a marked bulging of the nerve when its fibrous sheath is slit, in cases of classical "Bell's Palsy."

In my small series of seven operated cases, this was most clear-cut in recent facial paralysis, particularly in recurrent facial paralysis, which tends to show a remarkable improvement within a few hours, or a few days, after surgical decompression. I emphasize patients of recurrent facial paralysis, because whether their paralysis has been on the same side or the opposite side, we have, in these patients, a type

Let us examine the mechanism of how cold could produce facial paralysis We have a theory that this might lead, quite logically, to a common denominator, for all "Bell's Palsy" whether associated with virus infections, allergy, arteriosclerosis or what not

In the mesentery, the conjunctiva of the eye, the chorioallantoic membrane of a chick, the edge of the lung, the spleen and other areas where small blood circulation has been carefully studied, there is no question that chilling will produce local erythrostasis With slight changes of temperature there are produced contracted arterioles and venules also precapillary closures and, in addition, slow moving stasis, or so-called intravascular agglutinations—the "sludge" of Knisely[12] With more chilling, platelets and white cells collect in and along the vascular walls, and eventually the circulation in the region is affected by these intravascular elements, as well This seems to start in the collecting venules, spreads to the capillaries and eventually involves arterioles and arteriovenous shunts, just as does any other local trauma Clinically, this has often been observed in frostbite of the fingers, toes and ears Such erythrostasis in the small blood vessels not only results in anoxia of the part with edema and ground substance changes, but also subsequent susceptibility to milder episodes with slight changes in temperature It is known that similar hypersensitization[13] of nerve tissue can occur, and this may account for recurrent "Bell's Palsy"

Blockage of the small blood vessels with consequent tissue ischemia and secondary edema seems to occur in the VIIth nerve, with many factors other than refrigeration or cooling There may be an association with allergy or infection, thrombi from other parts of the body and with trauma I have seen two cases of peripheral facial paralysis which were otherwise identical with so-called idiopathic "Bell's Palsy," associated with perichondritis of the auricle and swollen lymph glands in the upper cervical chain, another case with granuloma of the external canal, which improved after partial removal of the low-grade infectious process near the exit of the nerve In one case with rubella, the glands were quite large in the region of the stylomastoid foramen, and I have seen another of control, because all of these patients were decompressed within a few days of the onset of their paralysis. In no case of recurrent "Bell's Palsy" have I seen as slow a recovery as occurred for the bout, or bouts, before decompression, whether the palsy was on the same side or the opposite side. In none of my patients with decompressed "Bell's Palsy" has there yet been a recurrence of facial paralysis after decompression. All of them have been done over one year and the oldest one is of 15 years' duration. Similar statements have been made by Sullivan[2] concerning a much larger series of operated "Bell's Palsy." Apparently, in acute cases, removal of bony and fibrous sheaths of the perpendicular part of the nerve within the mastoid relieves pressures and thus often leads to recovery from the paralysis; but is pressure on the nerve, *per se* the primary and only cause of the paralysis?

In 1936, Grunfest[7] reported an experiment with frog nerves and showed that it took 8,000 to 15,000 pounds per square inch to stop nerve impulses when the entire nerve was squeezed in a compression bomb filled with oxygenated mineral oil; however, if there was any bending of axones, neural impulses were reduced or blocked at that point. Perhaps more important, Lewis and his co-workers, Denny-Brown,[4] and more lately Moldaver, working with clips or tourniquet techniques, have shown that any pressure which interferes with the circulation of the nerve itself, will produce suppression of distal neural impulses; and if the ischemia produced by the pressure is kept up for a sufficient length of time, the palsy will be either long lasting or permanent.

What could instigate a primary ischemia in the facial nerve trunk, leaving aside for the moment, secondary edema and swelling? The story that "Bell's Palsy" often follows a cold draft to the side of the face has been generally accepted by most, since the time of Bell. Although this is vigorously denied by a few, the weight of evidence seems to indicate that a cold draft may precipitate the palsy, in some patients. Not so long ago, Sullivan and Smith incontrovertibly showed that cold can produce facial paralysis in rats, but there are undoubtedly other factors and other precipitating agents, as will be mentioned later.

Let us examine the mechanism of how cold could produce facial paralysis We have a theory that this might lead, quite logically, to a common denominator, for all "Bell's Palsy" whether associated with virus infections, allergy, arteriosclerosis or what not

In the mesentery, the conjunctiva of the eye, the chorioallantoic membrane of a chick, the edge of the lung, the spleen and other areas where small blood circulation has been carefully studied, there is no question that chilling will produce local erythrostasis With slight changes of temperature there are produced contracted arterioles and venules also precapillary closures and, in addition, slow moving stasis, or so-called intravascular agglutinations—the "sludge" of Knisely[12] With more chilling, platelets and white cells collect in and along the vascular walls, and eventually the circulation in the region is affected by these intravascular elements, as well This seems to start in the collecting venules, spreads to the capillaries and eventually involves arterioles and arteriovenous shunts, just as does any other local trauma Clinically, this has often been observed in frostbite of the fingers, toes and ears Such erythrostasis in the small blood vessels not only results in anoxia of the part with edema and ground substance changes, but also subsequent susceptibility to milder episodes with slight changes in temperature It is known that similar hypersensitization[13] of nerve tissue can occur, and this may account for recurrent "Bell's Palsy"

Blockage of the small blood vessels with consequent tissue ischemia and secondary edema seems to occur in the VIIth nerve, with many factors other than refrigeration or cooling There may be an association with allergy or infection, thrombi from other parts of the body and with trauma I have seen two cases of peripheral facial paralysis which were otherwise identical with so-called idiopathic "Bell's Palsy," associated with perichondritis of the auricle and swollen lymph glands in the upper cervical chain, another case with granuloma of the external canal, which improved after partial removal of the low-grade infectious process near the exit of the nerve In one case with rubella, the glands were quite large in the region of the stylomastoid foramen, and I have seen another

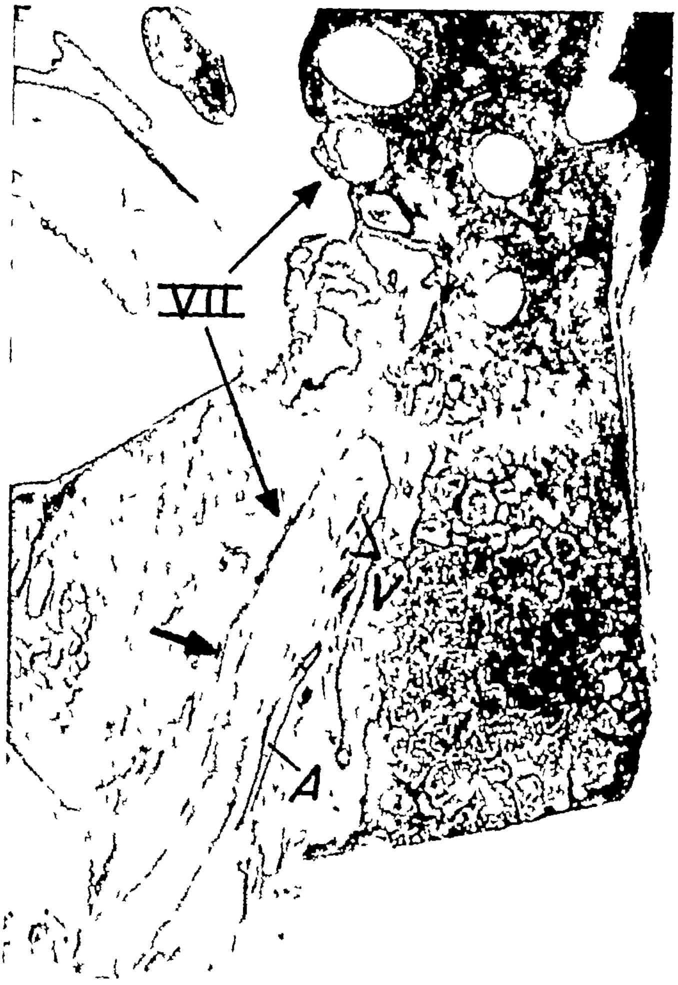

Fig 1 Vertical section through the temporal bone showing the descending part of the facial nerve (VII) as it goes through a normal stylomastoid foramen also a cross section of the nerve near the pyramid Arrow indicates where bony or fibrous narrowing has been observed A indicates artery V indicates veins

case with infectious mononucleosis, with glands in the same region

Sir Charles Bell himself described several cases in which there were abscesses, or large glands in the neighborhood of the stylomastoid foramen[1] Many times the paralysis occurs in patients with diabetes, or arteriosclerosis There are, of course, cases due to injuries from too tight packing in a mastoid wound, or to direct bruising of the nerve

Most otologists have seen facial paralysis with low-grade and seemingly insignificant concomitant serous otitis, or transudative otitis It is possible that these symptoms were due to blockage of the stylomastoid artery, which supplies not only the facial nerve but also the mucous membrane of the middle ear (see Fig 1) I have seen two cases where the bone and the canal were unusually soft but not infected, as described by Kettel[5]

As mentioned above, apparently anything which could lead to erythrostasis in the vessels in the bony facial canal can produce the palsy Even Herpes Zoster of the geniculate ganglion must produce a vascular lesion which produces swelling, ischemia and finally blockage of the nerve impulses, however, all these causes of facial paralysis seem to have a common denominator, namely, erythrostasis and ischemia from spasm, intravascular blockage or external pressure involving the small vessels of the nerve trunk The ischemia causes axone anoxia and secondary tissue edema, which aggravates the situation especially when it can kink the nerve, because anatomical factors such as a fascial collar or a small stylomastoid foramen are present

With this hypothesis as a background, and considerable experience with Menière's disease and sudden deafness, which undoubtedly are precipitated by similar vascular phenomena, it was decided to try vasodilation vigorously, and increased circulation treatment techniques for "Bell's Palsy" To date, the same regimen has been used which had proved successful with Ménière's disease, namely, one-tenth of 1 per cent procaine hydrochloride infusions, twice a day, using 250 cc of a glucose solution, to increase the flow of blood in the small blood vessels, after the patient had been well medicated with nicotinic acid, 50-100 mg 4 i d, p o,[14] to dilate the small blood vessels

We have, as yet, treated an insufficient number of patients to prove, definitely, that this or that regimen helps in a disease like "Bell's Palsy" Our results with a small series are given for what they are worth It has been variously stated that 55 to 80 per cent of "Bell's Palsy" cases recover without treatment Thomas[16] in 1955, published a paper in which he gave the comparison of length of time that "Bell's Palsy" took to recover against a regimen of Cortisone, the average was 24 days From this, and other[16] reviews of the literature, it is difficult to ascertain how the various authors classified their patients with partial, or no improvement I, therefore, indicated in each group how many had no improvement and how many had partial improvement, how many had full improvement, and the average time in which full improvement seemed to occur In all, we studied 100 consecutive hospitalized cases, in which there were sufficient notations in the chart for a report to be made Fourteen were treated with procaine and 86 treated with other methods In the 14 patients treated with procaine, all had considerable improvement, 12, or 86 per cent, had full improvement, two had partial improvement, the improvement occurred within four to 30 days, making an average of 12 3 days Of the 86 controls 14, or 14 per cent, had no improvement, another 12, or 14 per cent, had partial improvement, and the remaining 72 per cent had full improvement, ranging from five days to one year, making an average of 76 1 days Using nicotinic acid alone, there were six patients, two had partial improvement and four had full improvement, in an average of 24 2 days Seven patients had Cortisone treatment, one remained completely paralyzed, two had partial improvement, four had full improvement, in an average of 24 5 days, thus, the nicotinic acid and Cortisone treated cases seem to show better results than the physiotherapy treated cases, however, the nicotinic acid with intravenous procaine seemed to show the best results in this small series

Recently we have been treating our cases of sudden deafness with heparin and cumadin, in addition to procaine and nicotinic acid We have not yet tried this with "Bell's Palsy" but the dramatic improvement in circualtion with heparin, in experimental animals, in addition to that seen with procaine, suggest we should add this medication to our treatment regimen, if we see the patient early enough For the edema, we should, perhaps, use Cortisone as well, at least for a few days In any event, the patient must be hospitalized and the blood chemistry, venous clotting and prothrombin time, carefully controlled In our hospital this has been supervised by Dr Stuart W Cosgriff of the Department of Medicine, and carried out in the same manner as they treat venous thromboses, and as they control hormone therapy afflictions in other parts of the body

If medical treatment does not produce marked improvement in a "Bell's Palsy" in two months' time it has become our practice to decompress the facial nerve, according to the method of Duel,[6] except that a dental drill, under magnification, is used instead of a hammer and chisel More and more, electrical studies suggest that two months is too long to wait

Adequate criteria from electromyograms, chronaxies, and the like, for discovery and evaluation of those patients who will not recover without surgery has been fairly satisfactory in our hands, better prognostic tests are, we believe, urgently needed

Since the patients selected were almost all hospitalized, and, therefore, likely to be severe cases, perhaps our "Bell's Palsy" sample is skew This series, however, shows that watchful hoping, heat, massage and electrotherapy do not provide quick and full relief in a sufficient number of cases Our series compares favorably with the series of Thomas[15] for Cortisone Nicotinic acid is much cheaper than Cortisone, and much safer Perhaps one should use Cortisone in large doses for a few days, and then continue with nicotinic acid and procaine Although the use of i v procaine, plus anticoagulants and steroids, twice daily is difficult and somewhat dangerous, I suggest that further trial of such vigorous early treatment is indicated This paper should stimulate some interest and lead to comparative studies of the relative value of procaine, histamine, steroids, anticoagulants and the like, however, for success, we must persuade all physicians to send in their cases early We believe, "Bell's Palsy" is a medical emergency like sudden deafness, or any other vascular catastrophe If we do not start early we can not expect to eliminate the small blood vessel ischemia and secondary edema Axone degeneration will begin and theoretically we should resort, within a few days to surgical decompression

RESULTS OF FENESTRATION AFTER STAPES MOBILIZATION.**

ALLAN C. GOODMAN, Ph.D.,*
ROBERT C. BILGER, Ph.D.,†
and
THEO E. WALSH, M.D.,‡
St. Louis, Mo.

Otologists who write on the subject of the stapes mobilization operation are unanimous in stating that this procedure does not adversely affect a subsequent fenestration operation.[1-9] This opinion is based upon surgical and acoustical considerations, as well as upon clinical observations.

The clinical evidence reported as empirical validation of the position that the stapes mobilization procedure does not affect the results of a subsequent fenestration involves from one to 45 cases.[1-9] Meurman,[5] who reports on the 45 cases, states that his group had not been subjected to close study. Werth[9] has analyzed 16 cases in terms of average gain as predicted by the Shambaugh formula, but he did not compare these 16 cases to a group on whom the fenestration operation was not complicated by a prior stapes mobilization.

Because considerable clinical importance is attached to the claimed advantage for the stapes mobilization operation, *viz.* that a subsequent fenestration operation may be performed with no disadvantage in the final result, we felt that a statistical analysis designed to test this hypothesis would be useful.

There are 38 cases in the series of stapes mobilization

operations performed by one of us (T. E. W.), in which a subsequent fenestration operation was performed. This group of 38 cases was compared with a recent group of 227 fenestration operations[10] that were not complicated by prior stapes mobilization. Hearing level* for speech (spondaic words) is the datum that was used to compare the two groups. Residual hearing was used instead of gain, because residual hearing is the most logical measure of success in this context.[12]

TABLE I

Mean Hearing Level for Speech Three Months After Fenestration

	Fenestration after Stapes Mobilization	Fenestration Only
Number of cases	37	227
Mean	26.8	25.7
Standard Deviation	7.97	8.19

TABLE II

Distribution of Cases as a Function of Hearing Level for Speech Three Months After Fenestration

	Fenestration after Stapes Mobilization		Fenestration Only	
Hearing Level	%	No.	%	No.
20 db. or better	23.7	(9)	28.2	(64)
21-25	29.0	(11)	32.6	(74)
26-30	15.8	(6)	18.1	(41)
31-35	18.4	(7)	11.9	(27)
36-40	2.6	(1)	3.9	(9)
41 db. or worse	10.5	(4)	5.3	(12)
		38		227

First, the two groups were compared with respect to mean hearing level as measured three months after fenestration. The mean hearing level and standard deviation for each group of cases are presented in Table I. The difference between the two groups of 1.1 db. in favor of the uncomplicated fenestration group *is not statistically significant* (t = .72, p = .47). One case of stapes mobilization was excluded from this comparison because all hearing was lost after fenestration, and no value could be assigned to hearing level.

---

*The term "hearing level" is used here instead of the term "hearing loss" as recommended by Davis, Hoople and Parrack.[11]

In addition to the comparison between mean hearing levels for speech for the two groups, we have tabulated the percentage of cases in each group with residual hearing levels for speech of 20 db or better, 21-25, 26-30, 31-35, 36-40, and 41 db or worse These distributions are presented in Table II with the number of cases involved in each percentage enclosed in parentheses The case of prior stapes mobilization excluded from the comparison between group means, because all hearing was lost after fenestration is included in Table II in the "41 db or worse" interval The two groups were compared statistically with respect to the distribution of cases as a function of residual hearing level, and were found to be not different (Chi-Square $= 3\ 17$, $p = 53$)

The results then, of the statistical comparisons between the group of 38 cases in which a stapes mobilization preceded the fenestration operation, and the group of 227 cases for which the fenestration was not complicated by prior stapes mobilization, indicate that the two groups are not different with respect to mean residual hearing level for speech, or with respect to the distribution of cases as a function of hearing level These results confirm the opinions based upon surgical and acoustical considerations, as well as those based upon clinical experience, that the stapes mobilization procedure does not affect the results of subsequent fenestration

OSTEOMA OF THE EXTERNAL AUDITORY CANAL

JAMES L SHEEHY, Major,*

Medical Corps, United States Army

"The large solitary osteoma attached by a pedicle to the bony canal wall is an extremely rare condition"[1] The author was somewhat surprised to find this statement during the course of a literature review in connection with another subject[2] Four cases observed during the last two years were called to mind It is the purpose of this paper to define the subject, discuss the treatment, and report these four cases

DEFINITION

Dorland's medical dictionary defines an osteoma as any tumor composed of bony tissue Confusion has arisen clinically[1] between an osteoma of the external auditory canal and the exostosis, which is defined as any bony growth projecting outward from the surface of a bone By definition, any osteoma projecting outward is also an exostosis The confusion is increased by the fact that histologically there is no sharp line of distinction (if any) between a true osteoma and many closely related non-neoplastic hyperplasias of bone[3,4]

From the clinical standpoint it is important that a definition be agreed upon, that the two conditions be considered separately Osteoma of the external canal refers to the solitary pedunculated bony growth, attached to the tympanosquamous suture superficial to the isthmus (see Figs 1, 2) It may be attached to the tympanomastoid suture By contrast exostoses of the external canal are broad-based elevations of bone, usually multiple and bilaterally symmetrical, located deep to the isthmus, at the upper edges of the tympanic bone (see Fig 3)

INCIDENCE AND SYMPTOMS

A number of the current texts[5,6-8] do not mention osteoma of the external auditory canal, exostoses are mentioned briefly Morrison,[9] however, makes a clear-cut distinction between the exostosis and the osteoma, both from the standpoint of location and treatment

Exostoses of the external canal are common lesions, are usually bilateral and multiple, and rarely demand treatment[1,5,6-8,9] They are seen frequently in the course of examinations for other illnesses, and rarely, if ever, produce symptoms

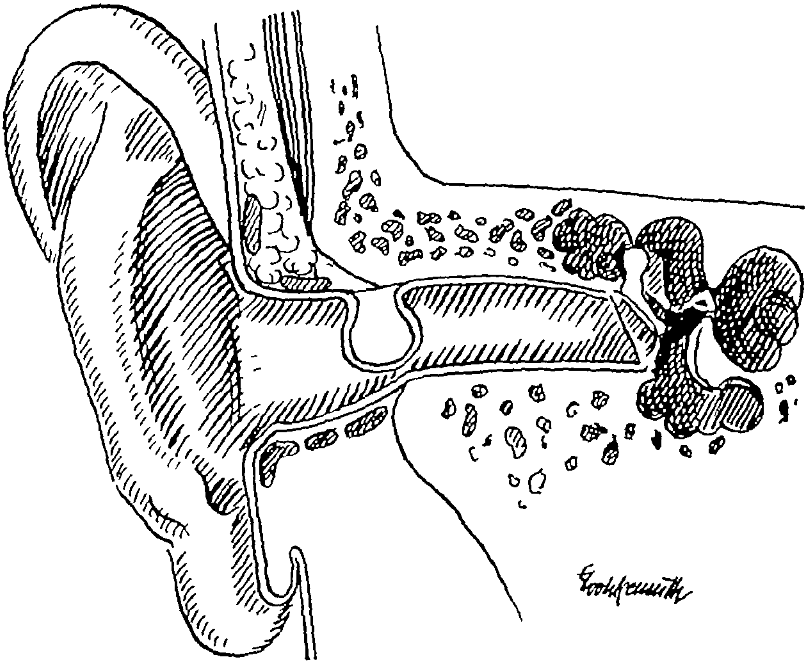

Fig 1 Osteoma of External Canal (Frontal Section)

The external auditory canal osteoma is always a single unilateral lesion and is considered to be rare Kline and Pearce[1] reviewed the literature up to 1954, and stated that it was difficult to say how many of the cases reported (over 37) were actually osteomata, and how many were exostoses

They reviewed in detail the four cases reported during the preceding 15 years, and added a case of their own They concluded that the condition must be extremely rare judging by the paucity of the reports Others agree with this conclusion [10]

Symptoms produced by an osteoma are the result of blockage of the canal Early there may be excessive wax accumulation deep to the tumor A complete block may occur after the introduction of water, and eventually hearing loss will develop, due to blockage by collected debris This often develops before complete occlusion by the tumor Eventually infection supervenes, accompanied by pain Initially the in-

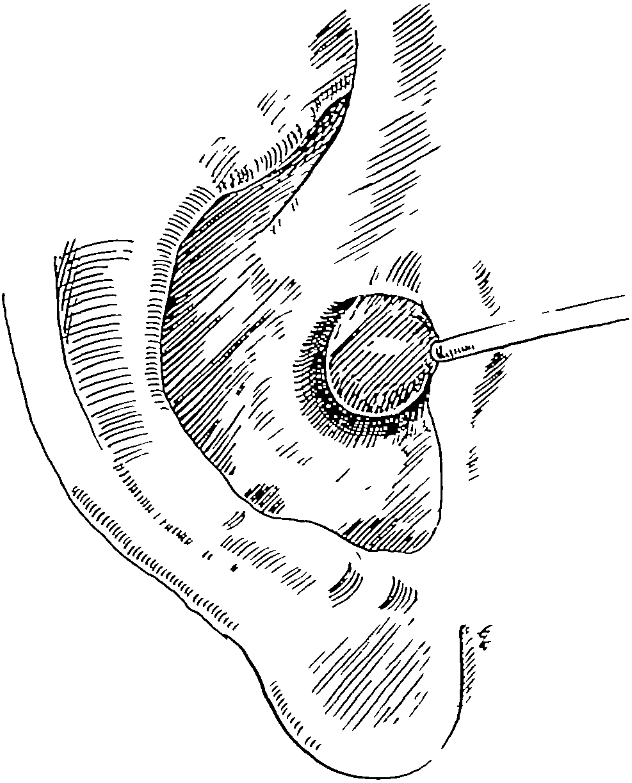

Fig 2 Osteoma of External Canal (Tragus retracted)

fection is limited to the external canal, but it may spread to the middle ear and mastoid A long-standing occlusion and infection will result in finding a situation not unlike a cholesteatoma, with extensive destruction of the mastoid and middle ear, necessitating radical mastoidectomy[1]

TREATMENT

A radical or modified radical mastoidectomy is necessary in an occasional case, to treat adequately the temporal bone suppuration secondary to the blockage by the tumor This was true in two of the five cases reviewed by Kline and Pearce[1] It would seem that modified radical mastoidectomy could have been avoided in two of the cases reviewed by them A simpler (transmeatal) procedure might have been more satisfactory for the patient

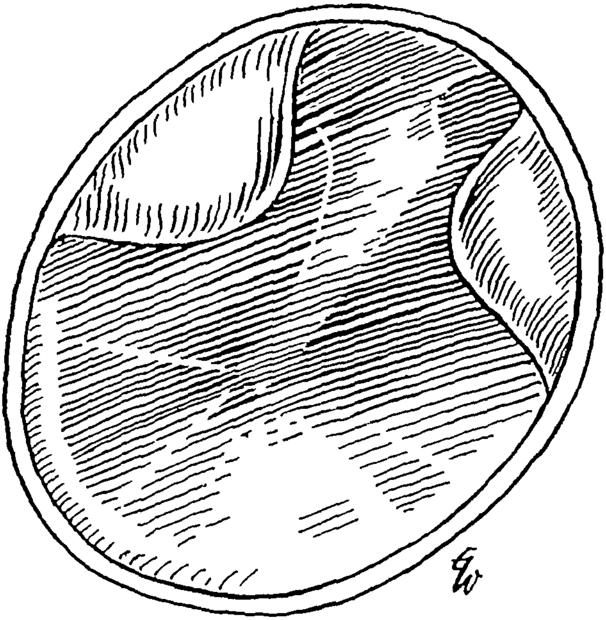

Fig 3 Exostoses of External Canal

Treated early, that is before complications develop, and with an understanding of the anatomy involved, the majority of osteomata may be removed transmeatally An endaural incision may be necessary to facilitate exposure The procedure found most satisfactory in the author's experience is as follows

General anesthesia, with an endotracheal tube, is used The ear is prepared as for mastoidectomy If the outer third of the canal is wide, and the tragus is not excessively prominent, no incision will be necessary Otherwise the upper arm of an endaural incision is made and a retractor inserted A sturdy attic hook or ear curette is inserted past the edge of, and deep to the osteoma (and is later used to deliver the tumor) This can usually be slipped deep to the tumor, even where no opening is visible In an occasional case, posterior canal wall bone may advantageously be removed before inserting the hook An assistant holds this hook A curved gouge is then directed at the pedicle and tapped lightly, loosening the tumor It is lifted out with the hook or curette It may be necessary to curette lightly or burnish the canal wall at the site where the tumor was attached

A small area of canal wall is left denuded If this is less than one-third of the circumference, as it usually is, a skin graft will not be necessary If greater than one-third of the circumference, it is wise to enlarge the canal with the burr, and apply a thin full-thickness skin graft removed from behind the ear The canal is packed with a finger cot filled with vaseline gauze, and a mastoid dressing is applied Any endaural incision is, of course, sutured

Antibiotics are given pre- and post-operatively The packing is removed on the third day, and a dry (powder) treatment is utilized thereafter until healing takes place

One last word on treatment an osteoma of the external canal as herein defined should be removed, even though not causing symptoms This tumor is in a position where it is continually exposed to trauma Continued growth of the tumor may result in complications necessitating radical mastoid surgery Surgery undertaken after the onset of complications is never so satisfactory

CASE REPORTS

Case 1 A 25 year old white male was referred because of a two year history of a gradually enlarging growth in the right ear canal Wax and water would collect deep to it Examination showed a bony tumor attached to the anterior superior bony wall, superficial to the isthmus, filling all but one mm of the canal diameter Hearing was normal

Under endotracheal anesthesia the upper arm of an endaural incision was made to facilitate exposure A small dull ear curette was passed deep to the lesion, which was seen to be attached by a broad pedicle to the tympanosquamous suture It was dislodged by a firm blow on a curved gouge the blade of which had been placed at the pedicle, and was delivered with the curette The tympanic membrane was normal The incision was closed and the canal was packed with a finger cot filled with vaseline gauze A mastoid dressing was applied The dressings were removed in three days, and the canal was healed in two weeks

Case 2 A 22 year old white male was referred for treatment of recurrent otitis externa Examination revealed a subacute right external otitis, due apparently to vigorous attempts by the patient to remove wax from the ear There was a small (3 mm) pedunculated bony tumor attached antero superiorly at the junction of the bony and cartilaginous canal

Removal of the tumor was advised after the otitis had subsided The patient refused treatment

Case 3 A 27 year old Negro male was referred because of a one and a half year history of intermittent discomfort in the left ear Hearing loss had been constant, and amounted to 40 dbs (conductive) Examination revealed a complete block of the left external canal by a bony growth which was attached by a pedicle to the posterior superior canal wall superficial to the isthmus

Under endotracheal anesthesia an S shaped endaural incision was made The membranous canal was separated for a short distance to the pedicle and cut to this point An external cuff of membranous canal was then fashioned, based inferiorly, and turned anteriorly With a bur some of the posterior canal wall was taken down until the pedicle could be seen clearly A sturdy attic hook was then passed deep to the osteoma The tumor was dislodged, using a mallet and curved gouge and delivered with the hook There was much epithelial debris impacted beneath this The tympanic membrane was normal The upper arm of the endaural incision was closed, the external cuff was thinned and replaced and the canal was packed with a finger cot filled with vaseline gauze A mastoid dressing was applied

The dressing and packing were removed in three days, and the canal was healed in three weeks Post operative audiogram revealed normal hearing

Case 4 A 23 year old white male was referred because of a four month history of wax impacted in the right ear with subsequent infection of the canal Examination revealed a pedunculated bony growth attached antero superiorly to the bone of the right external canal superficial to the isthmus, with less than one third of the normal lumen remaining The hearing was normal despite a large plug of cerumen

The osteoma was removed under endotracheal anesthesia* A small sturdy attic hook was placed deep to the lesion A tap on a curved gouge the blade of which had been placed at the pedicle resulted in separation of the tumor It was delivered with the hook. There was no bleeding The tumor had been attached to the tympano squamous suture The cerumen plug was removed revealing a normal tympanic membrane Gelfoam was placed in the canal and removed in one day The canal healed within a week

---

*Surgery performed by Colonel Edward J Whiteley

SUMMARY

An osteoma of the external auditory canal, although not common, is not extremely rare It must be differentiated from multiple exostoses, which are common These two lesions have been defined and discussed from the standpoint of symptomatology and treatment

An osteoma of the external auditory canal is always a surgical problem Four cases are reported

AN ELECTROPHYSIOLOGIC PROCEDURE FOR DETERMINATION OF AUDITORY THRESHOLD IN CHILDREN *

FRANK B WITHROW, JR ,
and
ROBERT GOLDSTEIN,†
St Louis, Mo

Several electrophysiologic indices have been used in clinical audiometry in the attempt to determine auditory thresholds in adults and children who cannot or will not respond adequately during conventional audiometric tests which use conditioned behavioral responses The most commonly used electrophysiologic index is some change in electric characteristics of the skin in response to auditory stimulation (electrodermal response or EDR) This change, presumably mediated primarily by the activity of the sweat glands of the skin, can be demonstrated by alterations in impedance to flow of electric current or by alterations in electric potential between two points on the skin Another index employed clinically is a change in the pattern of electric activity of the brain in response to auditory stimulation (electroencephalic response, or EER)

The principal value of auditory tests which use EDR and EER in response to sound as indicators of "hearing" is the information which they can contribute beyond that to be derived from observing behavioral responses Consequently, it is desirable that judgment of a change in an electrodermogram, or an electroencephalogram, as a response to a particular auditory stimulus be independent of the tester's knowledge of the stimulus and of the patient's overt behavior during stimulation It is also desirable that threshold be estimated

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication Feb 10 1958

from the distribution of responses on the basis of predetermined criteria, just as it is in the more conventional audiometric procedures

The procedure developed by Stewart[13] and elaborated clinically by Doerfler and McClure[9] satisfy the conditions mentioned in the previous paragraph Their procedure, however, requires some prior knowledge of a patient's auditory sensitivity in order, *1* to find a level at which a stimulus is definitely audible for a preliminary conditioning period, and *2* to establish a limited range of intensities within which their auditory stimuli can be randomly ordered Consequently, Doerfler and McClure did not determine thresholds independent of any knowledge of behavioral responses, they confirmed that threshold lay within a range previously established by behavioral responses

Preliminary determination of an approximate threshold is usually difficult with the particular adults for whom electrophysiologic tests are most necessary It is even more difficult with very young children, and with children who are mentally retarded, emotionally disturbed, or aphasic.

The purpose of this paper is to describe another procedure for determination of auditory thresholds using both EDR and EER as indicators of "hearing," and to report results of attempts to use this procedure to assess the hearing of some children with auditory disorders

SUBJECTS

The subjects for this study were drawn from the children enrolled in full-time classes at Central Institute for the Deaf (CID) These children represent a calibrated sample, in a sense, because their hearing has been evaluated yearly since their enrollment at CID

Apparatus *

The apparatus used in this study was described by Charan and Goldstein[2] The stimulating apparatus consisted of an audiometer and a device for applying electric shock Sound was delivered monaurally either through earphones held in place by a headband, or through hearing-aid type earphones held in place in the ear canal with the children's own earmold If the child did not have his own earmold, a stock-mold was used, and it was taped in place to minimize acoustic leaks and to prevent its falling out of the canal It is preferable to use the hearing-aid type earphone in the EER-Audio portion (to be described) during which the child is asleep These smaller earphones, without a headband, are less likely than the larger earphones, *1* to interfere with the comfort of the child's head during sleep, *2* to interfere with the EEG electrodes attached to the child's scalp, and *3* to loosen and to allow acoustic leaks

---

*The basic apparatus was a gift of the Children s Research Foundation St. Louis Mo

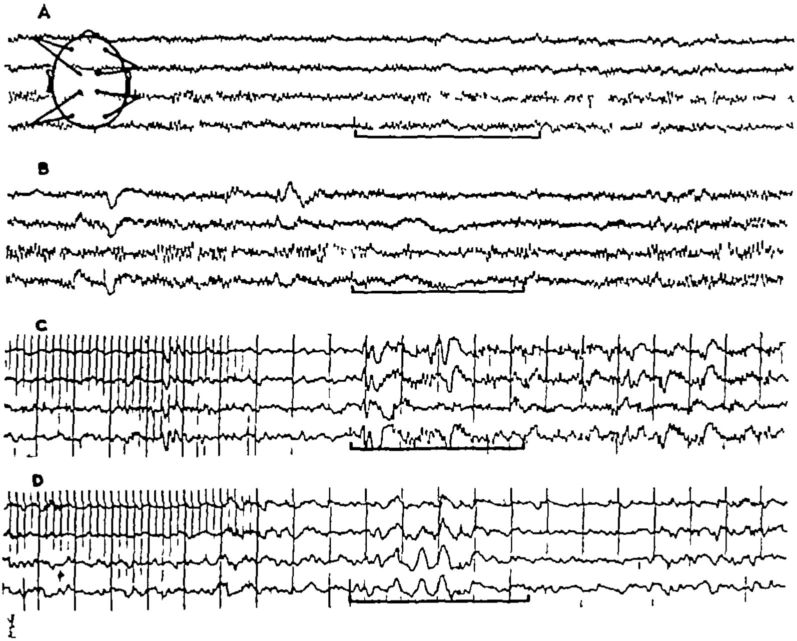

Fig 1 Sample electroencephalograms from the record of subject D during his EER-Audio The line under each strip indicates the duration of the auditory stimulus (approx. 5 sec) A and B Early stages of test child awake C and D child asleep Note clear electroencephalic responses in B C and D

The recording apparatus was a Grass four-channel electroencephalograph The electroencephalogram (EEG) was recorded by conventional procedures[6] The usual electrode placements were varied, however, according to a suggestion by Derbyshire,[3] so that the parietal lead was placed slightly posteriorly and the temporal lead was placed in a position in front of the usual parietal location The central leads from both sides were, therefore, bunched closely together near the top of the head Fig 1 shows the placement of the electrodes as well as a sample of the kind of recordings obtained from them The electrodes were attached to the head on portions of the scalp previously cleaned with alcohol Bentonite paste[6] insured satisfactory contact between the electrode and the scalp The electrodes were held in place with adhesive tape

The electrodermogram (EDG) was recorded on one channel of the electroencephalograph This method of recording has been described by Mays,[10] and by Goldstein, Ludwig and Naunton[9] In the present study, recording electrodes were taped to the tips of two fingers of the left hand The shock electrodes were attached to the calf of the left leg

PROCEDURE

EER-Audio[8]

The EER-Audio is performed when a child is asleep It is desirable that the children be tested in the evening or during regular nap-time, so that advantage can be taken of natural sleep whenever possible When a child does not go to sleep naturally, he can be lightly sedated The children in this study were given Seconal or Nembutal orally, under a neurologist's supervision

The test consists of 96 stimulus-conditions divided into six similar series of 16 A sample series is shown in Fig 2 Six different series are used to prevent inadvertent memorization of the sequence of stimuli in any series The order in which the six series are presented to any child is also randomized The stimuli are tones of 500 c p s or 2000 c p s with a duration of five seconds Each frequency is presented at three different intensities corresponding to the audiometric levels of 10, 50 or 90 db hearing-loss If his general behavior indicates that a child has normal or nearly normal auditory sensitivity, the range of intensities can be restricted to 10, 40 and 70 db hearing-loss If there is any doubt whatsoever, the broader range of 10, 50 and 90 db hearing-loss is used

The combination of two frequencies and three intensities in both ears makes a total of 12 stimuli Randomly scattered among these 12 stimuli are four control-intervals, *i e*, four times a stimulus-mark is recorded on the electroencephalogram when no auditory stimulus is presented to the child A number corresponding to the order of the stimulus or control in the pre-arranged schedule is placed by each stimulus-mark A minimum of 25 seconds is allowed to elapse between stimuli It is not always possible to complete all six series When a child awakes and will not go back to sleep or relax quietly, the test is discontinued

Fig 2 One of the series of stimuli used in the EER-Audio The other *five series have identical stimuli but in different sequences*

The records are not analyzed until after the test is completed

EDR-Audio [8]

The EDR-Audio is performed when the child is awake, either in the morning while he is alert, or in the afternoon after he has napped

This test, like the EER-Audio, consists of 96 stimuli, divided into six similar random series of 16 stimuli, and the stimuli are 500 c p s or 2000 c p s tones of five seconds duration (see Fig 3) Each frequency is presented at four different intensities corresponding to the audiometric levels 20, 40, 60 and 80 db hearing-loss Two frequencies and four intensities in both ears make a total of 16 stimuli for each series It is not necessary to use controls in the EDR-Audio because of the infrequency of random changes with the appropriate latency, time-course, and amplitude, which may be mistaken for responses to auditory stimuli

No	Ear	Frequency (in c p s)	Hearing-Loss (db)	Shock

16	R	500	20	+

Fig 3 One of the series of stimuli used in the EDR-Audio The other five series have identical stimuli but in different sequences

One-half of the 16 stimuli are followed by annoying electric shocks, regardless of the intensity of the auditory stimulus Because it is not required that shocks follow tones which are unquestionably audible, there is no need to have prior knowledge of an approximate hearing-loss We do not have certain knowledge as to what effect the use of shocks with inaudible tones will have on conditioning or responsiveness in general We have had some experience with adults, however, which indicates that shocks not preceded by audible tones do not depress responsiveness appreciably

As in the EER-Audio, only a number is placed by the stimulus-mark corresponding to the order of the stimulus in the pre-arranged schedule The records are analyzed after the test is finished

The EER-Audio is usually administered first, because the test involves no discomfort for the child, and he is not reluctant to return for the EDR-Audio Generally, it is more difficult to secure the cooperation of a child for the EER-Audio after he has been subjected to the shocks in the EDR-Audio

ANALYSIS OF THE RECORDS

The records are analyzed after the electrophysiologic tests are completed The only marks on the electroencephalograms and electrodermograms other than the tracings themselves are, *1* the various stimulus-marks, and *2* a number alongside of each mark corresponding to the order of the tone or control in the pre-arranged schedule The tester can note in a separate protocol the overt behavior of a child in response to a stimulus Judgments of responses to all 96 stimuli, or controls, are made before referring to the schedule

EER-Audio

Judgment of the presence of an electroencephalic response to a tone depends solely on how much the EEG pattern in or following the five seconds during which the tone is presented differs from the preceding pattern Derbyshire and his co-workers[4] have described the kinds of changes which can occur in response to a tone Fig 1 shows samples of electroencephalic responses from one of the children in this study (Subject D)

Although not all responses can be judged with equal certainty, a simple "yes" or "no" decision is made for each stimulus Responses to the 96 stimuli, or controls, are tabulated according to the scheme shown in Figs 4-10

EDR-Audio

Judgment of the presence of an electrodermal response to a tone depends primarily on the latency of a change in the impedance or potential of the skin following the onset of the tone The average latency is very close to 2 1 seconds Changes with latencies less than 1 5 seconds, or greater than 3 0 seconds, are disregarded unless a child consistently responds outside this range Changes of impedance or potential within this period usually are larger than the random changes, and usually reach maximum in a shorter time than do the random changes Responses to the 96 stimuli are tabulated in the same way as described for the EER-Audio

ESTIMATION OF THRESHOLD OR HEARING-LOSS

In a plot of behavioral responses as a function of intensity elicited by conventional audiometric procedures, one ordinarily finds a point of zero responses, a point of 100 per cent responses, and a sigmoid curve describing the locus of the intermediate points The 50 per cent point is usually chosen as threshold

TABLE I CRITERIA FOR ESTIMATION OF THRESHOLD

Number of false-positives in 24 control-intervals	Number of responses to six stimuli to be significantly* more than false-positives
0	2
1	2
2	3
3	3
4	4
5	4
6	4
7	5
8	5

*5 per cent level of a one-tailed distribution

The curve describing the frequency of electrophysiologic responses as a function of the intensity of the auditory stimulus usually does not have a zero point or a 100 per cent point, and the locus of the intermediate points is not certain A practical zero can be established for each individual, however, from the relative number of false-positives in the control-intervals The false-positives may be the result of faulty judgment during analysis of the records, or the result of an actual response to some extraneous stimulus Experience has shown that the number of false-positives in the EDR-

Audio is small, thus, practical zero is not very different from true zero In the EER-Audio, the percentage of false-positives is somewhat larger

Statistical calculations[13] provide a criterion for determining the stimulus-level at which significantly more responses than false-positives occur (see Table I) This criterion is based on the 5 per cent point for a one-tailed test The weakest stimulus-level at which this criterion is met is regarded as (or above) the subject's threshold

Because there are no control-intervals in the EDR-Audio, estimates of threshold are made conservatively One can assume that there would have been a maximum of two or three false-positives if 24 control-intervals had been used Thus, in the EDR-Audio there must be at least three responses to six stimuli at a given level to indicate "hearing" at that level

The following section describes the results of attempts to confirm the above criteria for threshold For this purpose we have chosen some children from the full-time classes at Central Institute for the Deaf, who have been tested repeatedly by conventional audiometry, and have shown the same audiogram over a period of several years We shall also describe the attempts to apply these criteria to the determination of hearing-losses in some children for whom conventional procedures produced inadequate or conflicting results Although the audiometric records were on file, we had no knowledge of the audiograms of any of the children before they were tested The results of the electrophysiologic and the conventional tests were compared only after the records from the electrophysiologic tests had been analyzed

RESULTS

The following examples will show how the application of the above criterion served to determine the hearing-loss within ±10 db of thresholds previously determined by conventional audiometry

SUBJECT A

Fig 4 Plot of responses from the EER-Audio and EDP-Audio for Subject A.

A 13 years old (see Fig 4)

Because a relatively small hearing-loss was suspected on the basis of general behavior, the hearing-losses of 10, 40 and 70 db (re audiometric zero) were used in the EER-Audio instead of 10, 50 and 90 db ordinarily recommended

There was not sufficient intensity at 70 db hearing-loss

Fig 6 Plot of responses from the EER-Audio and EDR-Audio for Subject C

C 7½ years old (see Fig 6)

Only five instead of the usual six series were given in the EER-Audio, because this child awoke before the end of her test On the basis of three responses to five stimuli as the criterion for "hearing," this child's hearing-losses were

	500	2000
Right - -	>90 db	>90 db
Left -	>50 <90 db	>90 db

The six series of the EDR-Audio were completed The hearing-losses according to this test were

	500	2000
Right	>60 <80 db	>80 db
Left	>60 <80 db	>80 db

The EDR-Audio showed "hearing" in the right ear for 500 c p s at the 90 db level, the EER-Audio did not

The following are the hearing-losses based on both the EER-Audio and EDR-Audio combined, along with the findings from conventional audiometry (in parenthesis)

	500	2000
Right	>60 <80 (85) db	>90 (>100) db
Left	>60 <80 (70) db	>90 (100) db

The discrepancy (approximately 10 db) between the findings determined electrophysiologically and psychophysically for 500 c p s in the right ear is not appreciably greater than differences in calibration or test-retest reliability

D 10 years old (see Fig 7)

On the basis of our criteria, this child's hearing-losses according to the EER-Audio were

	500	2000
Right	>10 <50 db	>50 <90 db
Left	>50 <90 db	>90 db

According to the EDR-Audio his hearing-losses were

	500	2000
Right	>40 <60 db	>80 db
Left	>60 <80 db	>80 db

The hearing-losses based on both tests and the results of conventional audiometry (in parentheses) are as follows

	500	2000
Right	>40 <60 (35) db	>80 <90 (95) db
Left	>60 <80 (75) db	>90 (>100) db

There are two minor discrepancies (approximately 10 db) between electrophysiologically and psychophysically determined thresholds for 500 c p s and 2000 c p s in the right ear As in the cases previously cited, these discrepancies can

SUBJECT D

Fig. 7 Plot of responses from the EER-Audio and EDR-Audio for Subject D

be accounted for by differences in calibration or by test-retest reliability

The preceding "calibrated" examples not only confirm a criterion for threshold derived from theoretical considerations, but also allow an estimation of the frequency with which judgments of false-positives are made In the EER-

Audio of each of the preceding instances, there were 3 in 24, 1 in 24, 1 in 20, and 3 in 24, respectively, false-positives in the control-intervals If stimuli below each child's threshold are considered as controls, a similar frequency of false-positives is noted 4 in 60, 3 in 48, 2 in 60, and 6 in 48, respectively On the basis of these four examples, one may expect anywhere from 4 to 13 per cent false-positives with the EER-Audio

In the EDR-Audio, these same children gave the following number of false-positives to stimuli below their thresholds 0 in 66, 2 in 48, 2 in 84, and 8 in 78, respectively On the basis of these four children, an observer should expect to judge from 0 per cent to 10 per cent false-positives in the EDR-Audio This is comparable to about 2 per cent false-positives found in another study on normal adults[12]

The data reported here is typical of that found in successful tests with cooperative patients, but it should be emphasized that the EER-Audio and EDR-Audio are not always so successful as in the four cases just described

In the following examples, varying degrees of success were achieved, and certain modifications in the criterion for threshold were made in order to salvage some usable information from the tests

E 8 years old (see Fig 8)

Because there were no false-positives in the 24 control-intervals of the EER-Audio, only two responses to six stimuli were required to establish threshold On this basis the hearing-losses for this child were

	500	2000
Right	>50 <90 db	>90 db
Left	>50 <90 db	>90 db

In the EDR-Audio there were no definite EDRs to any of the 96 stimuli What is plotted in the analysis of the EDR-Audio in Fig 8 were the only definite overt responses observed during the test On the basis of these overt responses, the hearing-losses were

	500	2000
Right	>50 <90	> 90
Left	>50 <90	> 90

0 false-positives in 24 control-intervals

	500	2000
Right	>60 <80	> 80
Left	>60 <80	> 80

All responses were overt. There were no EDR

SUBJECT E

Fig 8 Plot of responses from the EER-Audio and EDR-Audio for Subject E

	500	2000
Right	>60 <80 db	>80 db
Left	>60 <80 db	>80 db

On the basis of the evidence from both tests, the hearing-losses were estimated to be

	500	2000
Right	>60 <80 db	>90 db
Left	>60 <80 db	>90 db

Because the range of hearing-losses from the EER-Audio coincided with the range of hearing-losses estimated from overt responses in the EDR-Audio, the hearing-losses could be reported with considerable certainty. The findings allowed us to resolve a difference in educational recommendations based partially on differing pure-tone audiograms. Initially it was believed that this child had only a mild hearing-loss, and it was recommended that he be educated as an aphasic child. His educational development, however, was like that of a deaf child, and later audiograms determined by conventional audiometry, though they had been reported with qualifications, were confirmed by the above estimate of hearing-loss from the electrophysiologic tests.

F. 8 years old (see Fig. 9)

In the EER-Audio there were at least three responses to six stimuli only for 2000 c.p.s. in the right ear, at 50 db hearing-loss; there was only one response at 90 db hearing-loss. To the six stimuli of 2000 c.p.s. at 50 db hearing-loss in the left ear, there were two responses; at all other frequencies and intensities there were one or no responses. One might have assumed from the pattern of responses that the hearing-losses were

	500	2000
Right	>90 db	>10 <50 db
Left	>90 db	>10 <50 db

Such a pattern, however, is rarely, if ever, seen clinically and in this instance was not consistent with the child's usual reactions to sound. In addition, the total of 11 responses to all 96 stimuli is not significantly more than the two false-positives in the 24 control-intervals. Our assumption, therefore, was that the child's hearing-loss was greater than 90 db for 500 c.p.s. and 2000 c.p.s. in both ears.

In the EDR-Audio there were no responses to the 96 stimuli used either because this child was particularly difficult to condition, or because the sound was not sufficiently intense to elicit responses. We tested these possibilities at the end of the regular EDR-Audio by presenting sounds exceeding the

intensity for 90 db hearing-loss. The child consistently gave EDRs to these latter sounds.

The lack of electrophysiologic responses below the 90 db hearing-loss was in accord with his limited reaction to sound from the group hearing-aid in his classroom. The findings were also in accord with conventional audiometry (reported with limited certainty), and helped to resolve a difference in

Fig 10 Plot of responses from the EER-Audio and EDR-Audio for Subject G

educational recommendations similar to the previous case (Case E)

G 6 years old (see Fig 10)

From the distribution of responses shown in Fig 10, it is obvious that a hearing-loss based on the EER-Audio or EDR-Audio would have questionable validity In addition, the occurrence of a false-positive for every three controls in the EER-Audio requires five responses to six stimuli as evidence for hearing at a given stimulus-level. This criterion is met only at the 90 db. level for 2000 c.p.s. in the left ear.

There are slightly more EER and EDR to stimuli in the left ear than in the right. In the EER-Audio there is a small tendency for more responses to the more intense sounds than to the weaker sounds. Neither trend appears significant.

Conventional audiometry was relatively unsuccessful, and although the EER-Audio can be considered partially confirmative of the hearing-losses that were estimated, attempts to measure hearing-loss by electrophysiologic techniques were actually unsuccessful.

DISCUSSION

The procedures outlined in this paper appear to satisfy some of the requirements for objectivity: the response-mechanism is not dependent upon the active cooperation of the subject, no special variation in procedure is required for each patient (although the intensity range can be compressed if desired), and hearing-losses can be estimated on the basis of a previously established criterion. The electrophysiologic tests are also independent in that they require no prior knowledge of a patient's auditory behavior and no knowledge of a patient's overt behavior during the test.

The objectivity and independence of the test does not compel the tester to ignore the overt behavior of the patient. This behavior can be recorded in a separate protocol (cf. example E in section on results) and then be related to the results of the electrophysiologic test. Likewise, the results of other attempts to measure hearing-losses through behavioral responses can be compared with the results of the electrophysiologic tests. We endorse the view[1, 11, 14] that electrophysiologic tests should supplement, not supplant, the conventional methods of measuring hearing-loss.

On the basis of our own clinical and experimental experience, we believe that many of the EDR we elicit are unconditioned, certainly all of the EER during sleep are unconditioned We believe that we are able to maintain a relatively high rate of responses because of the variation in stimuli which is a consequence of the random schedule When the stimuli are varied with respect to frequency, intensity and ear, each stimulus tends to be somewhat novel and thus acts as an unconditioned stimulus

Because so little adaptation of the procedure is needed for each patient and because of the relative simplicity of the task of analysis, a tester need have little experience with electrophysiologic techniques to administer these tests successfully, providing that he has a good understanding of the general principles of clinical audiometry Audiologists with virtually no previous experience with either the EER-Audio or EDR-Audio have already used these techniques successfully in our clinics

The procedures described in this paper are not intended to be definitive or final, but rather to be a prototype for electrophysiologic procedures for determination of hearing-losses Since the preparation of this paper, we have already tried certain modifications in the procedures For instance, in the EDR-Audio we are testing the feasibility of using intensities corresponding to 20, 60 and 100 db hearing-loss instead of the 20, 40, 60 and 80 db presently used This change may serve to reduce the time of the test and make it more likely to elicit responses from profoundly deaf children

Much experimental work is needed to produce refinements that will insure more success with any particular procedure Such factors as the optimum duration of the stimulus and the optimum length of time between successive stimuli need to be investigated, as well as such technical aspects as control of the level of sleep, most satisfactory location of electrodes, and automatic analysis of records

The results we have obtained indicate that our procedures can be used practically Although we have presented results of our tests on children, there is no reason to believe that these tests could not work just as satisfactorily with adults

necessary to stimulate the auditory nerve to make it deliver enough impulses to the central nervous system to initiate two particular kinds of responses The thresholds reported, therefore, probably represent the minimum strength of sound to which a child is organically capable of responding

When a child is tested by both the EER-Audio and EDR-Audio, there is a greater probability of obtaining a certain estimate of a small range (±10 db) within which the hearing-loss lies than when only one of the tests is given Nevertheless, when either test is successful, it is possible to obtain a range for the hearing-losses certain enough and narrow enough to give important support for making particular recommendations for special education

Each test has advantages and disadvantages affecting its clinical practicality and desirability The EER-Audio is less desirable than the EDR-Audio for the following reasons *1* Technically, the EER-Audio is more difficult to administer (control of sleep, multiplicity of wires, more channels for recording, etc) , *2* When a child is asleep during the EER-Audio, naturally it is impossible for him to display his normal overt responses to sound, *3* It is impractical to condition electroencephalic responses in a sleeping child, as one would condition electrodermal responses to sound in a child who is awake, *4* It is more difficult to discern electroencephalic responses in an electroencephalogram than it is to discern electrodermal responses in an electrodermogram

The EER-Audio has these advantages over the EDR-Audio *1* Because no conditioning is used with the EER-Audio, there is no disturbance of the child with electric shock or other annoying unconditioned stimulus, *2* During the EDR-Audio, most young children are restless, and they squirm, partially in boredom during a long and uninteresting (to them) test Very often they scream, kick and are generally disturbed because of the discomfort of the shock and because they are aware of the wires, phones, and the strange circumstances of the whole test-situation During the EER-Audio the children are asleep (usually before the application of electrodes) and thus are unaware of and unfrightened by the test, *3* Con-

In fact, we do use a modified form of the EDR-Audio for *confirmation* of hearing-losses in adults

Success of the EER-Audio and EDR-Audio, as outlined in this paper, does not appear to be dependent upon the particular kind of child or the nature of his auditory disorder In the examples presented in the previous section, subject C is the only one who can be classified as an uncomplicated deaf child Subjects A and D are aphasic children with hearing-losses Subject B has a hearing-loss, and his problem in communication is complicated by a low intellectual capacity Subjects E and F are considered deaf children, although they were referred for education with a diagnosis of some defect of the central nervous system which impeded normal development of language Both of these children have serious behavioral problems which complicate their auditory difficulties The child who was unsuccessfully tested (subject G) is classified educationally as aphasic, and has additional complications of a probable hearing-loss and emotional problems

It has been our experience that there is no discrepancy or, at most, a minor discrepancy between the hearing-losses determined by procedures requiring overt responses and the hearing-losses determined by electrophysiologic techniques when the results of both kinds of tests are reasonably clear Because of this agreement, we usually feel confident that clearly determined hearing-losses from the EER-Audio and EDR-Audio can be reported as representing a child's sensitivity to sound, even when the results of the more conventional techniques are too inconsistent to be corroborative Occasionally there is an appreciable discrepancy between the findings from the EER-Audio and the EDR-Audio In these instances, the EER-Audio usually indicates less hearing-loss

We have no clear understanding at present of the anatomic structures or of the physiologic processes involved in the electrophysiologic responses to sound Although a report may be given within ±10 db of the intensities believed to be a child's "threshold of hearing," the report does not tell us how the child ordinarily reacts to sound at or above his threshold The findings merely state how much intensity is necessary to stimulate the auditory nerve to make it deliver enough impulses to the central nervous system to initiate two particular kinds of responses The thresholds reported, therefore, probably represent the minimum strength of sound to which a child is organically capable of responding

sistent electrodermal responses are difficult to elicit in very young children[7] According to Derbyshire,[4] electroencephalic responses to sound do not seem to be limited by age, and this seems to be true in our experience as well

If only one test or the other were to be used for young children, we should favor the EER-Audio, primarily on the basis of the greater ease of handling of the children and because of the greater likelihood of eliciting responses Reliability and narrowing of the range in which the hearing-loss lies could be achieved by successive EER-Audios We suggest, however, that if it is at all feasible, both the EDR-Audio and EER-Audio be done on the same child

SUMMARY

In two separate tests, electroencephalic responses (child asleep) and electrodermal responses (child awake) to sound are used as indicators of "hearing" In both tests, tones of 500 c p s and 2000 c p s at different intensities are presented to either ear, according to a previously prepared, random schedule The stimulus-levels in the first test correspond to 10, 50 and 90 db hearing-loss, and in the second to 20, 40, 60 and 80 db hearing-loss The records are analyzed only after the tests have been completed and without knowledge, at the time of analysis, of the particular stimulus (or control) which corresponds to the ordinal number placed near each stimulus-mark The combined results of both tests can yield an estimate of hearing-loss within ±10 db of thresholds determined from behavioral responses Separately, either test yields less certain and precise estimates of hearing-loss

associated with a columella that is too short The reason for dividing them in this manner is because each type requires a different treatment when the use of the orthopedic septo-columellar suture is considered

The orthopedic suture should never be used in the Type I tip and is never indicated, providing the cartilaginous dorsum of the septum is lowered adequately at operation I think this is of primary importance and should be emphasized The orthopedic septo-columellar suture, on the other hand, is obligatory in Type II Unless it is used in every tip of Type II the result will be an unsatisfactory rhinoplasty, even in the hands of the experienced surgeon

TYPE I NASAL TIP

This is the commonly encountered nasal tip, the one most frequently operated upon It is the large oversized nose with a prominent nasal tip that possesses adequate projection When the cartilaginous dorsum is left too high in such a nose, the judgment of the surgeon is usually at fault, and is the initial mistake leading to a train of errors In order to create a straight profile at operation, the surgeon makes a second mistake by elevating the nasal tip to the level of the too high cartilaginous dorsum of the septum This he accomplishes by means of the orthopedic septo-columellar suture applied high on the septum and low on the columellar What is desirable is not an increase in the elevation of the nasal tip Instead, the cartilaginous dorsum of the septum should be lowered to the level of the nasal tip The technique for lowering the cartilaginous dorsum of the septum adequately has been described in a previous article[3] The nasal tip, by means of this technique, stands up in its natural position unassisted and unsupported by artificial means Under these conditions, it will retain its position postoperatively Certainly, overcorrection of the tip on the septum by means of the orthopedic septo-columellar suture is contraindicated and should be condemned in every case of Type I tip Light catgut sutures between the vestibular skin of the columella and nasal septum will suffice in approximating the columella to the septum

EVALUATION OF THE ORTHOPEDIC SEPTO-COLUMELLAR SUTURE IN RHINOPLASTY

GUSTAVE B. FRED, M.D.,

Boston, Mass.

The beginner in rhinoplasty is usually taught that essentially all nasal tips fall postoperatively after the septo-columellar sutures are removed and that it is, therefore, necessary to overcorrect or elevate the nasal tip on the septum in every case. In order to effect this, he raises the tip by means of the so-called orthopedic septo-columellar suture applied high on the septum and low on the columella, with the hope that the tip will eventually come down just right and that the postoperative esthetic effect will result in an attractive nose. In many cases it does just that—it comes down just right. Frequently, however, the tip falls down too much, resulting in a nose that is too long, a tip too round, and the cartilaginous dorsum of the septum too high; and there are rare occasions when the tip for some unaccountable reason remains too high. Too much, therefore, is left to chance, and under these conditions there is no control over the amount of pull and direction that the tip will take.

The teaching is fallacious. There are times when the orthopedic septo-columellar suture is definitely contraindicated, and under no circumstances should be used. At other times it is obligatory and must be employed, otherwise failure will surely result. All rhinoplasty surgeons agree that the orthopedic septo-columellar suture should not be used routinely in rhinoplasty.

When the feasibility of using the orthopedic suture is contemplated, it is helpful to divide nasal tips into two types: Type I, which possesses adequate projection with a sufficiently long columella; and Type II tip with inadequate projection,

---

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication March 7, 1958.

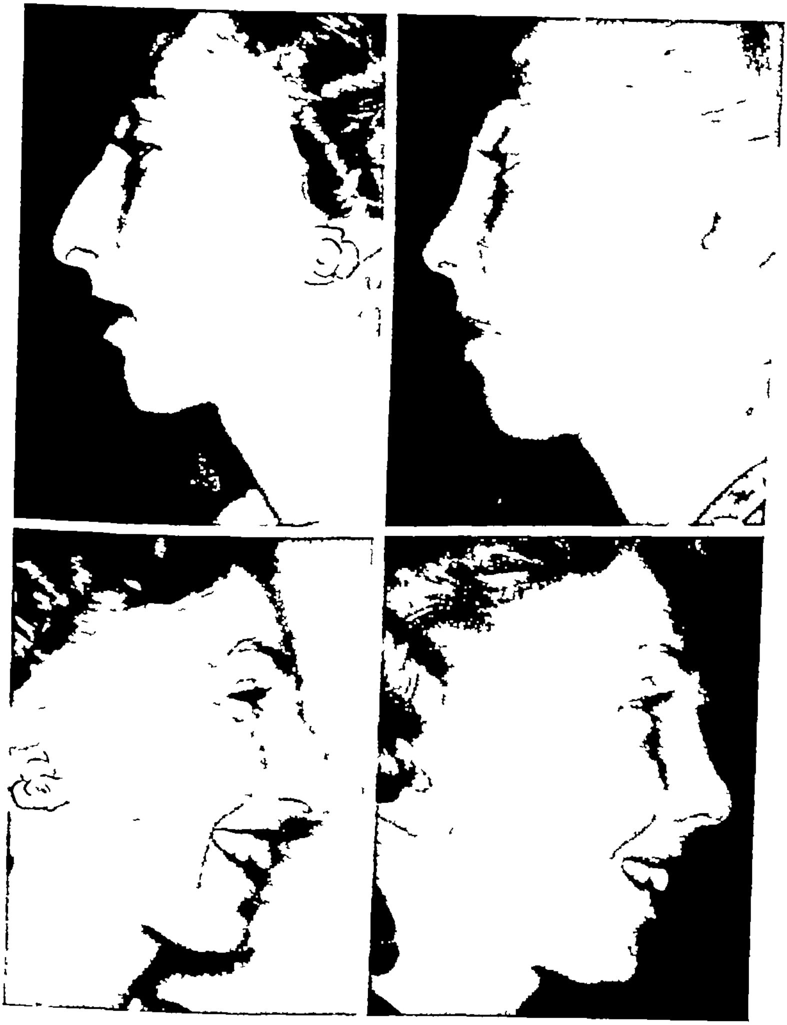

Fig 2 Type II nasal tip—Inadequate tip projection associated with a short columella The orthopedic septo-columella suture is indicated in every case of Type II and should be used in conjunction with invagination and severing the depressor septi nasi muscle in the columella

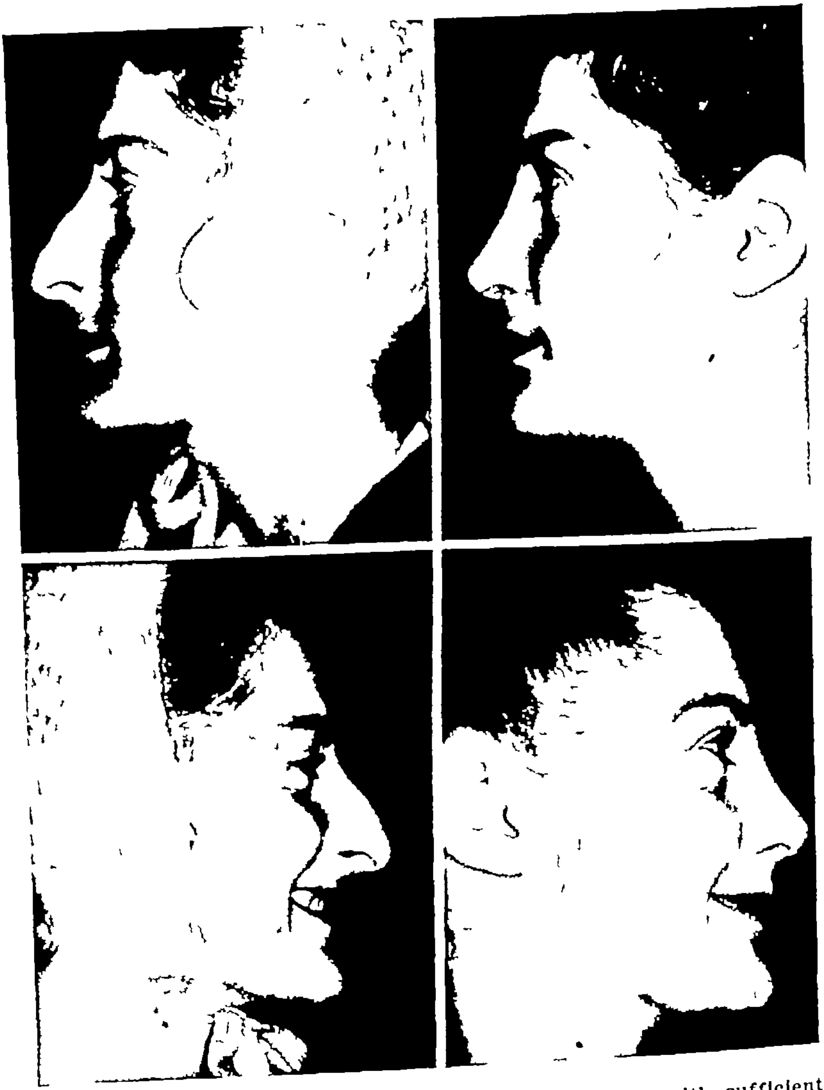

Fig 1 Type I nasal tip—Adequate projection of tip with sufficiently long columella The orthopedic septo-columella suture is never indicated in Type I nasal tip

orthopedic septo-columellar suture is obligatory in every case of Type II In order to keep the tip in the elevated position, overcorrection must be combined with invagination,[1] and severing all the fibers of the depressor septi nasi muscle[2] in the columella to insure the permanent stability of the elevated tip

TYPE II

The Type II nasal tip is totally different and far more difficult to correct than Type I Bold, heroic treatment is obligatory Overcorrection by means of the orthopedic septo-columellar suture is absolutely essential and must be resorted to in every case This suture, however, applied in the conventional manner will fail to hold the tip in the elevated position unless it is supplemented by other means In a previous article,[1] I advised invagination to insure the elevated position of the tip, and the lip-freeing technique[2] (cutting the depressor septi nasi muscle fibers in the columella) to prevent the lip muscles from pulling the tip down With these additional methods of treatment, the tendency of the tip to return to its former low position is minimized and often eliminated

An attempt should be made to lower the cartilaginous dorsum of the septum to the level of the nasal tip, as was done in Type I, but this is not always possible There is a limitation to which we can lower the anterior surface of the septum It should never be lowered less than 30 degrees in the nasofacial angle, otherwise the nose would be too small, the profile too low, and the tip too snubbed For esthetic reasons, therefore, the tip must be raised above the level of the cartilaginous dorsum of the septum in every case of Type II and the orthopedic septo-columellar suture is the only means of doing so with a reasonable chance of success

CONCLUSION

When the orthopedic septo-columellar suture is contemplated in rhinoplasty, the first point to determine is the amount of projection of the nasal tip Nasal tips can be profitably divided into two types Type I with adequate projection, and Type II with inadequate projection

The orthopedic septo-columellar suture is never indicated in any case of Type I nasal tip and will not be necessary, providing the cartilaginous dorsum of the septum is lowered adequately

Overcorrection of the tip on the septum by means of the

MUMMIFIED EPIDERMAL CYST, CALCIFIED EPITHELIOMA OF MALHERBE

Report of a Case

S D Greenberg, M D ,*
and
F E LeJeune, Jr , M D ,†
Iowa City, Iowa

The modern otolaryngologist is frequently confronted with tumors of the head and neck An accurate diagnosis is always stressed, for such is important for clinical treatment as well as academic interest The case herewith reported was recently seen in the Department of Otolaryngology and Maxillofacial Surgery, and in the Department of Dermatology at the State University Hospitals, Iowa City, Iowa The exact nature of this tumor was not appreciated until a frozen section was done at the time of surgical excision

CASE HISTORY

The patient a 13 year-old boy was admitted to the State University Hospitals April 1, 1957 The chief complaint of the patient was a slowly growing tumor beneath the skin overlying the posterior aspect of the right mastoid process The tumor was of two and one-half years duration There was no history of fever cellulitis suppuration, fluxuation, or breakdown of the tumor Two weeks before admission the growth was incised by the referring physician and yielded several drops of blood There was no regional lymphadenopathy The patient lived on a farm and drank unpasteurized milk

Physical Examination

The patient was a husky young white male who appeared to be at the stated age of 13 years He was neither acutely nor chronically ill Oral temperature was 99 2° F pulse was 88/min and BP was 110/70 mm Hg The tumor was firm and non tender and was overlying the right mastoid process (see Fig 1) It was conical and measured 3 5 cm at its rounded base and 2 0 cm in height, it was freely moveable within the sub cutaneous tissues The overlying skin was reddish brown and contained

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication Feb 12 1958

representing a pseudo-capsule Adjacent adipose tissue was present The tumor was composed largely of masses of eosinophilic material which varied in size and shape Some showed ghosts of former cells whose appearance was that of having originally been stratified squamous epithelium These cells had no remaining nucleus or visible cytoplasm and only the cell walls were seen (see Fig 5) Other eosinophilic masses were amorphous showing no cellular structure Within and about these eosinophilic masses there were minute foci of amorphous deeply blue staining bits of calcium (see Fig 5)

The stroma varied in composition being loose in several areas but appearing compact in most areas It was composed of strands of collagen and fibrous connective tissue In some areas an occasional fibroblast was seen Scattered about the stroma there was keratin debris about which there were several large foreign body giant cells and foci of lymphocytes (see Fig 5)

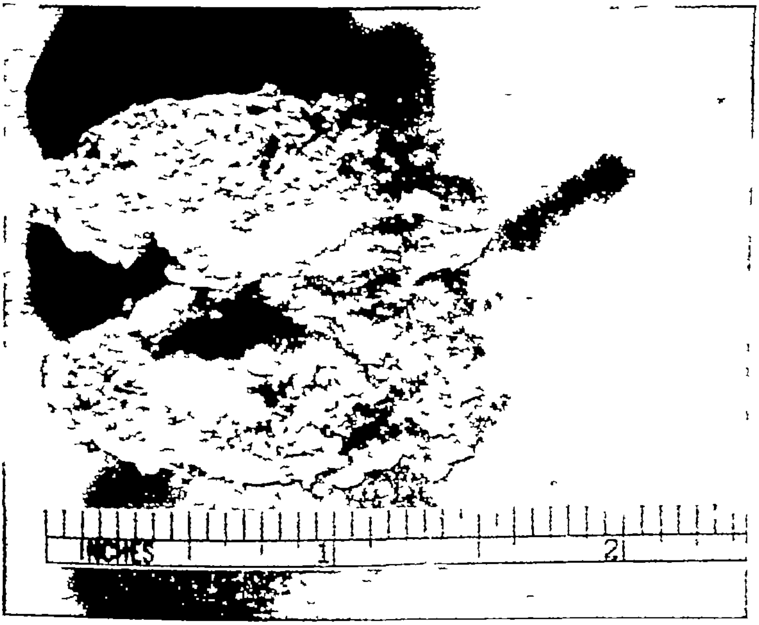

Fig 3 Photograph of the cut surface of the tumor

The most interesting feature was the large groups of actively proliferating epithelial cells which were intermingled within the areas of coagulative necrosis and amorphous keratin debris (see Fig 6) These cells were closely packed and had a large pale blue vesicular nucleus containing one to two nucleoli (see Fig 7) These cells resembled the basal cells of skin. The cytoplasm stained pale blue to light pink and the cell borders tended to be indistinct There were areas within these cell groups showing 4-5 mitoses per high power field (see Fig 7) Two fields showed transformation of these cell groups into degenerating

X rays of the paranasal sinuses showed minimal thickening of the mucosa of the right antrum An X ray of the tumor was interpreted as showing no calcification, chest X ray showed no change Serological test for syphilis was normal Intradermal tests for coccidiodomycosis, blastomycosis, and histoplasmosis were negative Intradermal second strength P P D test for tuberculosis was weakly positive

Hospital Course

The patient was seen in consultation by the Department of Dermatology whose impression was a low grade malignancy of connective tissue origin Excision was recommended The preoperative diagnoses included 1 Low grade malignancy of connective tissue origin, 2 chronic granuloma, and 3 possible xanthoma At the time of surgery the frozen section diagnosis was "Mummified Epidermal Cyst" The tumor was completely excised A primary closure was done, and post operative healing was uneventful

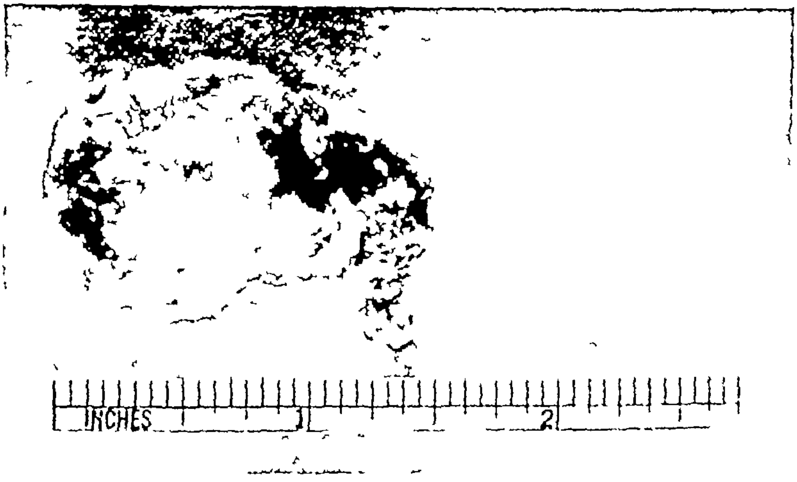

Fig 2 Photograph of the oblong irregularly lobulated tumor A portion of the closely adherent overlying skin is seen on the right

Gross Description The specimen consisted of an oblong irregularly lobulated firm grey brown tumor, measuring 1 0×2 5×2 0 cm (see Fig 2) An elliptical portion of overlying skin was closely adherent to the superior surface Attached fragments of adipose tissue were scattered about the surface On the cut surface (see Fig 3) the margins of the tumor were encapsulated by an intact covering of grey white tissue measuring 0 3 cm The central portion was composed of yellow grey compressed crumbly material which showed no particular pattern No odor was discernible

Microscopic Examination The tumor was within the subcutaneous tissues (see Fig 4) The stratified squamous epithelium of the overlying skin was well preserved and showed minimal acanthosis Within the compact dermis there was an increase in collagen and fibrous connective tissue and a sparse infiltration of lymphocytes

The tumor was bordered by a thin layer of compact connective tissue

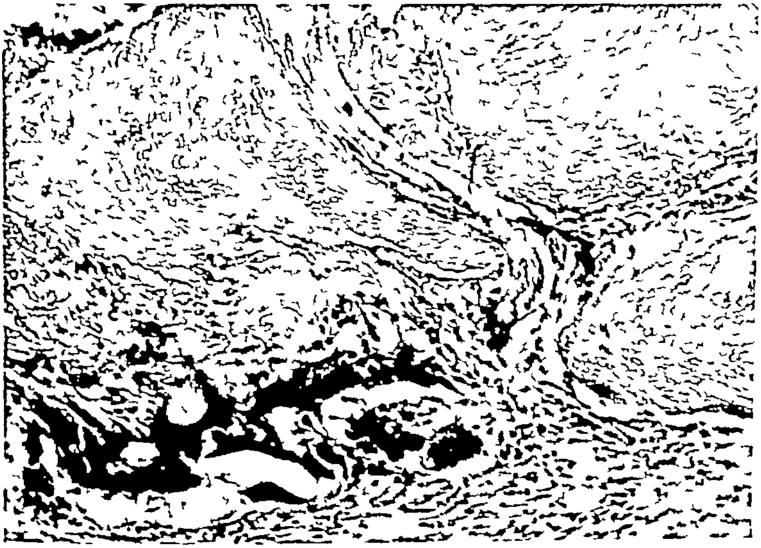

Fig 5 Photomicrograph showing three groups of ghost cells (degenerating stratified squamous epithelium) Within the stroma there are foreign body giant cells adjacent to keratin debris and flecks of calcium—300X.

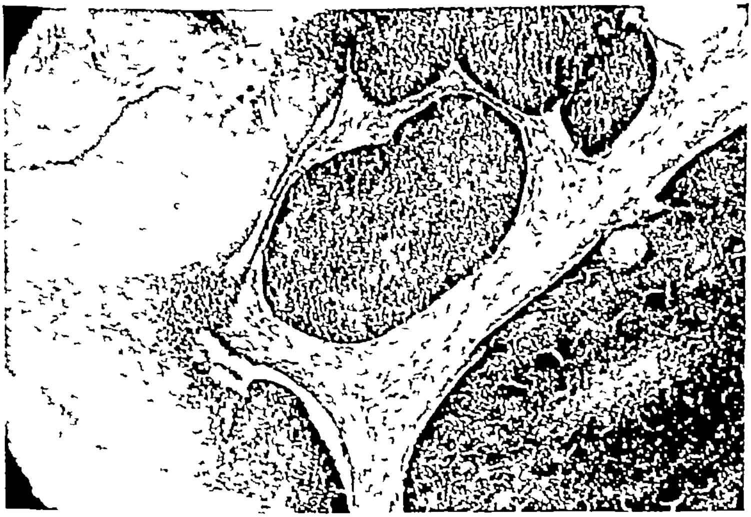

Fig 6 Photomicrograph showing groups of actively proliferating basal cell type epithelial cells The transformation of these basophilic cells into the shadow cells can be seen—100X.

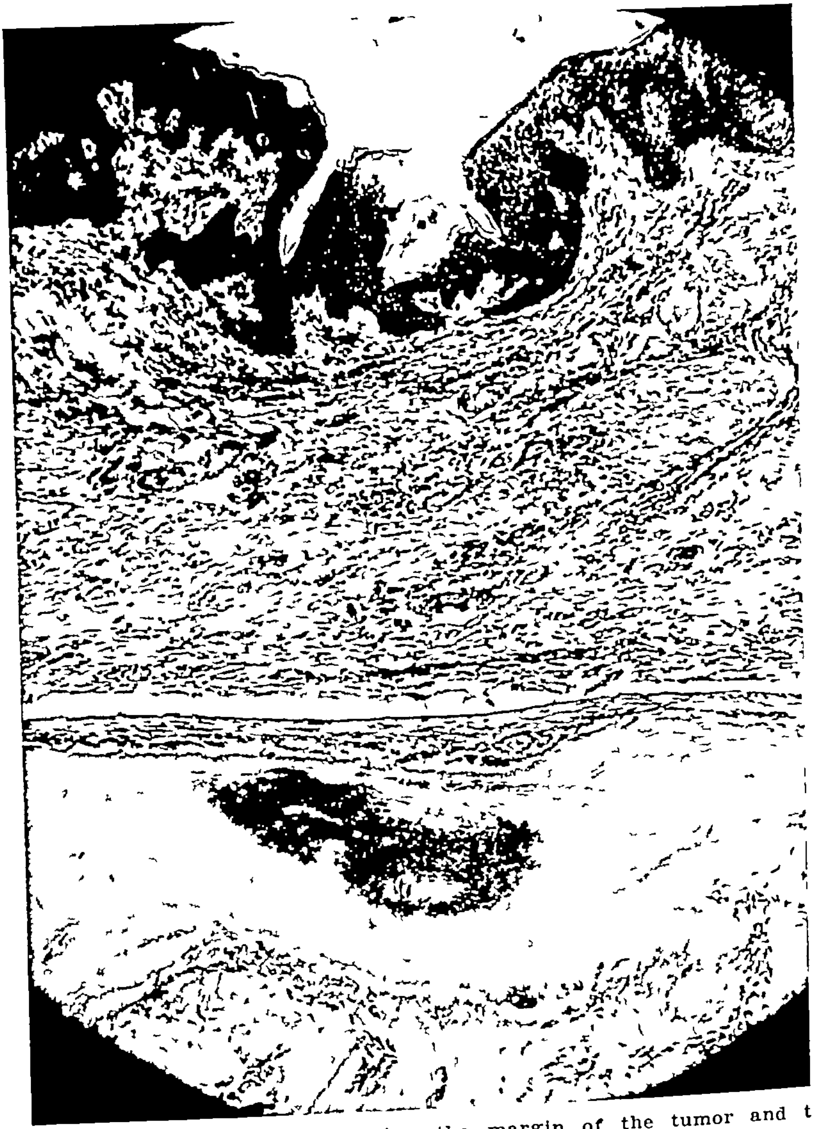

Fig 4 Photomicrograph showing the margin of the tumor and the overlying skin—75X.

stratified squamous epithelium In one focus there was dyskeratosis Two small keratin pearls were present within one basal cell group

DISCUSSION

This tumor was first described in 1880 by Malherbe (as cited by Lever[1]) It is unfortunate that Malherbe used the but it has recently been reported to be more common in childhood[4]

The growth may occur on the scalp, face, back, arm or thigh, but it is most common about the head and neck[5] The lesion is slow growing, and the majority have been present for an average of three years before being removed[6] The tumor is attached to the overlying skin, but it is freely moveable within the underlying tissues Rarely, there may be ulceration of the overlying skin[7] The tumor is non-tender and usually asymptomatic. It is rubbery to firm, to palpation Recommended treatment is surgical excision The most common preoperative diagnosis is a sebaceous cyst[4]

Grossly, the tumor usually measures between 1 0 to 4 0 cm in greatest dimension, although some have been reported up to 7 cm[3] The surface is grey-white, smooth to finely lobulated, and has particles of adipose tissue adherent to its thin capsule of fibrous connective tissue At times, the capsule is not complete The firm tumor often cuts with some difficulty because of the bits of calcium which are almost always present within its stroma[2] The cut surface is light tan to yellow brown, and varies from smooth to granular to crumbly[3] Microscopically, there are two basic cell types the "basophilic cells" or basal cell type, and the "shadow cells" (mummified epithelial cells) or squamous cell type[1 3]

The varying sized irregularly shaped groups of mummified or shadow cells are examples of coagulative necrosis, for although the cell borders are distinct, the nuclei and cytoplasm have undergone necrosis and do not stain In occasional foci the squamous type epithelial cells may show cornification, while in other areas this epithelial component may show dyskeratosis In other portions the necrosis may have progressed so that only amorphous hyalin debris remains

The basophilic cells, or basal-cell-like epithelial component are also found in varying sized groups There is no pallisading about the periphery of these groups, thereby differentiating them from basal cell tumors These cells have rounded to oblong prominent deep blue vesicular nuclei with one to two nucleoli The cytoplasm is scant and light blue with ill-term "calcifying epithelioma" in describing the lesion, for it neither metastasizes nor locally invades In 1933, Chin Kuang-Yu[2] reviewed the world medical literature on the subject, he postulated that perhaps these tumors arose from embryonic rest cells King,[3] in 1947, introduced the name of "Mummified Epidermal Cyst," for he believed, as do the authors, that the tumor is related to epidermal cysts of the skin In cases where there is a history of previous trauma to the skin overlying the tumor, there is little doubt as to the relationship of the tumor to an epithelial cyst or epithelial implant[3]

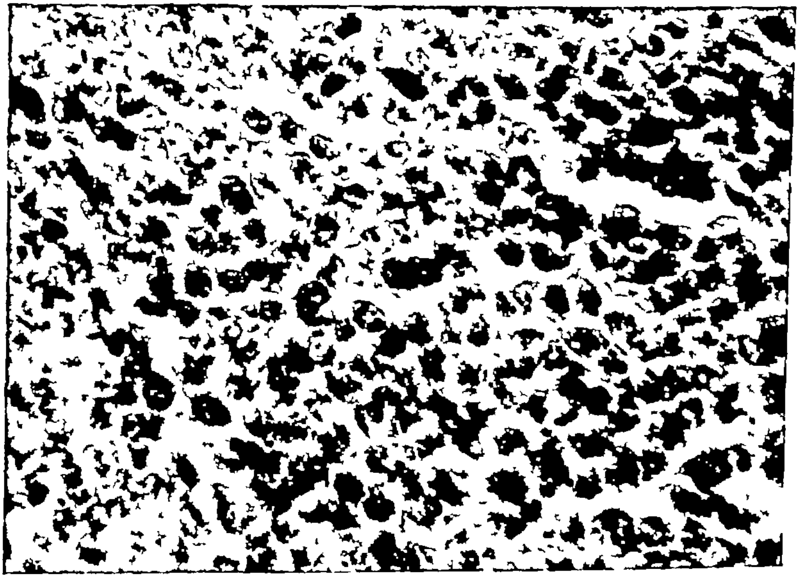

Fig 7 Photomicrograph showing the basal cell like epithelial component of the tumor Seven mitoses are seen in this field—600×

Various reports list different incidences for this tumor In the earlier report the incidence was sometimes one in ten thousand surgical specimens,[2] and in the later reports the incidence has been sometimes one in two thousand surgical specimens[3] There is apparently no difference in the incidence of the tumor according to sexes The tumor may appear any time between the ages of two years to 80 years,

defined cell borders Mitoses are not unusual In areas, one may see the transformation of the basophilic cells into the shadow cells [1]

Within the stroma there are varying scattered flecks of calcium, which stain blue-black with hemotoxylin and eosin There are also foci of foreign body giant cells about the keratinous debri The bulk of the stroma is composed of collagen and fibrous connective tissue

Although the microscopic picture of this tumor is easily recognized, a calcified epidermal cyst should be considered in the differential diagnosis Lever [1] states that a calcifying epithelioma of Malherbe differs from a calcified epidermal cyst, in that the latter does not contain the basophilic cells *or basal cell type This distinction, however,* is not universally recognized [3]

SUMMARY

1 Mummified epithelial cysts (calcified epitheliomas *of Malherbe) are relatively common tumors* of the head and neck

2 This tumor may occur in *any age* group, but it is most common in children

3 The lesion is slow growing, firm, sub-cutaneous, and freely moveable

4 The lesion has two basic cells types, the basophilic or basal cell type, and the shadow or mummified squamous cell type

5 The tumor does not *metastasize and does not* locally invade

6 The treatment *of choice is surgical* excision

Meeting Palmer House, Chicago, Ill

AMERICAN BOARD OF OTOLARYNGOLOGY

Meeting Palmer House, Chicago Ill

AMERICAN BRONCHO-ESOPHAGOLOGICAL ASSOCIATION

President Dr Francis W Davison Geisinger Memorial Hospital, Danville, Pa
Vice-President Dr George S McReynolds, 615 N Boulevard, Galveston Tex.
Secretary Dr F Johnson Putney, 1712 Locust St Philadelphia 3 Pa
Treasurer Dr Verling K Hart, 106 W 7th St, Charlotte, N C
Meeting The Homestead, Hot Springs Va, March 10 11, 1959

AMERICAN LARYNGOLOGICAL ASSOCIATION

President Dr Fred W Dixon, Cleveland Ohio
Secretary Dr James H Maxwell, Ann Arbor, Mich
Treasurer Dr Francis E LeJeune, New Orleans, La
Editor, Historian, and Librarian Dr Edwin N Broyles, Baltimore, Md
Meeting The Homestead, Hot Springs Va, March 8 9 1959

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, INC

President Dr Gordon Hoople, 1100 E Genesee St, Syracuse 10, N Y
President-Elect Dr Theo E Walsh, 640 So Kingshighway, St. Louis 10, Mo
Secretary Dr C Stewart Nash, 700 Medical Arts Bldg, Rochester 7, N Y
Place The Homstead, Hot Springs, Va, March, 1959

AMERICAN MEDICAL ASSOCIATION, SECTION ON LARYNGOLOGY, OTOLOGY AND RHINOLOGY

Chairman Dr Victor R Alfaro Washington D C
Vice-Chairman Dr Harold F Schuknecht Detroit, Mich
Secretary Dr Walter E Heck San Francisco, Calif
Representative to Scientific Exhibit Dr Walter H Maloney, Cleveland, Ohio
Section Delegate Dr Gordon F Harkness Davenport, Ia
Alternate Delegate Dr Dean M Lierle, Iowa City, Ia
Meeting Atlantic City, June 8 12, 1959

AMERICAN OTOLOGICAL SOCIETY, INC

President Dr Moses Lurie, Boston, Mass
President-Elect Dr R. C Martin
Secretary Dr Lawrence R Boies University Hospitals, Minneapolis 14, Minn
Place The Homestead Hot Springs, Va., 1959

AMERICAN OTORHINOLOGIC SOCIETY FOR THE ADVANCEMENT OF PLASTIC AND RECONSTRUCTIVE SURGERY

President Dr Joseph Gilbert 111 E 61st St, New York, N Y
Vice-President Dr Kenneth Hinderer, 402 Medical Arts Bldg Pittsburgh, Pa
Secretary Dr Louis Joel Feit, 66 Park Ave, New York 16 N Y
Treasurer Dr Arnold L Caron, 36 Pleasant St. Worchester Mass

AMERICAN RHINOLOGIC SOCIETY

President Dr Russell I. Williams, 408 Hynds Bldg, Cheyenne, Wyo
Secretary Dr Robert M Hansen, 1735 No Wheeler Ave, Portland Ore
Annual Clinical Session Illinois Masonic Hospital, Chicago, Ill, October, 1958
Annual Meeting October, 1958, Chicago, Ill (Definite time and place to be announced later)

AMERICAN SOCIETY OF FACIAL PLASTIC SURGERY

President Dr Trent W Smith, 327 East State St. Columbus 15, Ohio
Vice-President Dr Oscar J Becker Chicago Ill
Secretary Dr Samuel M Bloom 123 East 83 St. New York 28 N Y
Meeting November 12 1958 in conjunction with the Section on Laryngology Rhinology and Otology of the Medical Society of the County of Kings and Academy of Medicine of Brooklyn 1313 Bedford Ave Brooklyn N Y

AMERICAN SOCIETY OF OPHTHALMOLOGIC AND OTOLARYNGOLOGIC ALLERGY

President Dr Joseph W Hampsey, Grant Bldg Pittsburgh 19 Pa
Secretary Treasurer Dr Daniel S DeStio 121 S Highland Ave Pittsburgh 6, Pa.
Annual Meeting Palmer House, Chicago, Ill October 16 17 1958

ASSOCIACAO MEDICA DO INSTITUTO PENIDO BURNIER—CAMPINAS

President Dr Antonio Augusto de Almeida
First Secretary Dr Alberto Galo
Second Secretary Dr Alfredo Porto
Librarian Treasurer Dr L de Souza Queiroz
Editors for the Archives of the Society Dr J Penido Burnier Dr Guedes de Melo Filho and Dr Roberto Franco do Amaral
Meetings Twice every month first and third Thursday, 8 30 P M

ASOCIACION DE OTORRINOLARINGOLOGIA Y BRONCOESOFAGOLOGIA DE GUATEMALA

Presidente Dr Julio Quevedo 15 Calle Oriente No 5
First Vice-Presidente Dr Héctor Cruz 3a Avenida Sur No 72
Second Vice-Presidente Dr José Luis Escamilla, 5a Calle Poniente No 48
Secretario-Tesorero Dr Horace Polanco 13 Calle Poniente No 9 D

ASOCIACION DE OTO-RINO LARINGOLOGIA DE BARCELONA, SPAIN

Presidente Dr J Abello
Vice-Presidente Dr Luis Suñe Medan
Secretario Dr Jorge Perellò, 319 Provenza, Barcelona.
Vice-Secretario Dr A Pinart.
Vocal Dr J M Ferrando

BALTIMORE NOSE AND THROAT SOCIETY

Chairman Dr Walter E Loch, 1039 No Calvert St., Baltimore, Maryland
Secretary Treasurer Dr Theodore A. Schwartz

BUENOS AIRES CLUB OTOLARINGOLOGICO

Presidente Dr K Segre
Vice-Presidente Dr A P Belou
Secretario Dr S A. Aranz
Pro Secretario Dr J M Tato
Tesorero Dr F Games
Pro Tesorero Dr J A Bello

CANADIAN OTOLARYNGOLOGICAL SOCIETY
SOCIETE CANADIENNE D'OTOLARYNGOLOGIE

President Dr Robert T Hayes, 42 Cobourg St, St. John, N B
Secretary Dr Donald M McRae, 324 Spring Garden Rd, Halifax, N S

CENTRAL ILLINOIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr G C Otrich, Belleville, Ill
President Elect Dr Phil R McGrath Peoria, Ill
Secretary Treasurer Dr Alfred G Schultz, Jacksonville, Ill

CHICAGO LARYNGOLOGICAL AND OTOLOGICAL SOCIETY

President Dr Stanton A Friedberg, 122 So Michigan Ave, Chicago 3, Ill
Vice-President Dr Maurice Snitman, 408 So 5th Ave, Maywood, Ill.
Secretary Treasurer Dr Fletcher Austin, 700 No Michigan Ave, Chicago 11, Ill
Meeting First Monday of each Month, October through May

CHILEAN SOCIETY OF OTOLARYNGOLOGY

President Dr Enrique Grünwald S
Vice-President Dr Agustin Estartus
Secretary Dr Marcos Chaimovich S
Treasurer Dr Benjamin Kapkan K
Director Dr Alberto Basterrica A.

DALLAS ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Ludwig A Michael, 3707 Gaston Ave, Dallas, Tex.
Vice-President Dr Hal W Maxwell
Secretary-Treasurer Dr Edward A Newell, 1511 No Beckley, Dallas 8 Tex.

FEDERACION ARGENTINA, DE SOCIEDADES DE OTORRINOLARINGOLOGIA

Secretary of the Interior Prof Dr Atilio Viale del Carril
Secretary of Exterior Dr Aldo G Remorino
Secretary Treasury Prof. Dr Antonio Carrascosa
Pro-Secretary of the Interior Prof Dr Carlos P Mercandino
Pro-Secretary of the Exterior Prof Dr Jaime A. del Sel
Pro Secretary of the Treasury Dr Jorge Zubizarreta

FIRST CENTRAL AMERICAN CONGRESS OF OTORHINOLARYNGOLOGY

President Dr Victor M Noubleau San Salavador
Secretary-Treasurer Dr Hector R. Silva Calle Arce No 84 San Salvador, El Salvador, Central America

FLORIDA SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Chas C Grace 145 King St. St. Augustine Fla
President Elect Dr Jos W Taylor 706 Franklin St. Tampa Fla
Secretary Treasurer Dr Carl S McLemore 1217 Kuhl Ave Orlando Fla.

FOURTH LATIN AMERICAN CONGRESS OF OTORINOLARINGOLOGIA

President Dr Dario
Secretary
Meeting

GREATER MIAMI EYE, EAR, NOSE AND THROAT SOCIETY

President Dr William B Steinman
President Elect Dr James H Mendel Jr
Secretary Treasurer Dr H Carlton Howard
Meeting quarterly (March May October and December) on the second Thursday of the month 6 30 P M at Urmey Hotel Miami

INTERNATIONAL BRONCHOESOPHAGOLOGICAL SOCIETY

President Dr Jo Ono, Tokyo, Japan
Secretary Dr Chevalier L Jackson, 3401 N Broad St Philadephia 40 Pa U S A.
Meeting Seventh International Congress of Bronchoesophagology Kyoto Japan September 1958

KANSAS CITY SOCIETY OF OTOLARYNGOLOGY AND OPHTHALMOLOGY

President Dr Clarence H. Steele
President Elect Dr Dick H. Underwood
Secretary Dr James T Robison 4620 J C Nichols Parkway Kansas City, Mo
Meeting Third Thursday of November January February and April

LOS ANGELES SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Max E Pohlman
Secretary-Treasurer Dr Wendell C Irvine
Chairman of Ophthalmology Section Dr Carroll A McCoy
Secretary of Ophthalmology Section Dr Philip D Shanedling
Chairman of Otolaryngology Section Dr Robert W Godwin
Secretary of Otolaryngology Section Dr Francis O'N Morris
Place Los Angeles County Medical Association Bldg, 1925 Wilshire Blvd, Los Angeles, Calif
Time 6 30 P M last Monday of each month from September to June, inclusive—Otolaryngology Section 6 30, first Thursday of each month from September to June, inclusive—Ophthalmology Section

LOUISIANA MISSISSIPPI OPHTHALMOLOGICAL AND OTOLARYNGOLOGICAL SOCIETY

President Dr Fred D Hollowell, Lamar Life Bldg, Jackson, Miss
Secretary Dr Edley H Jones, 1301 Washington St, Vicksburg, Miss
Meeting Edgewater Gulf Hotel, Edgewater Park, Miss, May 15 16, 1959

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

Chairman Members serve as chairmen in alphabetical order monthly
Secretary Treasurer Dr Roland H Myers, 1720 Exchange Bldg, Memphis, Tenn
Assistant Secretary-Treasurer Dr William F Murrah, Jr, Exchange Bldg, Memphis, Tenn
Meeting Second Tuesday in each month at 8 00 p m at Memphis Eye, Nose and Throat Hospital

MEXICAN ASSOCIATION OF PLASTIC SURGEONS

President Dr Cesar LaBoide, Mexico, D F
Vice-President Dr M Gonzales Ulloa, Mexico, D F
Secretary Dr Juan De Dios Peza, Mexico D F

MISSISSIPPI VALLEY MEDICAL SOCIETY

President Dr Arthur S Bristow, Princeton, Mo
Secretary Treasurer Dr Harold Swanberg Quincy, Ill
Assistant Secretary Treasurer Dr Jacob E Reisch, Springfield Ill

NETHERLANDS SOCIETY OF OTO RHINO LARYNGOLOGY

(Nederlandsche Keel Neus-Oorheelkundige Vereeniging)

President Dr H Navis Sonsbeekweg 6, Arnhem
Secretary Dr W H Struben J J Viottastraat 1 Amsterdam
Treasurer Mrs F Velleman Pinto, Jac Obrechtstr 66, Amsterdam

NORTH CAROLINA EYE, EAR, NOSE AND THROAT SOCIETY

President Dr J C Peele, Kinston Clinic Kinston N C
Vice-President Dr George E Bradord Winston Salem, N C
Secretary Treasurer Dr J D Stratton, 1012 Kings Drive, Charlotte 7, N C
Meeting

NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY

President Mr G L Thompson 16 Ramshill Road, Scarborough Yorkshire
Vice-President Mr J H. Otty, Frizley Old Hall, Frizinghall Road Bradford, Yorkshire
Secretary and Treasurer Mr R Thomas 27 High Petergate York, Yorkshire

OREGON ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr David D DeWeese 1216 S W Yamhill St., Portland 5, Ore
Secretary Treasurer Dr Paul B Myers 223 Medical Dental Bldg Portland 5 Ore
Meeting Fourth Tuesday of each month from September through May Henry Thiele Restaurant 23rd and W Burnside Portland Ore

OTOSCLEROSIS STUDY GROUP

President Dr L R. Boies, University Hospital Minneapolis Minn
Secretary-Treasurer Dr Arthur L. Juers 611 Brown Bldg Louisville Ky
Meeting Palmer House, Chicago Ill

PACIFIC COAST OTO OPHTHALMOLOGICAL SOCIETY

President H. Leroy Goss M.D 620 Cobb Bldg Seattle 1, Washington
Secretary Treasurer Homer E Smith M.D 508 East South Temple Salt Lake City, Utah.
Meeting

PAN AMERICAN ASSOCIATION OF OTO RHINO LARYNGOLOGY AND BRONCHO ESOPHAGOLOGY

President Dr Jose Gros, Havana Cuba
Executive Secretary Dr Chevalier L Jackson 3401 N Broad St. Philadelphia 40 Pa. U S A.
Meeting Sixth Pan American Congress of Oto-Rhino-Laryngology and Broncho-Esophagology
Time and Place Brazil, 1958

PHILADELPHIA LARYNGOLOGICAL SOCIETY

President Dr Chevalier L. Jackson.
Vice-President Dr John J O'Keefe
Treasurer Dr Joseph P Atkins
Secretary Dr Louis E Silcox.
Historian Dr Herman B Cohen
Executive Committee Dr Harry P Schenck, Dr , Benjamin H Shuster Dr William A. Lell, Dr , William J Hitschler

PITTSBURGH OTOLOGICAL SOCIETY

President Dr Bernard L. Silverblatt 3500 Fifth Avenue Pittsburgh Pa
Vice-President Dr Emory A. Rittenhouse, 203 Masonic Bldg McKeesport, Pa.
Secretary Treasurer Dr John T Dickinson Mercy Hospital, Pittsburgh 19 Pa.

PORTUGUESE OTORHINOLARYNGOLICAL SOCIETY

President Dr Albert Luis de Mendonca.
Secretary Dr Antonio da Costa Quinta, Avenida, de Liberdale 65 1° Lisbon

LOS ANGELES SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY.

President Dr Max E Pohlman
Secretary Treasurer Dr Wendell C Irvine
Chairman of Ophthalmology Section Dr Carroll A McCoy
Secretary of Ophthalmology Section Dr Philip D Shanedling
Chairman of Otolaryngology Section Dr Robert W Godwin
Secretary of Otolaryngology Section Dr Francis O'N Morris
Place Los Angeles County Medical Association Bldg, 1925 Wilshire Blvd, Los Angeles, Calif
Time 6 30 P M last Monday of each month from September to June, inclusive—Otolaryngology Section 6 30, first Thursday of each month from September to June, inclusive—Ophthalmology Section

LOUISIANA MISSISSIPPI OPHTHALMOLOGICAL AND OTOLARYNGOLOGICAL SOCIETY

NEW CONCEPTS IN CORRELATION OF SURGICAL ANATOMY AND EMBRYOLOGY IN LATERAL CERVICAL VESTIGEAL STRUCTURES *†

M R HIMALSTEIN, M D ,

Bay Pines, Fla

The embryology of the cervical region is fascinating and complicated We may recall from our student embryology the phrase, ontogeny recapitulates phylogeny, or the embryological history of the individual organism recapitulates the history of the race The branchial arch structures represent that phase in the evolution of man wherein his forbears existed in an aquatic environment The word branchial is defined as pertaining to or resembling the gills of a fish Frazer[1] has several objections to the term branchial in describing this phase of development in man, especially since at no time are definitive branchial or gill structures formed in the recapitulation process The entire arch phase exists as a visible external structure for only three weeks Congdon[2] stated that the arches do not in any complete sense recapitulate their phylogenetic history, and that the process is much foreshortened and distorted

Most authors presenting a case of lateral cervical fistula stress the importance of embryology in understanding its surgical anatomy In attempting a correlation there are several points which tend to confuse The author was con-

the post-branchial phase, the head is curled directly over the pericardium Frazer[4] ascribes this to the fact that the dorsal structures of the head at first grow more rapidly than the ventral structures As the neck develops, the ventral area grows more rapidly, and the head is lifted from the pericardium The arch field lies initially from before backwards with each arch disposed in a superior-inferior direction As the neck develops a ventral arc is described due to the rapid ventral expansion, and the structures derived from the arches as the mandible and subjacent transverse flexure line of the neck are disposed in an anterior-posterior direction For this reason the terms dorsal and ventral as opposed to superior fronted with a case of complete lateral cervical fistula which opened internally into the tonsil fossa, then passed beneath the posterior belly of the digastric muscle, coursed anterior to the region of the carotids, and opened externally near the sternocleidomastoid attachment to the clavicle According to older writings this would appear to be a fistula of the second pharyngeal pouch breaking through the closing membrane into the second branchial groove and emerging externally through the duct of the precervical sinus Wenglowski,[1] however, maintained that the hyoid bone marked the inferior level of the branchial arch region on the postembryonic neck and, because complete fistulae often open much lower, he presented his thymic duct theory in 1913, and a wide measure of acceptance was recorded The thymic duct itself, however, is a third pharyngeal pouch derivative, and according to embryologists the internal opening should be in the pyriform fossa and it should not pass between the internal and external carotids as the majority of complete fistulae do To add to the confusion, second pouch fistulae should course between the internal and external carotids and not anterior to both, as in the author's and other reported cases

A historical summary by custom should be inserted here, but it will be entered later so that it may be better appreciated By organizing the literature, correlating the anomaly with this literature, and with some arm-chair hypothesizing a tenable concept can be evolved in explanation of the mechanism of development of lateral cervical vestigeal structures which does not violate accepted embryological concepts While this theory is not intended to represent the complete answer, it *is at least a reasonable correlation of surgical anatomy* and embryology, the pieces of the puzzle fit together to make a whole picture, but whether it is "the" whole picture remains to be seen

THE BRANCHIAL ARCHES

Before proceeding it would be well to orient ourselves topographically with regard to the arch area on the side of the head As can be seen in Fig 1, before the neck develops in

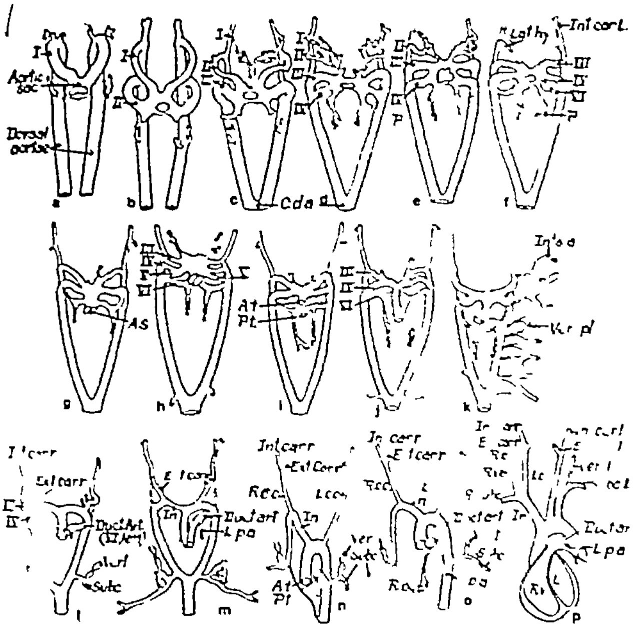

Fig 2 Ventral views of aortic arch system in a series of human embryos in the earliest stage only the first two arches are present The lengths of the respective embryos from which these diagrams were made are as follows a b 3 mm c d 4 mm e 5 mm f 6 mm g mm h 7 mm i 8 mm j k 11 mm l 13 mm m 14 mm n 16 mm o 18 mm p full term fetus

entodermal evagination corresponding to each ectodermal groove is termed a pharyngeal pouch These areas of contact or near contact are termed closing membranes and correspond to the gill membranes of aquatic animals

Some arch structures are evident before the arches are externally evident, e g Congdon reports the aorta of the first arch is present in a 1 3 mm , or 19-day-old embryo Similarly Frazer[4] reports that at the time the visible manifestation of

and inferior, and cephalad and caudal rather than anterior and posterior will be used

The arches appear externally from the fourth through the sixth weeks (embryo lengths 4 mm to 13 mm) Only four arches appear externally in man, the fifth and sixth arches not being represented on the surface The arches consist of mesodermal bars covered by ectoderm externally and entoderm internally Caudal to each bar, and numbered according to this bar, are the branchial grooves (clefts or furrows), here the ectoderm and entoderm approach each other, with the mesoderm in a relatively thin layer between them The

arch structures including the stylopharyngeus, the fistula may, and has, passed beneath, over or even through the muscle Much heated debate has ensued, the basis of argument revolving around the concept that if the anomalous fistula passed caudal to the third arch structure, the stylopharyngeus, the fistula should be of third arch origin As

the third arch externally is fading, the deeper structures associated with the arch have either disappeared or migrated

This process of appearance and disappearance, migration or non-migration, results in many controversies in regard to anomalies and their variation from case to case Several instances of this, in which earlier formed structures migrate or disappear before certain later structures appear, will be touched on in this paper For example, the stylopharyngeus muscle, a third arch derivative, migrates cephalad into the domain of the second pouch, and if an anomalous fistula develops from the second pouch, depending on the exact time of its development in relation to the migration of the third

coupled with the appearance and disappearance of major vascular structures in the branchial arch area

Each arch develops an aorta, a cartilage and muscle tissue and associated with each, but not developed initially within it, is a cranial nerve The Vth, VIIth, IXth and Xth nerves are associated respectively with the first, second, third, and fourth and fifth arches, the superior laryngeal division of the Xth nerve, with the fourth arch, and the inferior laryn-

will be brought out in this paper, the more pertinent criteria are the relation to vessels and nerves, and the site of internal opening for a fistula, relations to muscles, as with the stylo-pharyngeus, is not as decisive In the same manner it will be explained in more detail that whether a second pouch fistula passes between the carotid arteries or anterior or ventral to both, is a result of the developmental time lag, will of necessity pass caudal, or beneath the body of the hyoid, or through the thyro-hyoid membrane (see Fig 9) The muscles developed in the arches in some instances migrate a considerable distance, and their origin is identified by their innervation, *e g* , the occipito-frontalis is considered a second arch derivative, as it is innervated by the nerve associated with the second or hyoid arch, the facial or VIIth nerve The sternocleido-mastoid, tongue and infrahyoid muscles are thought to migrate from the occipital and upper cervical myotomes, as nerves from these regions innervate them The tonsil fossa is bounded by the palatoglossus and palatopharyngeus muscles, which are variously identified with the Xth and XIth nerves (via the pharyngeal plexus) and so cannot be definitely categorized as to arch of origin, if of arch origin In general, it can be stated that muscles are not always completely reliable guides in the study of branchial anomalies As Frazer points out, the most reliable relationship is to vessels and nerves, providing the vessels themselves are developed normally Wenglowski,[illegible] in his attempt to prove complete lateral fistulae were of thymic duct origin, claimed that fistulae opening in the region of the tonsil fossa, did not open into the fossa proper but were in relation to the palatoglossus, which he stated was innervated by the IXth nerve and so claimed this relationship indicated third pouch origin,

as are the stapes, styloid process and stylohyoid ligament An elongated styloid process may actually join with the lesser cornu of the hyoid The body of the hyoid is derived from the third arch, therefore, congenital fistulae or other anomalous branchial vestiges of second pouch and groove derivation will of necessity course above the body of the hyoid and dorsal to the lesser cornu (see Fig 4), while third pouch derivatives in fact, as will be discussed more fully later, fistulae do open into the tonsil fossa proper, and also in relationship to the posterior pillar, and even to Rosenmuller's fossa

THE BRANCHIAL OR CLOSING MEMBRANES

In aquatic vertebrates the ectodermal and entodermal tissues of the grooves and pouches make direct contact to form the branchial or closing membranes, which break through normally to form the gill slits and subserve thus a respiratory function Only in the first groove and pouch in man is direct and measurable contact made which persists post-embryonally as the tympanic membrane Even here, in line with the distorted recapitulation mentioned in the introduction, Hammar (1902) and Wenglowski[5] report that in human embryos the first pouch and cleft cross each other in "X"-fashion so that while contact is constant it is limited in area to this point of crossing According to Wenglowski, even the mesodermal bar of the first arch is twisted so that the pharyngeal aspect of the arch lies crosswise to the outer aspect In the pouch and cleft relationships caudal to the first there is similar distortion the only consistency being that there is some area of contact between the second pouch and cleft to allow for closing membrane formation, though not always at the same level Hammar, quoted by Wenglowski, found in a 5 mm human embryo that the area of contact was with the ventral horn or extension of the second pouch, while Wenglowski, in a 6 5 mm embryo, found the area of contact with the dorsal extension For the third and fourth pouches and clefts the relations are more inconstant, with closing membrane formation sometimes occurring for the third, and even less likely for the fourth In Hammar's embryo the third and fourth pouches extended into the mesoderm unrelated to the grooves In a 6 5 mm embryo, Wenglowski found the greater part of a short third pouch taken up in forming a closing membrane In an 8 mm embryo, there was variation between the two sides on one side there was a small closing membrane, while on the other side there was a thick layer of mesoderm separating the pouch and cleft Piersol (1888) quoted by Hyndman and Light,[2] and Wenglowski concluded from a study of rabbit

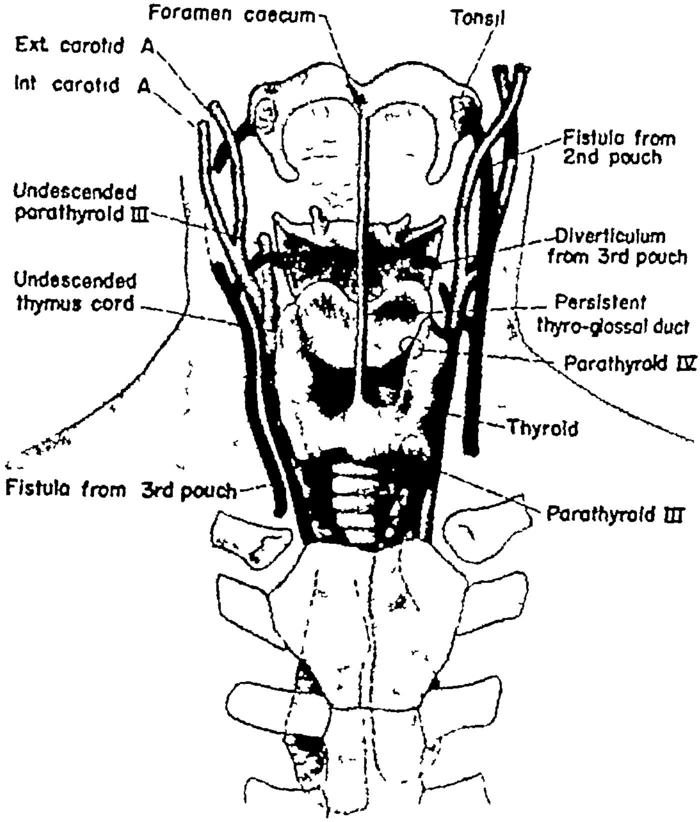

Fig 9 Schematic diagram from Braus Anatomie des Menschen Bd 2 as redrawn by Proctor[21] in which is collected a number of anomalous conditions On the subject s right note undescended parathyroid III residual thymus cord and a branchial fistula from pharyngeal pouch III A previous connection of the fistula with a diverticulum of the supratonsillar fossa is broken Center persistent thyroglossal duct. On the subject s left note a diverticulum of pouch III an incompletely descended thymus still attached to parathyroid III and a fistula of second pouch origin

Note The presentation on both sides of third pouch fistulae emanating from the thyro-hyoid membrane passing dorsal to the common carotid and then lateral to the great vessels however the presentation of the thymus cord passing medial and ventral to the carotid is not embryologically sound See Fig 3 and Frazer s Manual of Embryology[7] finitive form at the end of the arch phase from the mid-arch portion of the third arch aortae The dorsal aortae cephalad to the third arch continue as the internal carotids, and give rise to the ophthalmic and middle cerebral arteries Eventually the segments of dorsal aortae between the third and fourth arches disappear, to form the definitive internal carotids (see Fig 2, m) It must be assumed that a breakthrough from the second pouch to the second cleft, to form a congenital fistula, occurs in the arch phase, before the definitive external carotids are even formed In Fig 3 is Congdon's drawing of the lateral view of the aortic arches of the left side of an 11 mm human embryo, in the latter phase of the arch system, but before the definitive external carotids are formed I have taken the liberty of marking the approximate point of origin of the external carotid with "x" It is quite apparent that whether a fistula passes between the external and internal carotids, or ventral to both vessels, depends upon whether the external carotid links up with its cephalad course dorsal or ventral to the second pouch In several clinical descriptions the fistula courses between the carotids, and in the cases of Dowd,[15] Kleinert[16] and the author, the course is ventral to both The surgical significance lies in the fact that where the course is anterior or ventral to the carotids the surgery is rendered simple This relationship can be determined preoperatively by an X-ray study with the fistulous tract filled with a radio-opaque material It will be seen from the lateral X-ray (see Fig 4) that the tract crosses the hyoid almost at the lesser cornu, and lies far anterior to the usual course of the carotid sheath Where the tract crosses the hyoid more posteriorly, and is in topographical relation to the carotid sheath, it can be expected that the course will lie between the external and internal carotids, and the surgery rendered more difficult It also follows from Figs 3 and 6, that a third pouch derivative would have to course dorsal to the third arch vessels, the common, and, or internal carotids

Wenglowski admittedly could not follow the complex development of the arch vessels, and ignored these vessels in relation to the development of fistulae, he felt that muscle relations were more significant embryos that a breakthrough could occur only via the second closing membrane Carp and Stout[6] refer to Rabl's findings, that the second groove is deeper and persists longer, and so is the logical point at which a fistula could enter the pharynx They refer also to the progressively thicker layer of mesoderm between the grooves and pouches in the more caudal structures The third and fourth pouches are primarily concerned with the development of *the thyroid, parathyroid and thymus*

THE AORTIC ARCHES—ORIGIN OF THE EXTERNAL CAROTID ARTERY

The most recent and comprehensive study of the development and modification of the aortic arches of the human embryo is that of Congdon[2] (1922) The aortic sac or bulbus arteriosus, the heart primordium, communicates via the vessels of the branchial arches, termed the arch aortae, with the paired dorsal aortae (see Fig 2) Development of the arch vessels is accomplished by the fusion of dorsally growing sprouts from the aortic sac, with those growing ventrically from the dorsal aortae The first and second aortic arches disappear during the time the third pair of arches is forming (see Fig 2, a-f) A mandibular artery grows into the region *formerly occupied by the first aortic arch*, and a stapedial artery replaces the second aortic arch in the second or hyoid branchial arch These secondarily formed arteries are branches of the dorsal aorta, and have no continuity with the aortic sac It has apparently been assumed that the arch aortae of the second arch develop into the external carotids Obviously this is not so The arch aorta of the third arch is the most cephalad one, which persists as the primordium of an adult vessel The third aortic arches persist as the roots of the internal carotid arteries and from their anterior surfaces, just about the end of the branchial arch phase in point of time, there arise the external carotid arteries (see Fig 2, l) , hence, the base of each third arch between the external carotid and the aortic sac becomes the common carotid artery (see Fig 2, n)

To repeat for emphasis, the aortic arches of the second branchial arches disappear and take no part in the formation of the external carotid arteries which first appear in de-takes place, however, long after the arch phase has passed, that is, in the fourth month The crypts form in the lower portion of the angle The upper part hangs over this ingrowth as the supratonsillar fossa Lymphoid tissue infiltration takes place even later

In Wenglowski's time there was considerable controversy over the relation of fistulous openings to the stylopharyngeus muscle, which is innervated by the IXth nerve which courses just deep to it Being innervated by the IXth nerve, it is a third arch derivative As described above, however, the third arch mesoderm secondarily migrates into this area during the arch phase of development It would seem, therefore, that a fistula opening into the pharynx in this region emanates from second pouch area, and its relation to the stylopharyngeus muscle is accidental and of secondary importance in determining the origin of the fistula (see p 4 section on Arches) It would appear that a fistula opening anywhere from and including the tonsil fossa to the region of the Eustachian orifice is consistent with second pouch origin providing, of course, vascular and nerve relations are consistent with this Various sites of fistula opening mentioned in the literature are the supratonsillar fossa, Rosenmuller's fossa, posterior pillar, tonsil fossa proper and even just below the tonsil fossa In the author's case, dye injected into the tract preoperatively appeared in a large upper pole crypt Taylor and Burwell (1954) reported several cysts as residuals of the second pouch, which extended from the tonsil fossa to the region of the Eustachian orifice In two of these cases the cysts were bilateral, minimizing any contention that these might be ordinary retention cysts

The third pouch, like the second, develops dorsal and ventral angles The internal opening of a vestige of the third pouch would have to be related to the pyriform fossa, according to embryologists Its relationship to the carotid axis should be caudal If there were a closing membrane breakthrough with a complete fistula, it should open externally similar to a second membrane fistula The only difference from a second pouch complete fistula then would be in the level of the internal opening and the carotid axis relationship There is no case on

FATE OF THE PHARYNGEAL POUCHES—THE THYMUS

The foregut is a prolongation of the primitive intestinal canal There is no coelomic channel on either side of the gut at this level, the entoderm being separated from the ectoderm by solid mesoderm, thus, with general growth of the region the primitive pharynx increases in breadth Condensations in the lateral mesoderm cause thickenings to form the arches The lateral portions of the widened pharynx expand in a dorso-ventral plane to form the lateral pharyngeal pouches between the indentations caused by the arches The lateral pouches develop dorsal and ventral portions or angles The ventral angle of the first pouch is obliterated The dorsal angle, in conjunction with the dorsal angle of the second pouch, forms the tubo-tympanic recess (see Figs 6, 7)

In the case of the second lateral pouch the distance between the angles increases rapidly The dorsal angle is incorporated into the tubo-tympanic recess from which are formed the Eustachian tube and middle ear space The ventral angle extends from the Eustachian orifice to and including the tonsil fossa region According to Frazer, the separation of the dorsal and ventral angles takes place in this manner as the *tubo-tympanic recess is formed, the second arch lies ventral to the recess, the first arch comes to form the sloping cephalad wall and the third arch the caudal wall* The second *arch growth is most effective externally*, and it is a prominent structure externally *with its groove forming the transverse flexure line of the post-embryonic neck* The third arch, on the other hand, has its most effective growth *internally* Its internal bulge first delineates the tubo-tympanic recess caudally By continued growth of the third arch it approaches the first arch cephalad, thus narrowing the tubo-tympanic recess medially to form the definitive Eustachian tube and separating the dorsal and ventral angles of the second lateral pouch (see Fig 8) The ventral angle of the second pouch can then be seen to occupy the area laterally from the Eustachian orifice to the base of the tongue External to this entodermal expansion of second pouch origin is the third arch mesoderm From this ventral angle, entodermal ingrowths into the mesoderm form the tonsil crypts This herents claiming for them entodermal origin[9] Muscle and glandular tissue are not a part of normal post-embryonic thymus tissue, though commonly found in lateral fistulae

The origin of Hassall's corpuscles, the distinctive constituent of thymic tissue, is most controversial Frazer points out that there develops in some lower mammals a "superficial thymus" in association with the ectoderm of the third cleft His, in 1881, thought the thymus developed from the floor of the cervical sinus in the region of the third cleft, but later changed his mind Wenglowski in 1913, in attempting to explain stratified squamous epithelium in complete lateral fistulae which he claimed were vestiges of the thymic duct, stated the thymic tract is in relation to the third cleft in the sinus and has been seen to join with this ectoderm, and mentions this ectoderm as a possible source of Hassall's corpuscles He stated, however, that this taking on of ectoderm from the cervical sinus occurs only in those cases of fistula in which ectodermal, as well as entodermal, epithelium lines the tract

Norris[10] in 1938 described what he terms the discovery of the origin of Hassall's corpuscles He states that the ventral horn, or angle of the third pouch, contacts the ectoderm of the third branchial cleft in the precervical sinus, and that a portion of this cleft buds and joins the thymic anlage as an onlay covering the entodermal thymus cord to form the cortex containing the Hassall's corpuscles Maximow and Bloom,[11] in their textbook of histology, state however, that Hassall's corpuscles are predominantly medullary Garrett[12] in 1948 was unable to corroborate Norris' claim of a contribution of sinus ectoderm to the thymus, in fact, Garrett found that the thymic anlage coursed near, but received no contribution from the placodal duct of the Xth nerve rather than the third cleft, and took exception to Norris' illustrations on this point It is evident that an ectodermal contribution to the thymus has not been unequivocally established

Aside from the rare possibility of a persistent thymic duct, it is not unusual for bits of thymic tissue to remain in the cervical region, posterior and lateral to the thyroid lobes, or associated with parathyroid III (Ungerson, 1906, Gerard, record having the relations outlined above for a complete third pouch fistula

From the dorsal angle of the third pouch develops that portion of the parathyroid gland not derived from the fourth pouch, or parathyroid III From the ventral portion develops the thymus in the fifth or sixth week There is little actual descent involved, as it lies almost at once in relation with the pericardium to the lateral side of the great vessels The distal end of the duct enlarges to form the definitive thymus, while as growth goes on the stalk, elongates and then loses its pharyngeal connection and its lumen is obliterated The duct, by necessity, if it is of third pouch origin, has to emerge caudal or dorsal to the common-internal carotid axis, the artery of the third arch (see Figs 3, 6) This is the same relationship which would have to occur for an anomalous branchiogenic structure as a fistula Frazer describes the course of the thymic duct as given above, emerging from the third pouch, coursing dorsal to the carotid axis and then extending lateral to these vessels to the pericardium In older diagrammatic representations (see Fig 9) a different course is shown for a third pouch branchiogenic fistula (which is shown taking the expected course) and the thymic duct The thymic duct is shown emerging from the thyrohyoid membrane, consistent with third pouch origin, but it then turns down medial to the carotid axis Wenglowski admittedly could not follow the complicated development of the carotid vessels and discounted them as guides as to origin of fistulae He described the thymic duct as coursing "contiguous" to the vascular sheath, but does not specify as to whether it is contiguous dorsally, medially, laterally or ventrally It seems logical and consistent, however, in the light of Congdon's (1922) description of the aortic arch system and Frazer's description of the course of the thymic duct, to hold to these criteria in interpreting the origin of fistulae

The thymus briefly consists of a cortex and medulla, not sharply differentiated, and contains lymphoid tissue, Hassall's corpuscles and a stroma The origin of these elements, entodermal or otherwise, is controversial Even the syncitial portion of the connective tissue and lymphoid cells have ad-fourth, until in this manner the second groove and the more caudal arches and grooves are covered in by the second arch Rabl, in 1886, claimed the third arch did not override the fourth Rabl, in 1907, described a fusion between the second arch and the thoracic wall precursor as the means by which the sinus is closed According to Frazer, Rabl worked with moles and not human embryos[4]

The following description of the closure of the precervical sinus, based on Rabl's work, has for a long time been accepted The sinus is at first widely open laterally As the second arch grows caudally the opening of the sinus is narrowed to a duct, the precervical duct After closure of the duct externally, a closed space is formed, enclosing the second, third and fourth grooves, and the third and fourth arches (see Figs 6, 10) If one of the closing membranes breaks through, a communication is established between the primitive pharynx and the sinus, and if the precervical duct remains patent, a complete fistula is established With further growth of the embryo, the grooves entering the sinus are elongated into ducts and the arrangement described is that of the third and fourth ducts joining to form the precervical duct with the second groove duct opening into the neck of this precervical duct (see Fig 6) Eventually the ducts and sinus are narrowed and obliterated The explanation of whether a complete fistula opens high or low in the neck, based on this concept, depends on the length of the precervical duct, however, Wenglowski, Frazer and Garrett maintain, as shown below, that the third arch is not obliterated in the precervical sinus, and so makes difficult an explanation of the external opening of lateral fistulae based on a breakthrough of the second closing membrane communicating externally via the duct of the precervical sinus Wenglowski and Frazer hold that while the second arch grows much larger than the third, the third is not telescoped by it, and it is the third arch which fuses with the thoracic wall Wenglowski's contribution was that he first noted that the third arch was not obliterated in the precervical sinus development He erred, however, in maintaining that the third arch could not be represented postembryonically below the level of the hyoid Actually, the hyoid

1928, Norris, 1937) Conversely, a case with parathyroid tissue within the thymus is on record (Churchill and Cope, 1934) *Failure of descent* or *a true cervical thymus*, on the other hand, is rare

In summary, what should distinguish a complete fistula of third pouch origin from a fistula of thymic duct origin? For both, they should open internally in the pyriform fossa, pierce the thyrohyoid membrane and course dorsal or caudal to the carotid axis Frazer traces the course of the thymic duct as lateral to the great vessels to the thorax, while Wenglowski traces the course as "contiguous" to the vascular sheath and then along the anterior border of the sternomastoid A third pouch fistula, or a second pouch fistula for that matter, has an external opening embryologically through the corresponding branchial groove A thymic duct normally has no external opening, and Wenglowski, as will be discussed under "The Refutation of the Thymic Duct Theory," explains this as due to secondary suppuration

The fourth pouch contributes parathyroid IV A vestige of fourth pouch origin, because of its relations to the aorta of the fourth branchial arch, would have to loop around the aorta on the left or the subclavian artery on the right, as these are fourth arch aortae derivatives (see Fig 6) No such relationship has ever been reported for a fistula, also, should such a fistula exist, it would course caudal to the superior laryngeal nerve, the nerve associated with the fourth arch

THE DISAPPEARANCE OF THE PRECERVICAL SINUS

Initially the four external arches are equally distinct on the ventral aspect of the head The first and second arches grow *more rapidly, and soon the precervical sinus* is a depression between the second arch cephalad and the caudal margin of the sinus field, the precursor of the posterior neck and chest wall (see Fig 1-A) In this depressed area are the third and fourth arches and the grooves of the second, third and fourth arches His, in 1881, described the formation of the precervical sinus as a telescoping process, cephalad to caudad, with the second arch *overriding* the third, and the third the

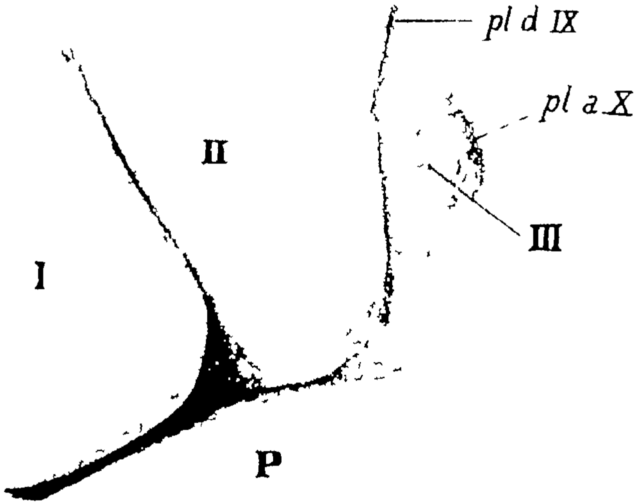

Fig 11 Region of the precervical sinus in a 10 mm embryo left side I II III branchial arches P pericardium pl d IX placodal duct of IXth nerve pl a. the hyoid, dorsal to the lesser cornu and beneath the posterior belly of the digastric, was ignored by Wenglowski in his claim that these were more properly of thymic duct (third pouch) origin

Frazer,[4] in 1926, working with human embryos, confirmed that the third arch is not obliterated in the precervical sinus, and in addition showed by logical inference that it is represented on the post-embryonal neck as the approximate region of the carotid triangles (see Fig 5) Dorsally the sinus area is bounded by the paraxial tissues delimiting the upper extremities of the third and fourth arches and their respective

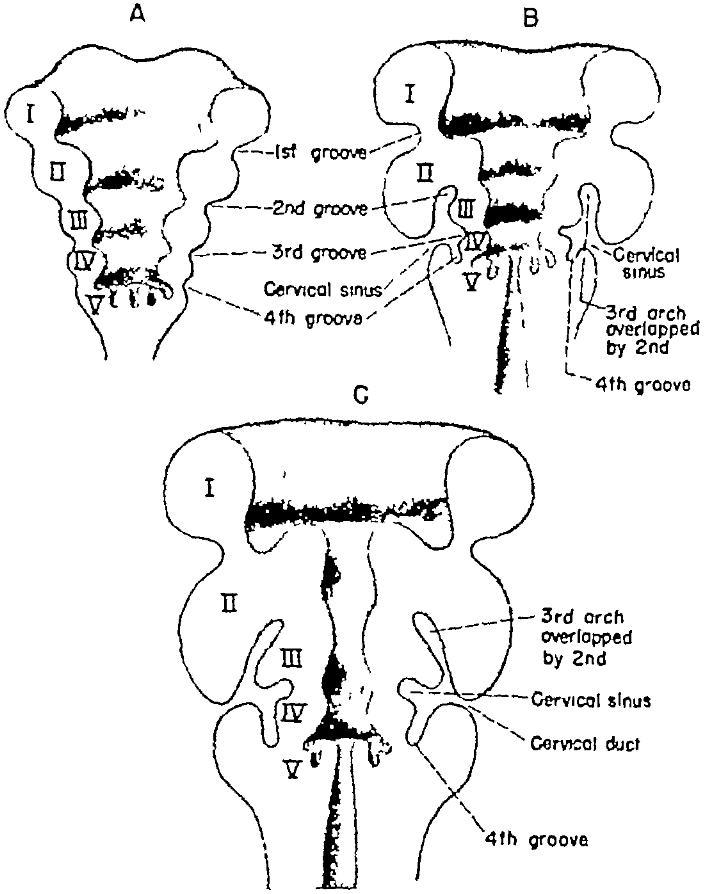

Fig 10 Showing early development of the pharyngeal wall A Showing proximity of ectodermal floor of branchial clefts to entodermal pharyngeal pouches B Rapid growth of the (hyoid) arch II overshadows postoral arches forming the cervical sinus C Occlusion of the cervical sinus

Note This is based on the old concept of Rabl Contrast with Figs 11 13 15 —(As redrawn by Proctor[21] from Ward and Hendricks[18])

is formed from both the second and third arch cartilages, with the second arch forming the lesser cornu and the third arch the greater cornu and body, thus a second pouch origin fistula passes above the hyoid but posterior to the lesser cornu The level of the second or hyoid arch is more accurately described as that of the posterior belly of the digastric and stylohyoid muscles, which are second arch derivatives, innervated by the VIIth nerve The course of lateral fistulae over veloped the clavicle, and ventrally its cell tracts contact the hyoid bone rudiment

Only the first or mandibular arches meet ventrally in the midline The ventral extremities of the more caudal arches are separated, with the gap progressively wider for the more caudal arches In apposition to this area of gapping is the pericardium (See Fig 12) The epipericardial ridge, as already described, turns medially beneath the ventral extremities of the third and second arches and then its cell tracts course between the pericardium ventrally and the pharynx dorsally to bury themselves in the mandibular arches In this interval between the arches ventrally are developed the tongue muscles and hyoid bone rudiment

At this early stage, Frazer calls attention to the presence of areas of thickened ectoderm, the placodal areas, in the paraxial boundary tissue dorsal and caudal to the sinus field This ectodermal thickening later becomes anatomically related to the nerve rudiments of the deeper lying ganglia of the IXth and Xth nerves Similar more cephalad thickenings are related to the Vth and VIIth nerve ganglia They appear to make no vital contributions to the nerves mentioned, and Frazer admits ignorance of their possible function Arey[15] states that epibranchial placodes originate at the dorsal ends of the branchial clefts, and in some lower vertebrates cellular proliferation from them clearly adds to the neighboring ganglia In higher animals and man, Arey states that the relations are less plain, and indications of contributions to the ganglia is in dispute Regardless, these ectodermal placodes overlay the upper part of the third arch and adjoining second cleft in relation to the deeper lying IXth nerve ganglion and encompasses also the greater part of the fourth arch and the caudal boundary of the field in relation to the Xth nerve ganglion By a process of thickening and infolding the placodes are first recessed and then form ducts leading to expanded vesicles in relation to the respective nerve ganglia Eventually the vesicles and ducts are obliterated In this process of thickening and infolding the structures of the cervical sinus are secondarily and passively affected The fourth arch is completely engulfed The duct of the IXth placode grooves, which make up the depressed area of the cervical sinus This paraxial tissue is continued caudally and ventrally The ventral continuation of this boundary tissue is known as the epipericardial ridge (see Fig 11) and is interposed between the ventral extremities of the second, third and fourth arches and the pericardium The ridge passes medially beneath the ventral extremity of the third arch, but the tract of cells forming the ridge continues forward to pass internally to the lower end of the second arch. The ridge thus connects the arches with the pericardium as far forward as the level of the second arch In the ridge are found structures vital to this discussion, namely the sternomastoid and infrahyoid muscles and the XIIth nerve Within its area is also de-

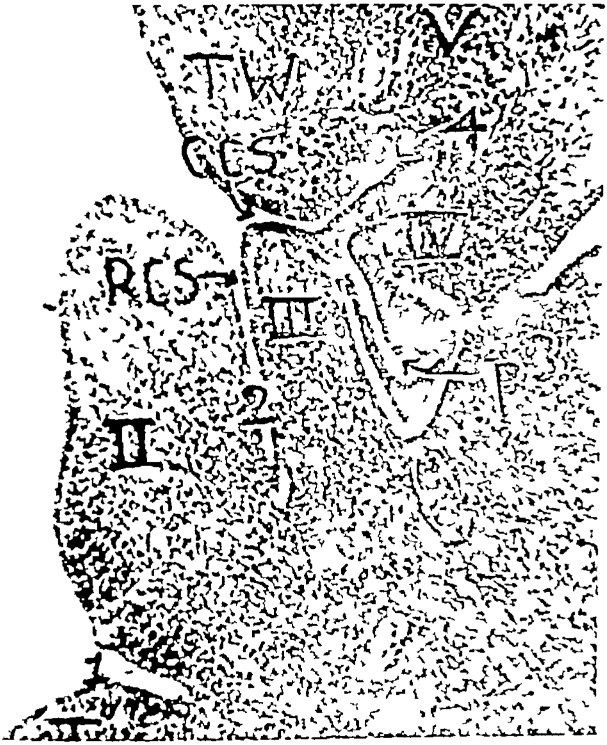

Fig 13 Human embryo 10 5 mm right side × 52 Third cleft obliterated I II III IV branchial arches 1 2 first and second branchial clefts 4 fourth branchial cleft engulfed by placodal duct of Xth nerve p-3 tip of third pharyngeal pouch RCS and CCS rostral and caudal parts of the cervical sinus TW thoracic body wall V vagus nerve In the preceding microphotograph in Garrett's paper that of an 8 mm embryo the placodal duct of the IXth nerve is shown as a dorso-caudal evagination from the second cleft into the tissue of the third arch to come into relation with the glossopharyngeal trunk The placodal vesicle of the Xth nerve reaches its greatest prominence later at about 12 mm when the last traces of its connection with the cervical sinus become obliterated —(From Garrett, F D Development of the Cervical Vesicles in Man[1] Fig 1 Plate I Anatomical Record 100 111)

and Xth nerves, or expressed simply, the cervical sinus obliterates by a fusion of its ectodermal lining from within toward the surface Second, he demonstrated that the third arch contributes to the formation of the ventral portion of the neck, namely, the area of the carotid triangles In effect, nevertheless, the third arch fuses with the precursor of the posterior neck and thoracic wall

At the time of the last flattening out of the third arch the can be seen (see Fig 11) to be located above the third arch in relation to the dorsal extent of the second groove According to Garrett, it forms an appendage to the second cleft Frazer states the thickening and infolding bulges above but does not cover or invade the third arch area Garrett,[12] in confirming and enlarging on Frazer's findings in 1948, states they have since been completely overlooked in the anatomical literature, and almost so in the clinical literature What older writers described as the precervical sinus disappearing through a fusion of the second arch with the thoracic wall, with the sinus reduced to an ectodermally lined cyst opening on the surface by a duct, has been disproven The precervical sinus itself is never closed off to form an ectodermal lined cyst, only the placodal ducts are involved One of Garrett's microphotographs in particular startlingly resembles the description of the precervical sinus duct arrangement of earlier writers, namely, that of the third and fourth clefts opening into the duct of the precervical sinus with the second cleft opening into this duct What appears to be the fourth cleft, however, is labeled the placodal duct of the Xth nerve with the third cleft obliterated, but with the third pouch appended to it but separated by a thin layer (see Fig 13)

The disappearance of the third arch as a projection on the surface is explained on the basis that the arch is concerned in the formation of many important structures in and about the pharynx, but not on the surface, and its appearance in the first place is only the result of its growth and condensation when the wall of the pharynx is relatively thin The second groove, on the other hand, outlines and maintains the prominence of the second arch because it becomes the transverse flexure line of the neck The second arch remains prominent posteriorly also, because from it and the adjoining first arch posteriorly are developed the pinna (see Fig 14)

To summarize Frazer's contributions here, he demonstrated, first that the cervical sinus was not obliterated by a fusion of the second arch with the thoracic wall precursor to enclose an ectodermal sac Rather, he showed that the branchial structures involved in the sinus are passively affected in the development and obliteration of the placodal ducts of the IXth

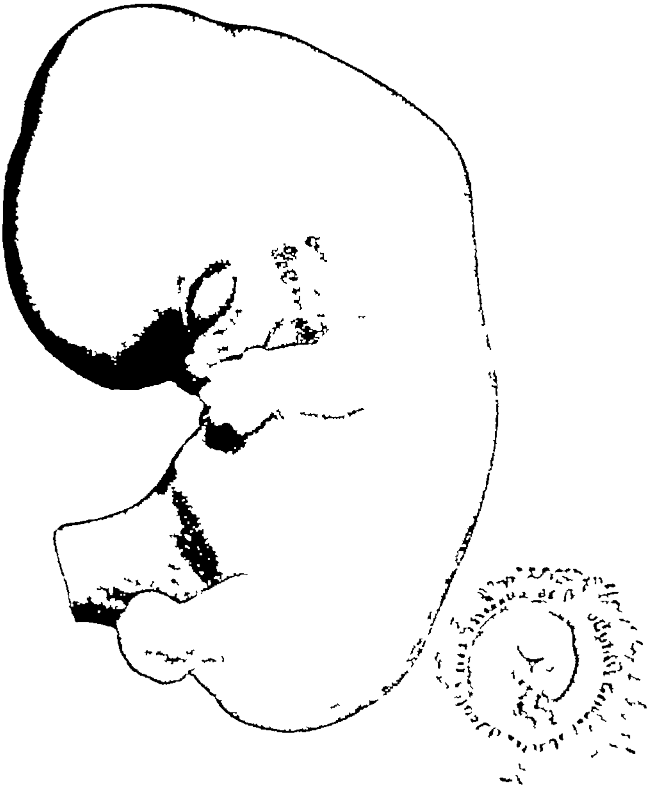

Fig 14 B Human embryo of about seven weeks (17 mm) The head is lifting from the pericardium as the neck is forming the mandible is evident, and the pinna is moving toward its final location (By courtesy of the Carnegie Institution of Washington)

occipital artery coursing laterally in the path of the XIIth nerve is engaged by it, and so the XIIth nerve comes to hook around this vessel in the neck (see Fig 5) Sometimes the parent vessel, the occipital artery, is hooked around It also stands to reason that a second pouch and cleft vestige would course ventral to the IXth and Xth nerves A third pouch vestige would emerge caudal to the IXth nerve and ventral to the Xth nerve

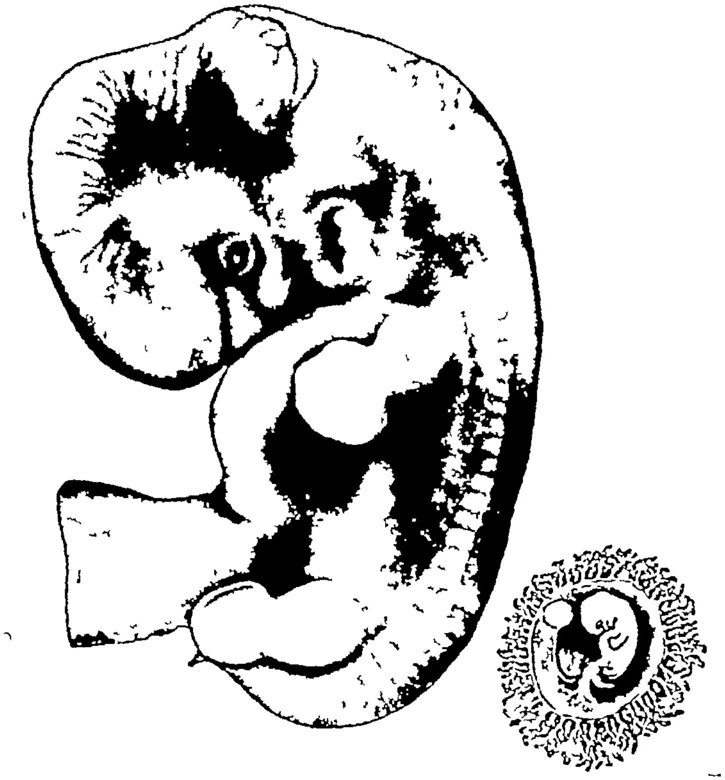

Fig 14 A. Human embryo a little over six weeks (14 mm) retouched photo The pinna is shown forming about the first groove posteriorly the head still remains curled over the pericardium the neck has not formed and the mandible has not grown sufficiently to force the pinna dorsally (From Patten[9] by courtesy of the Carnegie Institution of Washington)

sternomastoid is distinct in the caudal border of the sinus field (see Fig 15), also, coursing in this caudal boundary, but at a deeper level, and then turning to course ventrally to the sinus field in the epipericardial ridge, are the tongue muscles and the accompanying XIIth nerve It follows from this that any vestigial structure from the arch area must course ventral to the XIIth nerve, also, as the head grows away from the pericardium as the neck develops, and the XIIth nerve travels dorsally in the outer layer of the mesoderm of the body wall to its final position, it would engage any structures coursing laterally Frazer states that the sternomastoid branch of the ment condensation It is evident that the second groove at its ventral extremity is here in intimate relation with the clavicle and the infrahyoid and sternomastoid muscles The relationship is most pertinent (see Figs 15, 16) As ventral growth proceeds the infrahyoid muscles, fixed to the hyoid above and the clavicle below are drawn out on the ventral side The sternomastoid bounding the third arch caudally is a fixed structure behind The flexure line of the neck marks off the second and first arches cephalad, so that the third arch area by logical inference practically corresponds with the skin covering the carotid triangles Frazer does not contend that this correspondence to the carotid triangles is

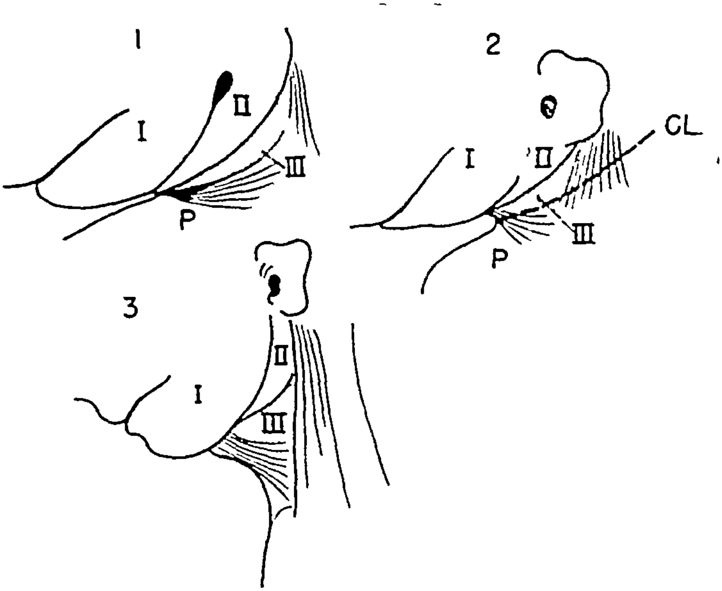

Fig 16 Three schemes to show the situation acquired by the third arch as the neck forms Cl gives the general position and line of the clavicle I II III branchial arches P pericardium

Note Visualize a persistent opening at the ventral end of the second groove in Scheme 1 then consider this opening trapped or maintaining its relation with the thoracic wall near the letter P As the infrahyoid muscles are drawn upward as the hyoid moves upward this opening is brought into relation with the anterior border of the sternomastoid the infrahyoid muscles rotate from a horizontal to a vertical position and the sternomastoid is drawn ventrally at its clavicular attachment —(From Frazer[4])

THE NECK FORMATION AND A THEORY EXPLAINING THE EXTERNAL OPENING OF FISTULAE NEAR THE STERNOCLAVICULAR JOINT

As noted above, the neck becomes evident as ventral growth becomes more active and separation from the pericardium is effected As this ventral growth starts, there are important changes rapidly taking place beneath the ventral extremities of the second and third arches in the epipericardial ridge and its environs The hyoid rudiment forms in the space between the ventral ends of the second and third arches The clavicular rudiment forms close by just caudal to the second groove (precursor to the transverse flexure line of the neck), where it is continuous with the episternal thickening ventral to the upper pericardium The infrahyoid muscles are in the epipericardial ridge here The sternomastoid muscle extends along the continuation of the caudal margin of the sinus field into the epipericardial ridge to contact the clavicular rudi-

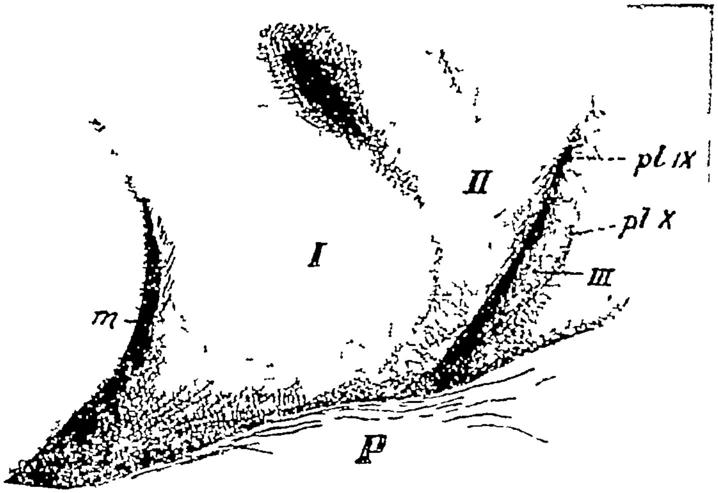

Fig 15 Left side of region in an embryo of 12 mm showing the structures behind the mouth m I II III branchial arches P pericardium ectodermal connections with placodal cysts indicated at pl IX, pl X The third arch is less prominent and is fading into the caudal boundary of the sinus field and epipericardial ridge with their contained sternomastoid muscle which serves to bound the anterior triangle of the neck posteriorly and inferiorly —(From Frazer[4])

is developed above and below the posterior extremity of the first (hyomandibular) branchial cleft from the first and second branchial arches respectively In Fig 14 it can be seen that the pinna when in its formative stages, before the neck is developed, is relatively ventral in location and close to the thoracic wall Arey[13] states that it persists in this location rarely, and when it does is in combination with agenesis of the mandible, with the mandible failing to force the ears laterally to the sides of the head It would seem, therefore, that with Frazer's demonstration of the persistence of the third arch on the neck, cartilaginous bars in this region would be more likely explained as due to a vestige of the third arch rather than a remnant of the pinna left behind Hyndman and Light[5] and Brown,[14] state that small bits of cartilage are often found at the external orifice of lateral fistulae These may be of second or third arch origin, and strengthen the case for branchial as against thymic duct origin

It can be seen from the above that branchial remnants can exist below the level of the hyoid A breakthrough in the third groove, as well as one from the second, could be related to the infrahyoid and sternomastoid muscles in the approximate region of the carotid triangles A fistula of third membrane breakthrough is primarily less likely from an embryological standpoint (see section on closing membranes), second, it would have to course posterior to the common-internal carotid axis and open internally in the pyriform fossa A breakthrough of the second closing membrane is more likely embryologically, and if it emerges in the ventral extremity of the second groove is closely related to the clavicle, infrahyoid and sternomastoid muscles (See Figs 15, 16) Its proximal relations would have to be either between the internal and external carotids or anterior to the carotids, and it would have to pass beneath the posterior belly of the digastric muscle, and open internally in the region from and including the tonsil fossa to the Eustachian orifice Perusal of the clinical literature indicates this latter set of relations holds for the usual lateral fistulae

Why is it that branchial cysts are found only in the upper

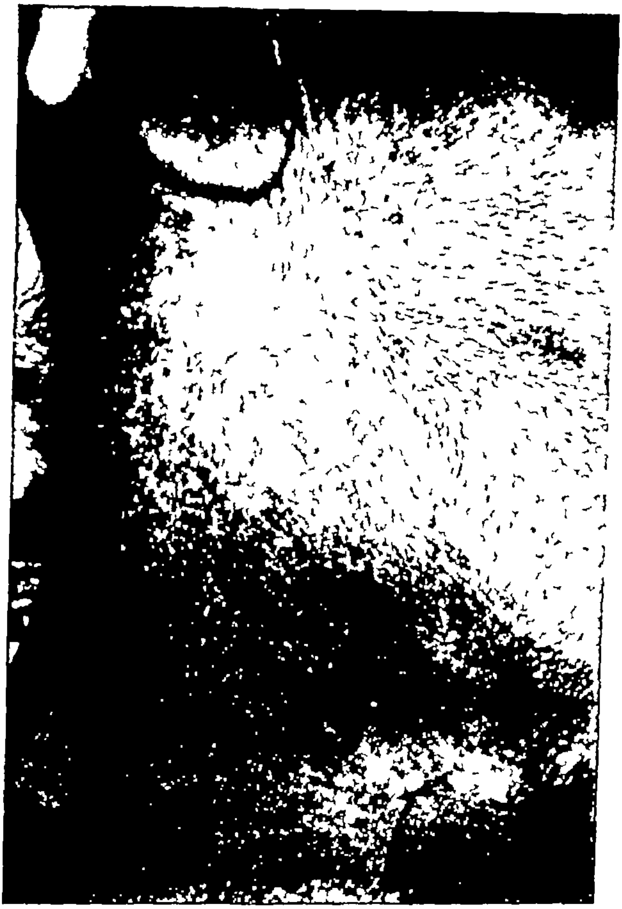

Fig 17 Photograph of a cervical cartilaginous bar Note that the bar is not at the anterior margin of the sternomastoid In this connection attention is called to Frazer's remark that the sternomastoid marks the posterior margin of the sinus field and that the third arch represented ectodermally on the neck is in the approximate region of the anterior triangle Also see under discussion of atypical external openings in Bailey H The Clinical Aspects of Branchial Fistulae British Journal of Surgery 21 173 1933

an exact one An external fistulous opening related to the posterior margin of the sternomastoid has been reported, in fact [22]

A cartilaginous bar in the general region of the carotid triangles, variously termed a cervical or auricular appendage, may well be a remnant of the cartilage of the third branchial arch Such a case is illustrated (see Fig 17) The pinna duct theory, as the thymic duct normally leaves the branchial area to course inferiorly.

How does Wenglowski explain the external opening of a fistula on the basis of thymic duct origin? A branchial fistula through the groove opens externally in the embryo, and if this condition persists there is a ready-made explanation for an external opening. Wenglowski states that fistulae open externally only by secondary suppuration. He reasons that only a thymic duct vestige would consistently open along the anterior border of the sternomastoid as this is related to its normal course, while a branchial fistula could just as easily open posteriorly in the neck, depending upon which haphazard direction the pus burrowed before pointing externally. While it is true that many fistulae show evidence of inflammation, I know of no other author who expressedly feels that this is the usual modus operandi of external opening of congenital fistulae.

How does Wenglowski get around the fact that the internal opening of lateral fistulae is in the second pouch area, let alone the course above the hyoid, which he accepts as of second arch origin in part? He concedes that the tonsil fossa proper is of second pouch origin. He argues, however, that fistulae opening in this region open not into the fossa proper but in relation to the palatoglossus muscle of the anterior pillar, which he claims is of third arch origin, innervated by the IXth nerve. The cases of Dowd,[15] Kleinert,[16] Blassingame,[17] and the author, however, exhibited openings within the tonsil fossa proper. Morris' Textbook of Anatomy states the palatoglossus muscle is innervated by the Xth nerve, the nerve of the fourth arch, while Gray's textbook states it is innervated by the XIth nerve; no mention is made of the IXth nerve.

Wenglowski decried Kanstanecki and Milecki,[3] who emphasized nerve and blood vessel relations as more significant than muscle relations. He stated that the development of vessels in this region was so confusing that no useful relation could be established. Frazer and Ward and Hendricks,[18] however, state that the relations to nerves and vessels are fixed, and third of the neck, while lateral cervical fistulae can open almost to the clavicle? I have presented a theory of the development of fistulae from a breakthrough of the second closing membrane at the time and place when the second cleft and the rudiments of the clavicle, infrahyoid and sternomastoid muscles are grouped close together It must be assumed that when an external opening occurs into the ectoderm at the base of the future neck, this opening is trapped in an area of relatively slow ectodermal expansion As the cephalic attachment in the region of the tonsil fossa grows away from this area in the ventral expansion, causing the formation of the neck, the fistulous tract is drawn out as are the infrahyoid muscles Where no caudal anchorage occurs, as in a branchial cyst or incomplete internal fistula, the vestige is carried upward or cephalad, maintaining its relations at the approximate hyoid level

REFUTATION OF THE THYMIC DUCT THEORY

Wenglowski[3] presented his thymic duct theory of the origin of lateral fistulae in 1913 Wenglowski stated that there was such a uniformity in lateral cervical fistulae that a common origin must exist He concluded, however, from his studies of human embryos that no vestige of the branchial arch apparatus could exist post-embryonally below the level of the inferior border of the hyoid bone This was based on his contention that the initial dorso-ventral relationship of the arches persisted, namely, the third and fourth arches remain dorsal to the second arch, and so no arch field derivative could persist caudally below the level of the second arch This has never been corroborated, and as has been shown by Frazer,[4] the third arch is represented on the neck in the region of the carotid triangles For this same reason, Wenglowski reasoned that any fistula of branchial origin could not turn down to reach a level below the level of the hyoid, but should course almost straight laterally to open in the region of the angle of the jaw Because most fistulae, however, do angle to course inferiorly and open on the neck, sometimes at the sterno-clavicular region, Wenglowski sought to find another explanation for fistulae, and came up with the thymic which he states shows close relationship to the thymus What does this imply as regards the usual lymphoid tissue in cysts above the hyoid level, which he will not contest as being branchial in origin? Lymphoid tissue is commonly associated with the pharynx

The author has encountered no clinical description of a complete fistula meeting the accepted criteria of third pharyngeal pouch origin, either thymogenic or branchiogenic This is confirmed by Dowd[15] quoting McKenty, Whitacre and Konig, and also by Taylor and Burwell[8] Rudberg reports a case in a 13-year-old girl presenting a swelling in the neck between the larynx and the carotid sheath which was found to lie in front of the sternomastoid with a small deeper ramification extending behind the common carotid, where it divided into ascending and descending branches The ascending branch ended blindly at the level of the carotid bifurcation, and the descending branch narrowed to a string ending in a terminal enlargement about a finger-breadth above the clavicle On microscopic examination the mass consisted of a few irregular cystic cavities lined with both flattened and stratified squamous epithelium, with considerable lymphoid tissue beside the cyst walls, and in this lymphoid tissue were a large number of small, rounded bodies resembling Hassall's corpuscles Rudberg stated most surgeons would consider this thymogenic, but, from its vessel relationship he considered it as a third branchial groove cyst with the additional presence of thymic tissue In the author's opinion, due to the absence of an external opening, this could well be a thymic duct vestige Certainly, the vascular relationship indicates third pouch origin, whether branchiogenic or thymogenic This case, however, is the exception that "proves the rule" Wenglowski developed his theory in explanation of the usual type of fistula, which as has been repeatedly demonstrated, opens in the region of the tonsil fossa, passes over the hyoid dorsal to the lesser cornu and passes either between the carotids or ventral to the carotid axis and opens externally near the sternoclavicular junction Rudberg's case meets the criteria of a third pouch-derived cyst and to prove it, exhibits the proper vessel relationship and demonstrates Hassall's corbarring vessel anomalies themselves, are the only constant guides as to origin of vestigial structures Wenglowski's paper erroneously states that the artery of the third arch is the external carotid

In further discussion Wenglowski argues that if a fistula is of branchial origin it should be lined by entodermal or columnar epithelium in its inner portion to correspond to the pharyngeal pouch portion, and by ectodermal or stratified squamous epithelium in its outer portion to correspond to the branchial groove, and that this arrangement does not occur, however, there are cases with just this arrangement, though they are not the rule Rudberg,[10] *e g*, cites several cases lined with stratified squamous epithelium which changed to ciliated columnar near the pharynx In fact, Rudberg found that squamous epithelium occurred in 90 per cent of cysts and fistulae, ciliated columnar, especially near the pharynx, in 8 per cent, and both types of epithelium in 2 per cent Carp and Stout[6] report branchial cysts with both types of epithelium side by side Wenglowski then found himself in the position of having to explain stratified squamous epithelium, supposedly indicating ectodermal origin, in thymic fistula and as noted in the section of "Fate of the Pharyngeal Pouches," explained it as based on contact with the cervical sinus ectoderm only in those cases where "ectodermal" epithelium occurred Actually, however, Maximow and Bloom[11] state that experimental studies of vertebrates show that many of the cells in the embryonic germ layers have no inherent specificity during early developmental stages, and that if they are moved from one place to another they will often develop in conformity with their new surroundings

Wenglowski has this to say about the presence of Hassall's corpuscles as evidence of thymic origin, and I translate as literally as possible "In cysts of the lower half of the neck are found clumps of flat epithelium which are similar to the Hassallian corpuscles" There is no specific case citation, nor is there reference to their ever having been found a complete fistula rather than a cystic structure, nor is there any statement as to the incidence of finding Hassall's corpuscles Much emphasis is placed on the wealth of lymphoid tissue felt not possible because of the thick layer of mesoderm intervening To him is ascribed the concept of the disappearance of the precervical sinus by fusion of the second arch with the thoracic wall, and the formation of the precervical duct as an explanation of the external opening of lateral fistulae Konstanecki and Milecki, in 1890, organized the literature to their time and were instrumental in discarding the schemes of Heusinger, Cusset and Bland-Sutton as not corresponding to anatomical facts They established the concept that the inner opening determines the origin of fistulae which is branchial, with the opening always in the inferior portion of the tonsillar fossa at the root of the tongue and so of second pouch origin

Wenglowski, in 1913, presented his thymic duct theory of the origin of lateral cervical fistulae with his major premise that no branchial vestige could remain beneath the level of the inferior margin of the hyoid bone His thymic duct theory has several weaknesses, as described His worthy contributions appear to be that he confirmed Hammar's (1902) findings that the points of contact of groove and pouch in the various closing membranes are not extensive and vary with the several membranes, even between sides of the same embryo, but that the most constant closing membrane, other than the first, is that of the second He also first described how the third arch was not obliterated in the precervical sinus

Frazer, in 1923 and 1926, demonstrated that the third arch not only was not obliterated in the precervical sinus, but also took part in the formation of the neck corresponding with the carotid triangles He also stated that the precervical sinus was not obliterated by a fusion of the second arch (Rabl) with the thoracic wall, but that the structures involved in the sinus are passively affected in the development and obliteration of the placodal ducts of the IXth and Xth cranial nerves He also demonstrated that all branchial vestiges must develop ventral or anterior to the XIIth nerve He also described the area from and including the tonsil fossa to the Eustachian orifice on the lateral pharyngeal wall as the postembryonal derivative of the ventral angle of the second lateral puscles If it exhibited Hassall's corpuscles and had vessel relations associated with accepted criteria of second pouch origin, then Wenglowski's theory would have some justification and embryologists would have to start over again

HISTORICAL SUMMARY [20,3,5,6]

Huncyowski, in 1789, probably reported the first cases of lateral cervical fistula The first accurate description of the branchial apparatus was in vertebrates by Rathke in 1825 He noted the resemblance of the branchial clefts to the gill apparatus of sharks but discarded any association phylogenetically Ascherson, in 1832, distinguished between median and lateral fistulae, and first associated lateral cervical fistulae with incomplete closure of the branchial clefts Cysts were included as branchial derivatives by Roser in 1859 Heusinger, in 1865 and 1876, reported that all fistulae opened internally near the base of the tongue and opened at various levels of the neck externally depending upon which branchial groove failed to close Cusset (1877) and Bland-Sutton (1895) presented different schema but based on identification of groove origin by level of external opening also

The next major contribution was by His, in 1881 He used human embryos and first used the more precise reconstruction method of studying them He described the closing membranes and noted their failure to break through normally, as in aquatic animals to form gill slits He described the precervical sinus and the triangular area ventral to the pharynx between the ends of the arches occupied by the pericardium, the mesobranchial field of His The prefix "pre-" in the term precervical sinus was intended to refer to a ventral orientation with regard to the neck (Rabl accused him of implying an oral orientation)

Rabl, in 1886 and 1907, described the closing membrane of the second pouch and groove as two layers of epithelium in contact and mentioned the proclivity for a breakthrough here to form a fistula He discounted a third membrane breakthrough possibility as a relation to the thymus or carotid body would have to exist A fourth membrane breakthrough was vestigeal fistulae and cysts below the mouth and ear regions Cysts and fistulae are of similar origin

2 The ventral angle of the second pouch is represented in the adult lateral pharynx as the region from and including the tonsil fossa to the Eustachian orifice A congenital fistula, with an internal opening anywhere in this region can be assumed to be of second pouch origin if it complies with nerve and vascular relationships If ever encountered, a third pouch fistula would open internally in the pyriform fossa and a fourth pouch fistula would open still lower, beneath the fold of the superior laryngeal nerve

3 A second pouch fistula courses over the hyoid, dorsal to the lesser cornu It then commonly passes between the internal and external carotid arteries, but may pass anterior or ventral to both An anterior course may be determined by preoperative X-ray of the tract filled with radio-opaque material An anterior course predicts a relatively simple operative procedure Embryological correlation of these variations is discussed

4 The relation to nerves and vessels is the determining factor in identifying the origin of a vestige, as well as the site of internal opening All branchial vestiges are found ventral to the XIIth nerve Second pouch fistulae should course ventral to the IXth and Xth nerves also

5 A third pouch vestigeal structure would have to open internally in the pyriform fossa, course beneath the hyoid and pass dorsal to the internal or common carotid artery No such relationship for a *complete* fistula has ever been reported A fourth pouch fistula would have to loop around the aorta on the left or the subclavian artery on the right, and again no such relationship has ever been reported

6 The thymic duct theory of Wenglowski as an explanation of the usual fistula under discussion is not in keeping with clinico-pathological and embryological facts

7 Embryologists list many possible sources of vestigeal structures,[21] and while they suggest the capability of producing vestigeal structures, only the second pouch and cleft pharyngeal pouch He would not conjecture as to the origin of vestiges in this region except in broad terms He mentioned the possibilities of the placodal ducts, as well as the grooves, under the heading of "abnormal persistence of normal states" or "delayed development" as well as "abnormal processes of development" Fistulae opening near the clavicle, he feels, could possibly derive by either method He apologizes for having ruined a duct system as part of the precervical sinus as a source of explanation

CASE REPORT

Mr J B W, white, age 33, was admitted Dec 22 1951 with a diagnosis of bleeding duodenal ulcer On routine physical examination the examining physician noted a small sinus above the sternal attachment of the sternomastoid which seemed to be attached to a cord under the skin, which ran cephalad On milking the cord the physician reported a clear mucus exuding from the sinus opening The patient was referred to the E N T clinic There was a history of drainage from the sinus opening as long as the patient could remember and the secretion was usually clear The patient does not recall ever having a sore throat A probe was passed to the upper level of the thyroid cartilage and passed beneath the sternomastoid at about its midpoint Probing caused coughing and a foreign body sensation in the throat at about the level of the superior border of the thyroid cartilage Lipiodol was instilled and X rays made These revealed a fistulous tract with no cystic enlargements in its pathway The tract passed over the hyoid just posterior to the lesser horn and then turned medially toward the pharynx On injecting the fistula with methylene blue, dye was seen to come from a large crypt in the upper pole of the right tonsil The tonsils were normal in appearance The fistulous tract was excised without difficulty via two step-ladder incisions The right tonsil was removed in the usual manner and the tonsil bed sutured There was no contact with the great vessels and the tract became quite thin as it approached the tonsil fossa Dissection was simple with no evidence of inflammatory reaction Post operative course was uneventful and a questionnaire three years later revealed the patient was asymptomatic as regards this lesion

The gross description was that of a tubular structure measuring 10 5 cm in length and varying in diameter from 4 to 6 mm An elliptical fragment of skin was noted attached to the specimen Microscopic description was as follows The tract is lined by stratified epithelium which does not show keratinization The epithelium is supported by connective tissue Definite smooth muscle structures are not seen There is very slight lymphocytic infiltration in this supporting connective tissue No structures similar to Hassall's corpuscles are seen Occasional fragments of salivary gland tissue are seen at various levels adjacent to the connective tissue This structure is surrounded by voluntary muscle and connective tissue Microscopic diagnosis was 'fistulous tract"

vestiges are significant clinically, with the exception of cartilaginous bars (see below)

8 The older concepts of the disappearance of the precervical sinus and the development of the neck appears to have been displaced by Frazer's work with human embryos The precervical sinus is passively affected in the development and obliteration of the adjacent placodal ducts (IX and X), with the sinus obliterating by a fusion from within toward the surface At no time is it represented by an ectodermal lined sac, all such simulation, according to Frazer and as confirmed by Garrett, is due to confusion with the ectodermal lined placodal ducts

9 The third arch is represented on the post-embryonic neck as the approximate region of the carotid triangles

10 The controversy over the significance of the relation of lateral vestiges to the stylopharyngeus muscle is critically discussed and a logical interpretation presented

11 A cartilaginous bar, also termed a cervical or auricular appendage, may well be a second or third branchial arch cartilage vestige unrelated to the pinna anlagen if found in the region of the carotid triangles

12 An explanation of why branchial cysts are confined to the upper third of the neck, while external or complete fistulae often open externally almost to the sternoclavicular junction is presented *

*This last concept was originally presented to a weekly surgical staff meeting March 30 1955 Lyall and Stahl independently presented a similar hypothesis in a published paper (Lyall D and Stahl W M. Jr Lateral Cervical Cysts Sinuses and Fistulas of Congenital Origin Surg Gyn Obst 102(5) 417-434 May 1956)

1 Aid in the clinical localization of the site of nerve damage

2 Equate the degree of impaired chorda tympani nerve function with the degree of facial nerve paralysis

3 Aid in measuring and predicting, if possible, spontaneous recovery of the damaged facial nerve

With a view to accomplish these objectives, this study presents a technique for measuring the salivary secretion of the submaxillary salivary glands as an accurate index of motor function of the chorda tympani nerve

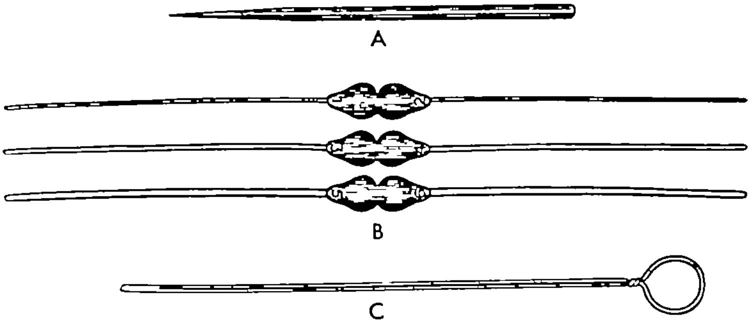

Fig 1 Apparatus for catheterization of the submaxillary salivary glands (Wharton's) ducts include A a lacrimal punctum director B Bowman's blunt-tipped probes C a section of polyethylene tubing PE No 60 and a fine wire stylet

TECHNIQUE

The equipment consists of a set of blunt-tipped Bowman lacrimal probes, a punctum director, polyethylene catheters No 60 (see Fig 1), and small Kahn type test tubes The patient is usually placed in the sitting position A solution of 10 per cent cocaine hydrochloride is applied topically to the orifice of each Wharton's duct This not only reduces the discomfort associated with dilation, but also makes the orifice visible by stimulating salivary flow Aseptic technique is used throughout the procedure

A lacrimal punctum director is inserted into the orifice of

SUBMAXILLARY SALIVARY FLOW: A TEST OF CHORDA TYMPANI NERVE FUNCTION AS AN AID IN DIAGNOSIS AND PROGNOSIS OF FACIAL NERVE PARALYSIS.*

JOHN E. MAGIELSKI, M.D.,
and
IRVING M. BLATT, M.D.,†
Ann Arbor, Mich.

Disturbances of taste and secretion of saliva are frequently associated with facial nerve paralysis of the peripheral type. The application of these phenomena in localization of the facial nerve lesion is well documented, but the accepted criteria and methods of testing these functions are often variable and unreliable. This is particularly true in testing for chorda tympani function by analysis of taste perception.

The accepted criterion of a functioning chorda tympani nerve is the ability to perceive taste on roughly the anterior two-thirds of the tongue on the corresponding side. In the process of testing, a patient, whose taste is found to be absent by one examiner, may have normal or subnormal taste when tested by another. Inadvertent withdrawal of the tongue results in quick perception by oral and posterior glossal taste buds; also, saliva coming in contact with the solution carries the test substance to the back of the mouth, which further diminishes the reliability of the taste observation.

Guided by the anatomical and physiological fact that facial nerve damage between the geniculate ganglion and the exit of the chorda tympani nerve from the middle ear is accompanied by impairment of chorda tympani nerve function, an attempt was made to find a more objective test which would serve to

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication April 3, 1958.

After each Wharton's duct has been catheterized the patient is asked to suck on a slice of lemon for 60 seconds, during which time the output of saliva from each submaxillary gland is collected and measured in drops per minute (see Fig 2) An assistant collects from one side while the examiner collects from the other The procedure may be repeated for multiple sampling, after which the catheters are removed and discarded

MATERIAL FOR STUDY

We have presumed to add to the lengthy literature on chorda tympani and facial nerve neuropathy because similar patients have been previously studied by the subjective sense, taste Before presenting our observations it may be well to state something about control tests In the study of normal individuals between the ages of ten and sixty, the flow of saliva from each submaxillary gland simultaneously is practically of identical volume regardless of the type of stimulus used For the first five minutes, the quantity is identical, over a 30-minute period the variations between the two salivary glands is not more than 0 50 to 1 0 cc The volume of saliva produced by lemon stimulation is greater than by chewing paraffin, but in each instance the right submaxillary gland will secrete the same quantity of saliva as the left [2]

Taste testing for chorda tympani nerve function is also included in this study to illustrate the variations in acuity which produce equivocal results In testing taste, the tip of the tongue is covered with gauze and held by the examiner until the taste on the anterior two-thirds has been identified by the patient At this moment the patient points to one of six items written on a card "taste nothing, taste something but don't know what, bitter, sour, sweet, salty" In all observations, two minutes have been the upper limit for taste determinations in this study Substances not detected within this time usually will not be appreciated at all with any degree of reliability

The patients for study have been grouped into the following categories

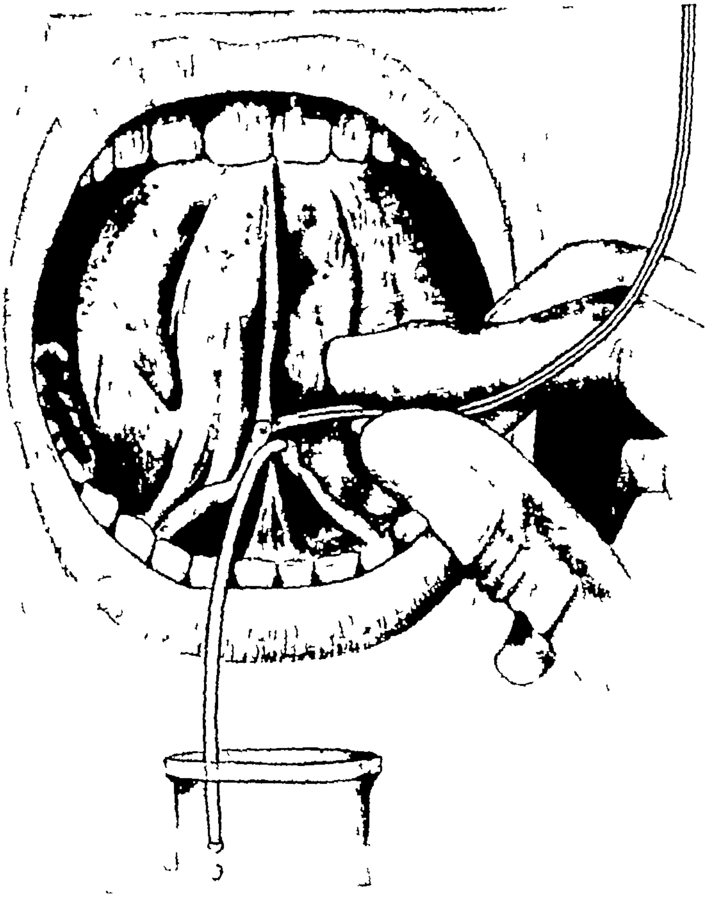

Fig 2 Catheterization of Wharton s duct and collection of submaxillary gland saliva An 8 to 10 cm section of polyethylene tubing is threaded onto a fine rigid wire stylet and is inserted into Wharton's duct for a distance of 3 to 4 cm The submaxillary gland saliva is collected in a small Kahn type test tube for each side while the patient sucks on a slice of lemon

Wharton's duct, after which dilation is accomplished with the Bowman probes, using sizes No 1 through No 4 A polyethylene catheter No 60 (sterilized in 1 500 aqueous benzalkonium chloride for at least 24 hours) is inserted into Wharton's duct for a distance of 3 to 4 cm This is best accomplished with the aid of a fine rigid wire stylet, onto which an 8 to 10 cm section of polythylene tubing is threaded[1] Precaution should be taken to avoid protrusion of the stylet beyond the open end of the polyethylene catheter

TASTE	Right (affected side) Seconds	Left. Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Taste Nothing	30
Sour	Taste Nothing	120
Salty	Taste Nothing	120
Bitter	120	120

SALIVA.	Right (affected side) Drops—Min	Left. Drops—Min
Lemon stimulation	0	32

At operation the chorda tympani nerve was found to be absent

At follow up examination one month later the following results were obtained

TASTE	Right (affected side) Seconds	Left. Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Taste Nothing	Not Recognized
Sour	Taste Nothing	Not Recognized
Salty	Taste Nothing	Not Recognized
Bitter	Taste Nothing	Not Recognized
Bitter	120	120

SALIVA.	Right (affected side) Drops—Min	Left. Drops—Min.
Lemon stimulation	0	42

DISCUSSION

Taste testing in these cases was equivocal In another patient in this group, the salivary flow on the affected side was reduced 50 per cent when compared with the normal side At operation, the chorda tympani was found imbedded in scar and granulation tissue In this particular patient preoperative testing of taste was highly equivocal, and no decision could be reached as to whether taste was present Thus partial function of the chorda tympani nerve may also be detected by comparing submaxillary salivary secretion from both glands

The first patient (C A) presented is characteristic of the individual who has an intact chorda tympani nerve prior to operation, which must necessarily be sacrificed in the performance of a radical mastoidectomy The paralytic effect of chorda tympani nerve section upon submaxillary salivary flow is illustrated

The second patient (G E) also demonstrates the difficulty

I Cases of chronic suppuration of the middle ear and mastoid

II Cases of facial paralysis due to idiopathic Bell's palsy

III Cases of facial paralysis associated with skull fractures including the temporal bone

IV Cases of facial paralysis associated with central nervous system disease

GROUP I CHRONIC SUPPURATION OF THE MIDDLE EAR AND MASTOID

Case 1 C A, No 859083, a 57 year-old mechanic was admitted on January 4, 1957, to University Hospital for a radical mastoidectomy There had been drainage from the right ear for approximately 50 years The patient was unaware of any taste deficiency On the day prior to operation the following results were obtained in tests for taste and submaxillary saliva

TASTE	Right (affected side) Seconds	Left Seconds
Water	Taste Nothing	Taste Nothing
Sweet (50% glucose)	30	30
Sour (vinegar)	30	30
Salty (Hypertonic saline)	30	30
Bitter (quinine)	30	30

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	42	41

At operation the chorda tympani nerve was found to be intact The nerve was sacrificed during the radical mastoidectomy There was no complaint of gustatory deficiency postoperatively Taste and saliva examinations on the fourth postoperative day and at the end of the second postoperative month were as follows

TASTE	Right (affected side) Seconds	Left Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Taste Nothing	30
Sour	Taste Nothing	30
Salty	Taste Nothing	30
Bitter	Taste Nothing	30

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	0	40

Case 2 G E No 809472 a 45 year-old salesman was operated upon at University Hospital on October 30 1956, for a chronically draining ear of about 25 years' duration There was no history of gustatory deficiency On the day prior to operation the following results were obtained in tests for taste and submaxillary saliva

type of facial paresis probably compatible with an hypertensive encephalopathy without other neurological deficit. Further examination noted that the patient could not smile on command or by emotional expression The hearing was normal Roentgenograms of the skull were normal The following results were obtained for taste and saliva tests

TASTE	Left (affected side) Seconds	Right Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Not Recognized	Not Recognized
Sour	Not Recognized	Not Recognized
Salty	Not Recognized	Not Recognized
Bitter	Not Recognized	Not Recognized
SALIVA	**Left (affected side) Drops—Min**	**Right Drops—Min**
Lemon stimulation	14	20

On the fourth hospital day there was a complete left peripheral facial paralysis without other neurological deficit Taste and saliva examination was as follows

TASTE	Left (affected side) Seconds	Right Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Taste Nothing	Not Recognized
Sour	Taste Nothing	Not Recognized
Salty	Taste Nothing	Not Recognized
Bitter	Taste Nothing	120
SALIVA	**Left (affected side) Drops—Min**	**Right Drops—Min**
Lemon stimulation	0	25

The patient was discharged on the fifth hospital day with the diagnosis of Bell's palsy One week later (13 days after the onset of the facial paralysis) there was partial motion of all the muscles of facial expression except forehead motion which was completely absent Taste and saliva test results were as follows

TASTE	Left (affected side) Seconds	Right Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Not Recognized	Not Recognized
Sour	Not Recognized	Not Recognized
Salty	Not Recognized	Not Recoginzed
Bitter	Not Recognized	Not Recognized
SALIVA	**Left (affected side) Drops—Min**	**Right Drops—Min**
Lemon stimulation	15	30

Eight weeks after the onset of facial paralysis there was complete return of function The results of taste examination were identical to those of the first test Submaxillary saliva examination results were as follows

SALIVA	Left (affected side) Drops—Min	Right Drops—Min
Lemon stimulation	50	49

encountered in eliciting a consistent response on the normal side It is of interest to note the reaction to bitter (quinine) in both cases The delay in identifying bitter taste in the second patient probably indicates that the test solution had travelled to the posterior one-third of the tongue, where practically all the gustatory receptors for bitter taste are located That there was no complaint of gustatory deficiency after recent complete removal of the chorda tympani nerve (Case 1) and after long term destruction of it (Case 2) appears to substantiate the observation of Crosby[3] She states that although modalities of taste can be recognized at subcortical levels, an individual's higher (cortical) centers are usually not concerned with the analysis of taste impressions from a specific geographical area on the tongue or palate, rather, the combination of taste, smell and texture, experienced during eating, are cortical associations which are acquired during the individual's own experience If a disturbance of taste does exist, the difficulty in localization may cause the patient to become confused and thus complain that a portion of the tongue feels "numb"

The second patient (G E) demonstrates the loss of chorda tympani function in long standing middle ear suppuration There is no flow of saliva by reflex chemical stimulation (sucking a lemon) preoperatively and postoperatively This phenomenon, observed in 11 similar patients in this Clinic, challenges the concept of reflex formation of saliva in the absence of secretory (motor) innervation—the so-called paralytic secretion of saliva In this instance absence of salivary flow exists after possibly two decades of chorda tympani destruction[1]

GROUP II FACIAL PARALYSIS DUE TO IDIOPATHIC BELL'S PALSY

Case 1 H W No 37565, a 53 year-old telephone lineman, was admitted to St Joseph Mercy Hospital on February 15 1956 because of inability to close the left eye and weakness of the left corner of the mouth for 24 hours On the day prior to admission the patient had been working in the rain

Physical examination revealed a blood pressure of 180/100 (RAR) the patient could not move the corner of the mouth or wrinkle the left side of the nose The left eye could be partially closed, there was no difficulty in wrinkling the forehead

The neurological consultant felt that the patient exhibited a central

TASTE	Right (affected side) Seconds	Left Seconds

Sweet	Taste Nothing	30
Sour	Taste Nothing	Instantly
Salty	Taste Nothing	Instantly
Bitter	Taste Nothing	Instantly

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	9	35

On May 15 1956 five days later there was no change in the facial paralysis The following results were obtained for taste and saliva tests

TASTE	Right (affected side) Seconds	Left Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Not Recognized	Instantly
Sour	Not Recognized	Instantly
Salty	Not Recognized	Instantly
Bitter	120	Instantly

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	28	40

Eighteen days later the patient showed considerable return of facial nerve function Only the frontalis muscle showed minimal activity Tests for taste and saliva were as follows

TASTE	Right (affected side) Seconds	Left Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Not Recognized	Instantly
Sour	Not Recognized	Instantly
Salty	Not Recognized	Instantly
Bitter	Not Recognized	Instantly

SALIVA	Right (affected side) Drops—Min	Left Drops—min
Lemon stimulation	37	40

Twenty four days after the onset of facial paralysis there was complete return of facial movement

Case 4 E T No 820213 a 48 year old colored housewife complained of inability to move the right side of the face for the past 24 hours Physical examination on August 18 1955 revealed a complete right peripheral type of facial paralysis without other neurological deficit. Otologic testing showed normal hearing The tuning fork and Tschiassny stethoscope tests for phonophobia were positive in the right ear The following results were obtained for taste and saliva tests

TASTE	Right (affected side) Seconds	Left Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Taste Nothing	Instantly
Sour	Taste Nothing	Instantly
Salty	Taste Nothing	Instantly
Bitter	30	Instantly

Case 2 B L, No 805312, a 32 year old white housewife, suddenly developed weakness of the left corner *of the mouth during an upper* respiratory infection Twenty four hours after onset there was a complete left facial paralysis On February 15, 1955, two days after the onset, the patient visited the Otolaryngology Clinic at University Hospital She complained of a *deficiency of taste on the left side of the* tongue Loud noises had an "echoing quality," and she did not wish to listen to radio or television because the sound "hurt" her ears, particularly the left one The physical examination revealed a complete left peripheral type of *facial paralysis without other neurological deficit.* A pure tone audiogram showed normal hearing The tuning fork and Tschiassny stethoscope tests for phonophobia were positive in the left ear Roentgenograms of the mastoid bones revealed no abnormalities The *following results were obtained for taste and saliva tests*

TASTE	Left (affected side) Seconds	Right Seconds
Water	Taste Nothing	Not Recognized

Bitter	Not Recognized	Instantly

SALIVA.	Left (affected side) Drops—Min	Right Drops—Min
Lemon stimulation	29	43

On the thirty fifth day after onset of facial paralysis, the patient showed virtually complete return of facial function except for a slight weakness of the forehead There were no complaints of phonophobia or gustatory deficiency The following results were obtained for taste and saliva tests

TASTE	Left (affected side) Seconds	Right. Seconds
Water	Recognized as Sweet	Taste Nothing
Sweet	30	Instantly
Sour	30	Instantly
Salty	"Sour or Bitter"	"Sour or Bitter"
Bitter	30	Instantly

SALIVA	Left (affected side) Drops—Min	Right Drops—Min
Lemon stimulation	56	54

Forty five days after onset of facial paralysis there was complete re*turn of facial movements*

Case 3 D S, No 41361 a 32 year old mechanic noted weakness of the right corner of the mouth on arising in the morning Twenty four hours later, on May 10 1956, there was tearing and difficulty in *closing the* right eye No gustatory deficiency was noted Physical examination revealed a complete right peripheral type of facial paralysis without other neurological deficiencies Otologic studies showed a conductive hearing loss of long standing compatible with clinical *otosclerosis* Roentgenograms of the mastoids revealed no abnormalities The following results were obtained for taste and saliva tests early in the course of facial paralysis, may be erroneously diagnosed as a central type of facial paralysis, however, submaxillary salivary testing of chorda tympani nerve function was helpful in differentiating central from the peripheral type of facial paralysis The fact that the chorda tympani nerve was impaired, though functioning, is evidence of a peripheral rather than a central lesion In this instance it was also apparent that the degree of impaired chorda tympani nerve function could be correlated with the degree of facial nerve paralysis In this instance the recovery of chorda tympani nerve function corresponds with facial nerve recovery

The last three patients of this group demonstrate the more common situation observed when the patient consults a physician for a condition which turns out to be a complete unilateral peripheral facial paralysis due to Bell's palsy It is of note that such a patient may demonstrate partial chorda tympani nerve activity by salivary testing, in the presence of a complete facial paralysis This observation suggests the possibility that the patient may be spared the sequelae of imperfect facial nerve recovery It may justify also the prediction of a favorable prognosis for spontaneous recovery from complete peripheral facial paralysis when it can be demonstrated that the chorda tympani nerve retains its function or rapidly becomes functional early in the course of Bell's palsy It would appear also that the involvement of the facial nerve, by whatever pathologic process in Bell's palsy, is not severe, if the chorda tympani nerve is partially spared Further study is necessary, however, if these assumptions are to be confirmed

The fourth patient (E T) demonstrates the sequelae of imperfect recovery and facial disfigurement The partial return of facial nerve and chorda tympani nerve function appears to correlate for a two-year period Since the rate of chorda tympani nerve recovery did not exceed that of the facial nerve, the prognosis for facial nerve repair, in retrospect, appears to have been poor

In this group of patients we note the variability and un-

SALIVA.	Right (affected side) Drops—Min	Left Drops—Min

DISCUSSION

Ten patients with Bell's palsy were studied in this investigation Four have been selected for presentation because they demonstrate certain refinements in diagnosis of facial nerve disease which heretofore have not been reported

The first patient (H W) presents the complete clinical picture of Bell's palsy from its inception Such a patient, seen

TASTE.	Right (affected side) Seconds	Left. Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Not Recognized	Instantly
Sour	Not Recognized	Instantly
Salty	Not Recognized	Instantly
Bitter	Not Recognized	Instantly

SALIVA	Right (affected side) Drops—Min	Left. Drops—Min
Lemon stimulation	20	65

Four months after injury the patient could close the right eye almost completely had good symmetry of the face in repose but the motion of the forehead was not noticeably improved Taste examination was the same as performed six weeks after injury Saliva examination was as follows

SALIVA.	Right (affected side) Drops—Min	Left. Drops—Min
Lemon stimulation	40	60

The patient subsequently left Michigan and has not been heard from since

Case 2 R.K No 805674 a 23 year-old male student was admitted to University Hospital on March 2 1955 because of a right facial nerve paresis On February 13, 1955 he had sustained a severe head injury with a linear fracture in the right temporal region from an automobile accident. Physical examination revealed a right sided weakness of all the facial muscles of expression the muscles of the forehead being the most severely impaired Otologic examination showed a hemotympanum and a conductive deafness A.D Roentgenograms revealed a fracture through the occipital bone occipito-temporal suture extending into the petrous portion of the temporal bone

Taste and saliva studies were as follows

TASTE	Right (affected side) Seconds	Left. Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Not Recognized	Instantly
Sour	120	Instantly
Salty	120	Instantly
Bitter	120	Instantly

SALIVA.	Right (affected side) Drops—Min	Left. Drops—Min
Lemon stimulation	32	58

Three weeks later facial mobility was much improved Taste examination was the same as performed previously Saliva examination was as follows

SALIVA.	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	86	105

Nine weeks after injury the return of facial movements was complete except for minimal frontalis weakness Taste and saliva studies were as follows reliability of taste testing in situations where there is impaired function of the chorda tympani nerve and facial nerve with subsequent spontaneous recovery of both In the third patient (D S) absence of taste was recorded in the presence of minimal but definite chorda tympani nerve activity as evidenced by submaxillary salivary flow on lemon stimulation

The fourth patient (E T) demonstrates another reason for the unreliability of taste testing on the anterior two-thirds of the tongue Engstrom and Wohlfart[4] state that in embryological development some fibers of the glossopharyngeal nerve may be drawn forward in the tongue and serve to conduct gustatory impulses in the absence of chorda tympani innervation This concept may be substantiated by the fact that bitter taste was the only definite gustatory experience unequivocally identified by this patient

GROUP III FACIAL PARALYSIS ASSOCIATED WITH SKULL FRACTURES

Case 1 J B , No 807846 a 20 year old student was admitted to University Hospital on April 8, 1955, for a severe head injury sustained in an automobile accident Physical examination revealed a complete right peripheral type of facial paralysis, conductive deafness and hemotympanum Roentgenograms revealed a slight tempor parietal fracture which extended into the petrous ridge toward the medial portion of the internal auditory canal Taste and saliva studies performed on April 18 1955 were as follows

TASTE	Right (affected side) Seconds	Left Seconds
Water	Taste Nothing	Taste Nothing
Sweet	Taste Nothing	Instantly
Sour	Taste Nothing	Instantly
Salty	Taste Nothing	Instantly
Bitter	Taste Nothing	Instantly

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	6	68

Three weeks after the accident a complete facial paralysis was still present. Taste examination was unchanged The submaxillary salivary studies were as follows

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	12	55

Six weeks after injury the hearing had returned to normal There was some motion of the forehead and the upper lip on the right side Taste and saliva studies were as follows

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	70	72

Case 3 G S, No 854039, a 28 year-old welder, was transferred to University Hospital on October 3, 1956 On September 29, 1956, the patient was involved in an automobile accident and sustained a severe head injury and fractured mandible Physical examination revealed a complete right peripheral type of facial paralysis There was an extensive keratitis in the right eye A deformity of the superior portion of the external auditory canal prevented adequate visualization of the right tympanic membrane There was a conductive deafness on the right side Roentgenograms revealed a fracture of the mandible and a temporo parietal fracture with extension through the osseous right external auditory canal

Taste studies were omitted because of difficulty in protruding the tongue Submaxillary salivary examination was as follows

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	0	52

On October 8, 1956, decompression and neurolysis of the facial nerve was performed through a modified radical mastoidectomy approach Open reduction of the mandible with internal fixation and a lateral band tarsorrhaphy were subsequently performed

In February, 1957, four postoperative months, there was only minimal motion of the upper lip and nasal ala Salivary studies were as follows

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	9	65

In October 1957, one year after facial nerve decompression, minimal motion of the upper and lower lips and side of the nose was present Submaxillary salivary testing showed the following

SALIVA	Right (affected side) Drops—Min	Left Drops—min
Lemon stimulation	4	70

DISCUSSION

Six patients demonstrating facial nerve paralysis associated with skull and temporal bone fractures comprise this facial nerve trauma group Three cases have been described to deal of difficulty in moving the right corner of the mouth and that it seemed to droop.

Examination by the neurologists revealed a right-handed white female with a blood pressure of 150/100 (RAR). There was a lower facial paresis with poor delineation of the nasolabial fold. Minimal impairment of frontalis movement was also found. There was no other neurological deficit. The clinical impression was Bell's palsy.

Otolaryngological consultation on May 26, 1955 revealed only a lower facial paresis. Audiometric studies showed presbycusis. Roentgenograms of the skull were normal. Taste and saliva studies were as follows:

TASTE	Right (affected side) Seconds	Left Seconds
Water	Taste Nothing	Taste Nothing
Sweet	30	30
Sour	30	30
Salty	30	30
Bitter	30	30

SALIVA	Right (affected side) Drops—Min	Left Drops—Min
Lemon stimulation	20	20

Two weeks after onset of facial paresis there was minimal weakness of the right upper and lower lips. Taste and saliva studies revealed no change from similar testing performed on May 26, 1955.

Seven months after the patient's initial visit there was complete facial symmetry. Taste and saliva studies were consistent with those performed at the time of the first otolaryngological consultation. Final diagnosis: Mild hypertensive encephalopathy.

DISCUSSION

Three cases comprised this group: a patient with hypertensive encephalopathy, second, a patient with a nuclear lesion of the VIIth cranial nerve due to bulbar poliomyelitis, and a patient with a brain tumor in the floor of the fourth ventricle. Other patients with obvious central facial paralysis were studied for documentary purposes only. Indeed, the presence of equal submaxillary salivary flow on lemon stimulation indicating an intact chorda tympani nerve is another diagnostic aid in localizing a facial nerve lesion.

SUMMARY

A clinical test for chorda tympani nerve function by measuring submaxillary salivary secretion is presented as a practical office procedure. The technique of submaxillary (Wharton's) duct catheterization is described. It has been demon-

emphasize certain clinical and neuro-anatomical obser
pertaining to chorda tympani nerve testing

As noted in the Bell's palsy group, it appears that
of the facial nerve due to trauma may not be severe
chorda tympani nerve is partially spared (Obviously
temporal injury of the facial nerve will not involve the
tympani nerve) Since chorda tympani nerve func
present in the first (J B) and second (R K) pati
seemed in retrospect to indicate potential spontane

POST GRADUATE COURSES AT TEMPLE UNIVERSITY SCHOOL OF MEDICINE AND HOSPITAL

A Postgraduate Course in Bronchoesophagology, February 16th to 27th, 1959, and a Postgraduate Course in Laryngology and Laryngeal Surgery, April 13th to 24th, 1959, will be given by Temple University School of Medicine

These courses are to be given in the Department of Laryngology and Broncho-Esophagology, Temple University Medical Center, under the direction of Drs Chevalier L Jackson and Charles M Norris

The tuition fee for each course is $250 00 Application blanks and further information concerning dates of subsequent courses may be obtained by writing to Jackson-Research, Laboratory 604, Temple University Medical School, 3400 N Broad Street, Philadelphia 40, Pa strated that this procedure is a far more accurate index of chorda tympani nerve function than are tests for taste

Chorda tympani nerve function by measurements of submaxillary salivary gland secretion can serve as an aid in the clinical localization of facial nerve damage The peripheral and central types of facial paralysis can be determined when such differentiation is not obvious

In the peripheral type of facial paralysis, submaxillary salivary testing of chorda tympani nerve function appears to be a consistently reliable adjunct for intra and extra temporal localization of facial nerve injury

The degree of impaired chorda tympani function can be correlated with that of facial nerve paralysis when both are involved A good prognosis for spontaneous recovery might be predicted if it can be demonstrated that the chorda tympani nerve retains its function early or becomes functional rapidly in the course of Bell's palsy or traumatic facial nerve injury, however, further studies are necessary to substantiate this observation

The chorda tympani nerve contains the pre-ganglionic secretory fibers which activate the submaxillary ganglion and other parasympathetic ganglion cells imbedded in the substance of the submaxillary gland If the chorda tympani nerve is destroyed, no submaxillary salivary secretion occurs when the gland is stimulated by reflex chemical stimulation (eating) because the secretory fibers have been removed This observation challenges the concept of reflex formation of saliva in the absence of secretory innervation—the so-called paralytic secretion of saliva

Taste perception as an index of chorda tympani function is variable, and in many instances unreliable in testing the normal and abnormal sides of the tongue in conditions where there is simultaneous impaired function of the chorda tympani nerve and facial nerve *

ETIOLOGY AND AGE

Of the 51 cases, 33 had a history of contact with lye, and eight with ingestion of commercial preparations under the trade name of Drano and Sani-Flush.[1] These commercial preparations are composed approximately of 95 per cent sodium and potassium hydroxide. Another which should be included in this group was from potash used to prepare a "hair oil mixture." Four cases were a result of drinking Lysol, two from household ammonia water, and one each from cresylic acid, phenol, and potassium permanganate (see Table I).

TABLE I

Agent	No. of Cases	Degree of Burn (Esophagoscopy) None	Mild (Erythema)	Moderate
Lye	33	21	5	7
Drano	7	4	2	1
Sani Flush	1		1	
Potash	1	1		
Lysol	4	4		
Ammonia Water	2	2		
Potass. Permanganate	1	1		
Phenol	1		1	
Cresylic Acid	1	1		
Total	51	34	9	8

Although evidence of mouth burns was present in all nine cases of chemical ingestion not in the alkali group, no burns were detected by esophagoscopy except one from phenol, which was classified as mild and required no treatment. This finding would agree with Owens,[1] in his report of 131 cases of chemical burns, in which he concluded that "ingestion of household chemicals, other than lye, in general use today need not receive the drastic treatment given the latter, as stricture formation from their ingestion is a rarity."

All 51 patients were five years of age, or under. Thirty-two were two years of age or under, and 19 were from three to five years of age (see Table II). This finding, in a hospital which admits patients to the age of 13, would indicate that most of these accidents occur in children who are not old enough to differentiate poisons from the usual food and

DIAGNOSIS AND MANAGEMENT OF CHEMICAL BURNS OF THE ESOPHAGUS*

LYLE G. WAGGONER, M.D.,

Detroit, Mich.

Ingestion of a corrosive substance creates a very difficult problem, both to the unfortunate patient and the attending physician, in treatment of the damaged esophagus. Solution of this problem has been sought since the time of Pliny, when it is recorded that the ashes of plants were treated with lime to produce sodium and potassium hydroxide for use in the manufacture of soap.

It is the purpose of this manuscript to illustrate how the treatment of many of the suspected cases of esophageal burns can easily be resolved, and to correlate a rational regimen for the management of all cases suspected of ingesting a corrosive chemical.

From January, 1952, to the present time esophagoscopy has been done on all patients presenting themselves at Children's Hospital of Michigan with a history of ingestion, or with evidence of fresh burns of the lips, tongue, mouth or pharynx, within the first ten days of contact with the chemical. This procedure was accomplished against moderate opposition from some of the endoscopic staff, who felt that esophagoscopic examination at this period carried considerable risk. It was also suggested that a damaging burn might escape notice through the esophagoscope. Both of these fears proved to be without foundation; therefore, the case study to be presented represents 51 patients admitted, for examination and treatment from January, 1952, through July, 1957, to a hospital which limits its admissions to children under 13 years of age.

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication May 15, 1958.

scarring from phenol, formaldehyde, ammonia water, Lysol, sulfuric acid, nitric acid, lactic acid, potassium permanganate, iodine and bichloride of mercury, but it is admitted that these do not usually cause strictures

Alkalies are the most destructive because of their ability to penetrate deeply into the layers of the esophagus to produce a liquifying necrosis Acids cause less destruction because they cause a coagulation of the superficial layers, forming a firm eschar which limits penetration to the deeper layers Destruction of the stomach is apt to be much more significant from acids The others, such as Lysol, may produce a mucosal surface erythema or superficial esophagitis, but the healing is rapid without sufficient scar to form strictures, therefore, this discussion of pathologic changes in the esophagus will be limited to ingested caustics

The relationship between the depth of penetration of the lye, and its concentration, has been shown in experimental animals by Krey,[3] who examined the effects of a ten-minute contact of different strengths of sodium hydroxide on the rabbit's esophagus He found that a N-solution (3 8 per cent) produced necrosis of the mucosa and submucosa, with some involvement of the inner longitudinal layers With a 3 N-solution (10 7 per cent), the necrosis extended to the circular muscle A 5 N-solution (16 4 per cent) involved the outer longitudinal muscle Necrosis extended throughout the esophageal wall with a 7 N-solution (22 5 per cent), and some effect occurred also to the periesophageal tissues These findings are significant when it is considered that ordinary washing powders may contain a concentration of caustic soda in excess of 7 N-solution, also, it is obvious that only small quantities of a concentrated caustic, mixed with the saliva and swallowed, may produce severe lesions of the esophagus Larger quantities of a more dilute solution, as in a suicidal or homicidal attempt, may cause not only severe trauma to the esophagus, but the stomach and duodenum are also in danger of involvement

The histopathologic tissue changes will depend upon the depth of penetration drink The seven-months-old baby was accidentally given phenol, which had been used as a toothache remedy by the family Another chewed a potassium permanganate tablet mistaken for candy Some ate from cans of lye crystals left open on the floor Others drank a solution of lye from bottles

From these findings, it is obvious that most of these accidental burns are due to the careless accessibility of open cans of lye to children, the placing of caustics in containers used for food (cup, glass, or soda pop bottle), or medicine cabinet accidents Lye in solution is a whitish, cloudy mixture which can easily be mistaken for milk by a child

Holinger and Johnston,[2] in their study of 96 cases during a 13-year period, found in the five to ten year age group, one who drank lye on a "dare," and another who drank muriatic acid from a coke bottle In the 11 to 20 age group, all were females, most of whom drank a corrosive chemical because of disappointment in love Over age 20 were those with psychopathic personalities intent on suicide

TABLE II

Age	No of Cases
7 months to 2 years	32
3 years to 5 years	19
6 years to 12 years	0

All of the cases in the present study can be considered accidental, since they were age five or under, and a social service worker examined the homes and carefully questioned the parents when any possible suspicious circumstance was encountered In none was there found any evidence of homicidal intent

PATHOLOGY

As previously stated, lye in its pure form, or in the commercial products where it is present in high concentrations, is by far the most damaging agent In the present series, none of the other chemicals caused significant changes in the esophagus Other reports in the literature contain cases of

When healing is finally accomplished, a dense fibrous coat has replaced the submucosa and muscular layers, and the newly formed epithelium is of a low stratified type without glands This end-result consists of an esophageal lumen with many pockets and channels, or the lumen may be completely obliterated

3 A still deeper penetration will cause necrosis through the entire wall of the esophagus causing a periesophagitis, and may even result in perforation with mediastinitis, pericarditis, or broncho-esophageal fistula A burn of this severity may not allow the patient to live through the stages of contraction and stricture formation Blassingame, et al ,[5] list early deaths as being due to severe pulmonary edema from aspiration of lye solution, massive necrotizing esophagitis, or severe shock

SIGNS AND SYMPTOMS

Marked edema and redness is evident immediately on the parts contacted by the corrosive The lower lip is usually involved to the greatest degree, with the mouth, tongue and pharynx being involved to a lesser extent A white membrane forms very rapidly in the more severely burned areas Immediate dysphagia occurs, accompanied by profuse salivation, which lasts from two or three days to a week.

DIAGNOSIS

Every patient with a history of ingestion, or evidence exhibited by burns of the lips, mouth, or pharynx from contact with a corrosive, must be considered to have an esophageal burn until proven otherwise A dilute solution may not show mouth burns, because of an extra heavy coating of mucous and saliva at the time of the ingestion, but still cause damage to the delicate esophageal membrane, therefore, suspicion of a burn of the esophagus should be aroused on history alone It was felt by the author that many of these patients with presumptive evidence of ingestion of a corrosive, did not suffer significant esophageal damage, and for this reason the 51 patients included in this study were esophagoscoped

1 A superficial burn may be represented by only a surface erythema, or there may be destruction of areas of surface mucosa without damage to the deeper tissues These areas will heal without scar formation, and there need be no fear of a stricture

2 A deeper burn will penetrate the submucosal and muscular layers, causing a desquamation of the mucosa, leaving these underlying layers exposed Belinoff[4] divided the course of this degree burn into the four stages of necrosis, ulceration, granulation, and scar formation, from observations on the experimentally-burned dog's esophagus The tissue cells of the submucosal coats are destroyed by coagulation of the intracellular proteins, and an intense inflammatory reaction is set up All layers of the esophagus have become involved in this acute inflammation during the first week, and the organ becomes semi-rigid The inflammation also involves the myenteric plexus of nerves, including both Meisner's and Auerbach's, so that both the muscles and nerves are involved in the degenerative process During this stage, the patient is seriously ill and is frequently unable to swallow his own saliva

Following this, new blood vessels begin to form with the proliferation of numerous fibroblasts By the end of the second week, collagen fibers have been laid down by the fibroblasts to fill the defect Extensive granulations form with new blood vessels freely ramifying through this newly formed connective tissue At this time, the swallowing function returns approximately to normal, and the patient may be mistakenly believed to be out of trouble

Beginning about the third week, the collagen fibers begin to contract Adhesions, forming between the granulating areas, form bands and pockets with gradual narrowing of the esophagus As this contraction continues over a period of several months, the return of dysphagia may be apparent only in a change of the patient's eating habits, he will eat fewer solids, washing down each mouthful with water or milk, and he will learn to gag himself to raise food when it becomes impacted has been done in most cases since the beginning of the study in 1952, by repeated barium examinations, and none to the present time has shown evidence of esophageal narrowing. If any of these patients should develop dysphagia in the future, it is safe to assume that the narrowing would be of the semi-lunar or "shelf type," which would respond readily to a few dilatations.

It is also demonstrated in Table III that the long prevalent assumption that lye burns of the lips, tongue, mouth and pharynx usually infer esophageal damage is false, since only eight out of 43 patients were found to have burns of the esophagus requiring treatment. These findings are even more startling than those of Cody[11] who reports a series of 23 cases of mouth burns in which only 12 demonstrated esophageal pathology. From these data it is obvious that a false impression may have been presented by many of the reports in the literature of the prevention of stricture formation by early dilatation, since a large percentage of these patients undoubtedly had no esophageal damage at the beginning.

The findings in this case study would agree with Stumboff,[12] who asserts that esophagoscopy can be safely performed during the first stage of an essophageal burn "because the wall of the esophagus is covered with a thick membrane," and he doesn't feel that it is a safe procedure later during the presence of ulcerations and granulations. Daly[13] warns against esophagoscopy in the third week, when scar tissue contraction has begun. This belief is supported by one of our cases, when there were no complications following diagnostic esophagoscopy done eight days after the ingestion of lye, in which a severe burn was demonstrated, however, an ill-advised esophagosocpy and dilatation two weeks later resulted in perforation, followed the next day by air and exudate in the right pleural space and mediastinitis, and death within two days.

It has been our practice to use general anesthesia to reduce risk of trauma, and a careful examination of the hypopharynx is done before entering the esophagus. If a burn is found in this area, the esophagoscope is carefully introduced through from five to ten days after the accident It was felt that this was the *only way of making a positive diagnosis* of an esophageal burn, other than waiting for the formation of a stricture

Many authors have condemned early esophagoscopy because of the supposed hazard of perforation Others recommend delaying the procedure for two to three weeks (Jackson,[6] Woodward[7]) Lederer[8] advises that esophagoscopic examination is indicated only in "those patients who have no burns in the mouth or pharynx and when the agent is not known" Hanckel[9] states that esophagoscopy should be done in all cases, but not for several weeks after the burn has occurred in order to avoid perforation

Analysis of the 51 cases in this study has proven esophagoscopy to be a safe procedure, when done during the first five to ten days, *in that there were no complications from the* procedure in a single instance, and most of the examinations were done by the resident, in training, under competent staff supervision The value of such a procedure is shown in Table III, where 34 patients had no evidence of esophageal burn, nine had areas of mild erythema which required no treatment, and only eight demonstrated a burn requiring follow-up treatment *Many unnecessary and unpleasant treatments by* dilatation were thus avoided by 43 patients, much valuable time by the medical staff was preserved, and several extra days of expensive hospitalization and precious beds were saved

TABLE III

Physical Findings	No of Cases	Degree of Burn (Esophagoscopy) None	Mild (Erythema)	Moderate
Burns of Lip, Mouth, Tongue, or Pharynx	43	27	9	7
No Visible Burns External	8	7	0	1

It is granted that there has not been enough lapse of time in the more recent cases to be sure that the untreated cases may not develop a narrowing of the esophagus at a future date Stothers[10] mentions a case of sudden acute impaction occurring 40 years after the accident, however, follow-up extent and depth of penetration The resulting fibrosis of the gastric mucosa obliterates the gastric glands, altering digestion Varying degrees of pyloric stenosis will be caused by cicatricial penetrating burns

TREATMENT

As in causes of other serious accidents, treatment should begin with prevention The passage of the "Federal Caustic Act," requiring the use of conspicuous "Poison" labels, which was accomplished by years of work from the Committee on Lye Legislation of the Section on Laryngology of the American Medical Association, has reduced the incidence of lye burns to the esophagus by 90 per cent according to Jackson[6] The remaining 10 per cent would be greatly reduced if the public were educated to the seriousness of corrosive ingestion so that these preparations would not be brought into the home unless absolutely necessary, and any excess would be promptly discarded or made inaccessible to children The cases of suicidal intent cannot be reduced, of course, except by restriction of sale of these preparations to the public

For convenience, management of esophageal burns can be divided into immediate treatment, intermediate therapy, and the treatment of the formed stricture

Immediate Treatment

Attempt at neutralization is advocated by most authorities Administration of vinegar in one-half strength, dilute acetic acid (2 per cent), or orange juice, along with copious amounts of water, is recommended for ingested alkalies Sodium bicarbonate in water is suggested for neutralizing acids Kiviranta[16] demonstrated that antidotes have no value unless administered immediately, he found no evidence that attempts to neutralize after the first minute had any effect on the clinical course of the patient, and even taken within one minute it did not prevent injury to the tissues by a corrosive substance The thought has also been advanced that the chemical action of neutralization might produce enough heat even to increase the burn the cricopharyngeus and advance of the instrument is immediately halted at the first sign of damage except in the presence of only mucosal erythema In case of the latter, the examination is continued until signs of actual penetration are encountered

Under these circumstances, it is felt that the procedure carries little if any risk, while offering valuable information as

1 Proof of whether further treatment is necessary

2 Estimation of the length of time treatment dilatations will be necessary A complete circumferential burn will have to be dilated over a much longer period of time, if cure is possible, than one which involves only part of the circumference

3 Value of early bouginage can be more accurately evaluated

4 Prognosis as to whether dilatations will provide a cure A deep, ulcerated, cicatricial burn will probably form a stricture in spite of dilatations

Although diagnosis of stomach damage, resulting from the swallowing of a corrosive, is not included under the subject of this review, possibility of its occurrence must always be kept in mind McKibben and Lee[14] warn that pyloric stenosis has not only been reported in patients with esophageal stricture, but has occurred also in patients with no demonstrable esophageal lesion

A review of the literature back to 1882, by Gray and Holmes[15] in 1948, revealed 139 cases of pyloric stenosis following the ingestion of some corrosive Although alkalies will exert most of their damaging effect on the esophagus, and acids on the stomach, the swallowing of an alkali can cause severe damage to the stomach Conversely, acid ingestion can cause esophageal trauma, and in most cases where an acid causes an esophageal stricture, a stricture at the pylorus of the stomach will also occur As in the esophagus, the severity of stricture at the pylorus will depend on the was no difference in the amount of granulations if Cortisone administration was delayed over 48 hours after the injury

Rosenberg and associates[20] reported that large doses of Cortisone resulted in a remarkable decrease in the tendency towards fibrous stricture formation in lye burns of the rabbit's esophagus, but there was spontaneous perforation of the esophagus in five of the 44 rabbits under Cortisone, which they attributed to the antianabolic, antifibroplastic effects retarding the laying down of a granulation tissue barrier These experiments are paralleled by reported cases of exacerbation and perforation of existing peptic ulcers during treatment with Cortisone Weisskopf,[21] carrying out similar experiments on dogs, reported the formation of no strictures in the group treated with Cortisone, whereas all of the control animals living over 35 days developed strictures Eleven patients with presumptive evidence of esophageal lye burns (mouth burns and dysphagia) were given steroid therapy by Ray and Morgan[22] Of these, ten patients did not develop strictures, and one formed a clinical stricture after three months, the one failure was attributed to the Cortisone's not having been started until four days after the lye ingestion

From the preceding investigations, it is apparent that Cortisone therapy, if started within the second day of the accident, will greatly reduce the number of strictures resulting from ingested lye, but a note of caution must be inserted regarding the possibility of its use promoting a greater risk of esophageal perforation and mediastinal infections

The swallowing of a string, as soon as possible, during the acute phase is recommended by most authorities This helps to prevent complete atresia in severe cicatricial burns, and provides a guide for later endoscopic examination and dilation The use of an indwelling feeding tube is unwise, because of the danger of pulmonary complications and because of its acting as a foreign body to stimulate greater formation of granulations Daly[13] also suggests that it may delay the passage of food with the result that food particles may become enmeshed in the granulations, also causing foreign body reaction

Stomach lavage is contraindicated when the ingested agent is an alkali (Crowe[17]), because of the danger of further damage to the walls of the esophagus and stomach. When the agent is an acid, washing-out of the stomach might be of value in avoiding pyloric stricture.

Administration of olive oil and milk during the first 24 to 48 hours at frequent intervals, is generally accepted treatment of value. They have a soothing influence on the inflamed areas.

Since the patient will frequently refuse to swallow, even his own saliva, during the first two or three days, intravenous fluids may be indicated to prevent dehydration and to provide nourishment. Addition of vitamins *B* and *C* to these parenteral feedings may promote healing.

A bland soft or liquid diet can be given as soon as the patient will swallow, except in the very severe burns where perforation of the esophagus may be suspected.

Adequate antibiotic therapy should be started at once in the form of penicillin and streptomycin, or the "broad spectrum" variety. It was demonstrated by Bosher, Burford, and Ackerman,[18] in their experimentally produced lye burns of the esophagi of dogs, that there was evidence of bacterial invasion of the muscularis varying from actual phlegmon formation to localized intramural abscesses, within 48 hours, therefore, the amount of eventual scarring, and the danger of complications from immediate perforation, will be greatly lessened with the early institution of vigorous antibiotic therapy.

Cortisone administration during the acute phase has several enthusiatic supporters. Many experiments have been carried out on animals which demonstrate the potent inhibitory influence of Cortisone on the inflammatory response of tissue to injury. Spain, Molomert, and Haber,[19] in mice experiments, found scant collections of fibroblasts, insignificant collagen formation, and no new capillaries, if Cortisone was started within the first few hours of injury, however, there course of treatment, daily dilatations were again resumed. Each treatment was begun with a bougie two sizes smaller than the largest used in the preceding treatment. The largest bougie used in each treatment was left in place for as long as possible up to 30 minutes. Of the 41 patients treated by this method, only one developed a stricture, conversely, of 14 patients of their series who received no dilatations, six formed strictures. The safety of this method was demonstrated by no accidents or deaths occurring in the 41 patients so treated.

The rationale for treatment of esophageal burns by early dilatations is based on the supposition that contraction of the collagen fibers laid down in the damaged area, is prevented. This form of treatment has also been championed by Crowe,[27] Kernodle,[28] and Holinger.[29]

Other authors disagree with the management of esophageal burns by early dilatations. This is based on the belief that the esophagus should be put at complete rest during the inflamed period, and that early dilatation serves only to maintain the inflammatory state. Stumboff[12] recommends direct bouginage through the esophagoscope when the stricture starts to form on the third to the sixth week. Dilatations were started by Vinson[30] only after the lumen had contracted by scar tissue to a size that would not permit the free passage of fluids, his report included a high percentage of deaths, revealing the danger of vigorous dilatation of a contracted scar.

Belief that dilatations of any kind are useless, was expressed by Burford, et al.,[31] who felt that modern esophageal surgery had outmoded this form of treatment. They maintained that all established strictures of the esophagus were surgical problems.

Late Treatment

When a cicatricial stricture has formed, weighted bougies of the type used in early dilatations are not effective, although they may still be of value in the semi-lunar or "shelf type" of narrowing.

Blind bouginage, other than with the mercury or lead-filled

Intermediate Therapy

Since the burned esophagus tends to start contraction during the third week, prevention of a stricture becomes the main concern during this latent phase Supportive measures should be continued as outlined under immediate treatment In addition, the advisability of dilating the damaged esophagus, as soon as the patient is able to swallow, must be considered

Salzer[23] is credited with being the first to advocate early dilatations In 1920 he reported 12 cases in which dilatations had been started on the second to sixth day after ingestion of the corrosive

Attention was drawn to Salzer's report by Bokay,[24] in 1924, when he reported the use of early dilatations in 132 patients with excellent results in 117 Good results in 90 per cent of 180 patients was reported in 1934 by Salzer[25] with his method of early dilatations

In this country, Martin and Arena[26] reviewed the subject of lye ingestion and reported three cases of early dilatation in 1939

Early dilatations were begun, in 1924, by Gellis and Holt[27] in the Harriet Lane Home of the Johns Hopkins Hospital They reported on 110 children with a history of lye ingestion in 1942 Dilatations in 41 of these patients were started immediately if there was not great swelling of the fauces, and it was never postponed more than four days Bougies consisting of soft rubber catheters filled with lead shot were used from No 14 to 34 French Dilatations were started with a small size bougie and worked up until the largest size passed with difficulty No force was used in passing the bougie, and if evidence of bleeding appeared the treatment was discontinued for the day The amount of treatment required was found to vary with each patient, however, the usual schedule consisted of daily dilatations for two weeks, three times a week for the next two weeks, twice a week for two months, once a month for six months and two or three times a year for two or three years

If any increasing difficulty was encountered during the

4 Persistent ulceration for many weeks, as evidenced by blood streaking on the bougie

5 When the scarred esophagus cannot be dilated without danger of periesophagitis and mediastinitus

6 When cooperation of the patient cannot be obtained for the necessary regular dilatations because of a psychotic personality

Surgery of the esophagus has made great advances during the past 20 years, due to improved surgical techniques, greater knowledge of physiology concerning fluid and electrolyte balance, the great advances in anesthesiology, and the introduction of chemo- and antibiotic therapy

Many techniques have been developed for restoration of the normal swallowing mechanism in the damaged esophagus which cannot be rehabilitated by bouginage These methods can be conveniently divided into the antethoracic and intrathoracic approach

Antethoracic

In 1913 Torek[34] reported the first successful case of resection of the thoracic esophagus for carcinoma He brought the cervical stump of the esophagus out to the skin surface A long rubber tube was fixed in the gastrostomy opening, and the patient placed the other end into the cervical esophageal opening when he wished to swallow

A skin-lined tube connecting the cervical esophageal fistula with the gastrostomy opening was done on six patients by Yudin[34] in his report of 80 cases of surgical construction of the artificial esophagus He claimed a good functional result in these patients that survived, but one patient died between procedures, and two developed fatal peptic ulcers in the skin of the new esophagus This complication, plus the necessity of many surgical stages and prolonged hospitalization with a distasteful cosmetic result, has limited the use of this procedure

Subcutaneous jejunal substitution was used by Yudin in most of his cases, in conjunction with a cutaneous tube if type has long been condemned, because of the danger of hemorrhage, production of false passages, or perforation with mediastinitis Before other methods were available, Tucker[32] quotes Trousseau "Sooner or later, all cases of stricture of the esophagus die of the bougie"

If dilatation of the established stricture is considered to have a chance of success, the acceptable methods include

1 Direct dilatation through the esophagoscope, using Jackson dilators This method can be used in cases of a single stricture, but it is hazardous in the presence of multiple strictures

2 Olive-tipped bougies passed over a previously swallowed string eliminates the danger of the bougie entering a blind pouch This method does not require gastrostomy, and simplifies the task of the surgeon if *gastroesophageal anastomosis* is to be done later

3 Retrograde bouginage by the continuous string method of *Tucker*[32] *in gastrostomized patients*, is the safest *method* for extensive or multiple strictures

4 Pneumatic bougies placed under fluoroscopic control

It is generally accepted that dilatation of esophageal strictures should be continued until it becomes apparent that a functional esophagus cannot be obtained, or until it appears that further attempts at bouginage are dangerous Only then should a resort to surgical methods of repair be considered

The indications for abandoning dilatations and resorting to surgery are

1 Impermeable strictures *where there is a complete* stenosis and attempts to establish a lumen have failed

2 Scarring that has resulted *in pocketing* and marked irregularity or fistulas

3 Persistent poor response to dilatations where the lumen cannot be maintained at a functional size logically, to any form of external esophagoplasty as a method of restoring functional continuity of the upper alimentary tract"

Esophagogastric anastomosis may be the procedure of choice in strictures of the lower third of the esophagus As the level of the anastomosis goes beyond the level of the aortic arch, greater difficulty is encountered, especially with a previously gastrostomized scarred stomach, and the risk of an anastomotic leak is greatly increased

Fatti, et al,[11] reported 40 cases of esophagogastrostomy, all of which were anastomosed above the aortic arch There were 24 patients in whom restitution was complete, eight who required occasional bouginage, and eight who died after operation, a 20 per cent mortality They attributed the unsatisfactory results to the anastomosis being made at, or below the site of esophageal fibrosis The deaths occurred from peptic esophagitis and gastric ulceration with perforation

Intrathoracic esophagojejunostomy has been advocated by some authors for lesions involving the upper third of the esophagus Reinhoff[12] described this method of mobilization of the jejunum and anastomosis with the esophagus in 1946 The main disadvantage of this procedure is that the stomach, duodenum and upper jejunum are side-tracked by the food, and serve only to secrete juices into the intestinal tract

More recently, the ascending and transverse colon have been used in esophagocologastrostomy or pharyngocologastrostomy, and two cases were reported by Nardi[13] this year for repair of extensive lye strictures without resection of the esophagus Mahoney and Sherman[14] reported one case of total esophagoplasty, using intrathoracic right colon for carcinoma in 1954 This procedure has the advantage of the colon providing enough length so that the upper anastomosis can be made at the most optimal site, and all of the scarred area can be by-passed The colon also seems to have a higher resistance to the acid-peptic secretions of the stomach, as demonstrated by Dragstedt and Vaughan,[15] who found that a loop of colon transplanted to the stomach of a dog was the jejunum would not reach He feels that this is the procedure of choice, and he is joined in this belief by Finnerty,[15] however, the esthetic result of this procedure is also subject to criticism

Most surgeons at the present time feel that the antethoracic approach is obsolete in comparison with the improved methods of intrathoracic substitution

Intrathorac

Resection of the scarred area, and end-to-end anastomosis of the esophagus, can be done for the single short stricture of less than five cm Gross[36] in 1948 reported one successful case treated in this manner This type of repair is not frequently applicable, because cases severe enough to warrant surgical intervention usually have multiple strictures

Esophagogastrostomy, with or without resection of the damaged esophagus, has been very popular with many surgeons Biondi[37] is credited with doing the first studies for this procedure in 1895, but he reported difficulty with leakage, and frequent recurrence of stricture formation at the site of the anastomosis In their series of esophagogastrostomy in 52 dogs, Carter, et al ,[38] reported that no strictures formed if the end-to-side type of anastomosis was made, where one end of the esophagus was anastomosed either to the edges of the incision in the fundus of the stomach, or to the edge of a circular area excised from the fundus, they also reported an 89 per cent incidence of perforation at the line of anastomosis when no anchoring sutures were placed in the stomach or esophagus, and no incidence of perforations when both the stomach and esophagus were anchored in position

The first case of esophagogastrostomy found by this author, was that reported in 1935 by Decker,[39] done for carcinoma This procedure was championed by Sweet[40] in 1946, in his report of three successful cases done for esophageal stricture in which he states that, "in cases of intractable stricture of the esophagus resulting from chemical burns, an esophagectomy followed by a high intrathoracic esophagogastric anastomosis is superior anatomically, physiologically and psycho-the upper third with some delay of the barium Weekly dilatations with olive tipped bougies over a string were started Barium study of the esophagus 13 months later did not show any abnormality, although bouginage had been discontinued three months previously

A 16-month-old baby did not receive the advised follow-up treatment and developed a stricture requiring gastrostomy This patient is now under treatment with weekly retrograde bouginage She is currently dilated to a size-34 French This gastrostomy could probably have been avoided if early dilatations had been instituted

Another patient, who did not have follow-up treatment, became completely obstructed and a gastrostomy was done in another hospital When he came under our care, he had been fed through the gastrostomy for six months Numerous attempts to pass a string were unsuccessful External esophageal exploration was done by the surgical department, and a silk string was inserted, with the ends threaded into the mouth and out the gastrostomy fistula The patient expired 12 days after this procedure, with post-mortem findings of an esophagopleural fistula, left pyopneumothorax, pulmonary atelectasis, pneumonia, and barium in the lung and mediastinum

Comment Early treatment by bouginage might have rehabilitated this patient When attempts to pass a string failed, surgical reconstruction with one of the intrathoracic methods would have been preferable to the attempt that was made

The other patient of this series has been discussed previously He had no ill effects from diagnostic esophagoscopy done nine days after contact with lye, however, an ill-advised esophagoscopy done 27 days after the ingestion resulted in perforation and death in two days

Comment This case illustrates the safety of early esophagoscopy and the danger of the same procedure during the period of slough and scar tissue contraction If this patient had been started on dilatations with the mercury-filled bougies normal both macroscopically and microscopically after one year

It may not be practical to remove the scarred esophagus if there is considerable periesophageal fibrosis, since the planes are obliterated and severe bleeding may occur In such a case, the transected ends may be turned in to form a blind pouch Denton and Bradshaw[46] showed in experiments on nine dogs that the closed-off esophagus becomes a mucous filled cyst which produces no adverse effect The cyst is self-limited in size, since the pressure developed from within causes atrophy of the mucous glands If the esophagus is left *in situ* the vagi are not interrupted, and the annoying sequellae of gastric atony and retention are avoided, however, the possibility of carcinomatous development arising from the strictured site still remains Carver and associates[47] reported two such cases in their analysis of 233 patients with lye strictures, Cecil[48] reported two similar cases, and this author has had one in a patient that had undergone an esophagogastrostomy by the thoracic surgical department

When resection of the esophagus is done, it has been noted that the more rigorous the bouginage was pursued prior to surgery, the healthier the strictured portion appeared Cody[11] found cases in which there had been little or no effort at dilatation, to have the most reaction and infection

ANALYSIS OF CASE STUDY

In this series of 51 patients, with history of evidence of chemical ingestion, early diagnostic esophagoscopy revealed only eight that needed follow-up treatment

Four patients were treated by the "Salzer Method," approximately as outlined by Gellis and Holt[27] One had a complete circumferential burn of the upper third of the esophagus and the other three demonstrated linear burns All have been kept under observation for over two years, and none have developed signs of esophageal narrowing

One patient was not started on immediate bouginage, and an esophagogram one month later revealed narrowing in proaches are the most desirable, and of these, the use of the colon appears to offer the best chance of success

following the first esophagoscopy, he could probably have been rehabilitated

It appears evident that the five patients who received adequate peroral bouginage will have a satisfactory result The three others, who should have had the same treatment, might well have had a similar outcome

The nine patients who revealed areas of mild erythema by early esophagoscopy, so far have shown no need for further treatment These, and the 34 others who had no evidence of esophageal damage, escaped the unpleasant ordeal of repeated bouginage, and none have returned with evidence of esophageal narrowing

CONCLUSIONS

1 Diagnostic esophagoscopy is a safe procedure in lye burns of the esophagus when done within five to ten days after the ingestion

2 Every patient with a suspected lye burn of the esophagus should be examined by esophagoscopy during this period to determine presence or absence of a burn

3 Severity of a burn, approximate length of time treatment will be necessary, and chances of ultimate cure can be determined by this initial esophagoscopy

4 Esophagoscopy is a less safe procedure during the third and fourth week after the ingestion of lye

5 Ingested chemicals, other than lye, do not ordinarily penetrate to the extent of causing ultimate stricture formation in the esophagus

6 Early dilatations, with weighted bougies, is preferable to delaying them until the stricture has formed

7 Whether the procedure of dilatations is of the early or late variety, it should be given adequate chance of success before the recommendation of surgical intervention is advised

8 When surgery becomes indicated, the intrathoracic ap-

lowing, gagging, or cough It should permit manipulation of the instrument at the carina and in the bronchi, and passage of suction tip and biopsy forceps without stimulation of reflex coughing To obviate personal bias the endoscopists in this study were unaware of the method of anesthetization employed

3 Subjective Evaluation by the Patient The induction of anesthesia should be accomplished with a minimum of discomfort to the patient because of compromising positions distasteful solution in the mouth, etc The anesthesia should be sufficiently complete, that the actual operation causes neither pain nor discomfort In addition to pain or discomfort, freedom from a degree of reaction to the anesthesia characterized by apprehension, a feeling of ill-being, palpitation, increased perspiration, and faintness are considered significant in influencing the patient's interpretation of the satisfactoriness of the anesthesia

METHOD

Observations were made upon 67 consecutive diagnostic bronchoscopic examinations Premedication consisted of phenobarbital, 0 1 h s , the evening before operation, and seconal 0 1, and morphine sulfate, 0 016, by hypo approximately one hour before operation The patients were anesthetized in a room adjoining the bronchoscopy clinic, and care was taken that the bronchoscopist did not ascertain the method used The two methods were varied indiscriminately The spray-drop method was used in 29 cases and the transtracheal in 36 In the transtracheal group 3 cc of 5 per cent cocaine were introduced in 21 cases, and the same amount of 10 per cent cocaine in 15 cases Two cases were eliminated from the scoring because bronchoscopy was not completed, due to anatomical difficulties in introducing the instrument at the time of the investigation

EVALUATION

Results were observed and tabulated at the time of introduction of the scope, and again during manipulation of the intrument deep within the trachea or bronchi Each case was scored, using the arbitrary standards of 5 for excellent

TOPICAL ANESTHESIA FOR BRONCHOSCOPY*

JAMES R MCKINNEY, M D ,†
McKinney, Tex

The advantages and disadvantages of various anesthetic agents for anesthesia in bronchoscopy have been extensively argued This study is concerned with the employment of a single drug (cocaine) in varying concentrations and by different techniques We have tried to evaluate as objectively as possible the relative merits of the transtracheal technique of anesthetization as compared with a spray or drop instillation of the agent In the first of these the anesthetic is introduced into the tracheal lumen by a syringe and needle passed through the skin of the neck and the crico-thyroid membrane In the spray and drop method the pharynx is sprayed, using an atomizer and 5 to 10 minutes later, a laryngeal mirror is introduced and anesthetic solution dripped through the glottis into the larynx and trachea

The evaluation is based upon three criteria

1 *Safety*—which implies avoidance of systemic reaction to the drug and accidents inherent to the technique itself It is recognized that various drugs have relative degrees of safety in this respect, but both the total amounts in milligrams and the concentrations of cocaine used in this study are considered to be within acceptable limits

2 *Objective Evaluation by Endoscopist* Anesthesia must be adequate to permit the introduction of the bronchoscope without causing discomfort or provoking troublesome swal-

---

*This study was carried out under the direction of the late Dr James Carswell Jr Chief of Thoracic Surgery at the V A Hospital McKinney Texas The bronchoscopic procedures were performed by Drs Milton Hoffman and William Viar of that section and the anesthesias were administered by Drs Frank Davidson and James McKinney of the Section of Anesthesiology Observations of the factors chosen to satisfy the criteria were made as a joint effort by two or more of these physicians in each case The data were collected by Drs Davidson and McKinney The statical significance of the data was determined by Mr John Geers Clinical Psychologist attached to the Section of Anesthesiology

t = 1.33	d.f. = 35		Not significant

INTERPRETATION OF SIGNIFICANCE OF RESULTS

On the basis of this study it appears that the transtracheal technique is significantly superior to the spray and instillation technique for bronchoscopy, insofar as introduction of the in-

4 for good, 3 for fair, 2 for poor, and 1 for unsatisfactory, for each of these factors—swallowing, gagging, coughing, general comfort and general behavior during introduction of the bronchoscope Thus a perfect score for introduction was tabulated 5, 5, 5, 5, 5 with a total of 25, entirely unsatisfactory anesthesia for introduction resulted in a score of 1, 1, 1, 1, 1 with a total of 5

A second score was compiled for satisfactory results during manipulation of the instruments in the trachea, and based on the factors of coughing and general comfort and behavior These were similarly scored 5, 5, 5 for a total of 15 for entirely satisfactory, and 1, 1, 1 for a total of 3, if quite unsatisfactory

A summary of the scores follows

SUMMARY OF TRANSTRACHEAL VERSUS SPRAY TECHNIQUE

COMBINED NUTRITIONAL AND PSYCHOSOMATIC MANAGEMENT OF MUCOSAL DISEASE

The Stress Concept Applied to the Treatment of Ear, Nose, and Throat Diseases *

W D CURRIER, M D,

Pasadena, Calif

Dietary supplementation as part of the treatment of ear, nose and throat diseases has been so widely discussed in the literature that the subject seems well-nigh exhausted Convincing results were obtained with various dietary regimens and by the prescription of an appropriate vitamin therapy Clinical experience of this kind has been confirmed, not only by animal experiments but also by controlled tests in human volunteers, thus a number of deficiency diseases were recognized and standard treatment methods developed, but beyond these pathologic conditions there is a wide range of partial or potential deficiencies with ill-defined and variable signs and symptoms which may or may not respond to a change of diet or to vitamin therapy

Partial deficiencies or borderline states are by their very nature difficult to recognize Each case is different and occurs in an individual setting of physiologic and environmental conditions, thus generalizations are of doubtful value and little can be expected from use of the statistical method Animal experiments are at best suggestive, and the same holds true with regard to tests in volunteers or group observations Small wonder, then, that the field is rife with controversy and abounds with subjective statements from opposing camps Under these circumstances not much can be expected from a mere review of past observations, and the only hope for clarification of the issue lies in a fresh approach

strument is concerned, and also for actual manipulation within the trachea and bronchi

The relative ease with which transtracheal anesthesia can be accomplished, and the rapidity with which anesthesia develops are further factors which, while outside the scope of this investigation, lend significant support to the conclusion of its superiority

It is of interest that the substitution of 10 per cent for 5 per cent cocaine in the transtracheal technique did not significantly improve the anesthesia

Since this investigation was carried out the technique has been modified to permit the use of smaller quantities of solution for the procedure, and in most cases it has been found that 2 cc of solution are adequate

INTERNATIONAL SYMPOSIUM ON RADIOLOGY IN OTOLARYNGOLOGY

On December 7 and 8, 1958, the Gruppo Otorinolaryngologica of the Alta Italia will sponsor an International Symposium on Radiology in Otolaryngology under the direction of Prof Luigi Pietrantoni, Direttore della Clinica dell' Universita de Milan, Prof Ardumo Ratti, Direttore dell' latitudo di Radiologica dell' Universita de Milan, and Honorary President Prof Felice Perussia For further information write the Secretary of the Symposium, Clinica Otorinolaryngologica dell' Universite di Milan, via Commenda 16, Italy the days of Hippocrates,[15] but it was Selye's contribution that he based his all-encompassing concept on findings in the field of hormonal interaction and tested it by exact laboratory experiments

This new approach has greatly stimulated research as well as the treatment of various diseases The stress concept was taken up by different medical specialties, foremost among them endocrinology, with psychosomatics running a close second, but there is no branch of medicine which has not profited by the discovery of stressors and the evaluation of stress-producing situations With ever more sensitive techniques of investigation the number of stress-producing agents and situations is constantly increasing

It would, however, seem that in paying attention to specialized applications of the stress concept Selye's basic idea of a unified theory of disease has been lost sight of In the light of his original plan the most remarkable discoveries in the field of hormonal interaction, or in any other of the specialties, are only means of clarifying the common basis of health and disease A frame of reference for hitherto unrelated biological events has been established This is important for the recognition of pathologic processes, but its significance does not end there It is only one step from a unified concept of disease to a unified concept of therapy By improving several seemingly unrelated functions we come closer to the ultimate objective of all medicine—to promote health The coordination of as yet separate methods or procedures into an integrated plan of treatment holds out promise of a much greater and more lasting therapeutic effect

Research and therapeutic experience have progressed far enough for such a unified approach to be applied in the management of common ear, nose, and throat diseases This can be best demonstrated with regard to the status of the mucous membranes of the ear and the respiratory passages, in health and disease

Nobody will underestimate the value of topical treatment, particularly chemo- and antibiotic therapy, in combating carriers of infection, but still more important are the natural to the problem of dietary deficiencies and nutritional supplementation

We might begin by considering the basic difference between pathology (morphology) and biochemistry, as pointed out by Williams[21] He remarked that the pathologist is often unable to distinguish morphologically between healthy cells and those which are deficient in some essential principle Pathology is limited to the study of end-products of disease processes, while the field of biochemistry is much larger, concerned as it is with all phases of life—not only the destructive ones This distinction is of greatest importance in modern therapy which is no longer restricted to the treatment of symptoms, but also aims at improving the patient's general health by attention to the underlying factors

What is health? If we consult the dictionaries we do not receive any real answer Webster defines health as "the state of being hale or sound in body, mind, or soul, especially freedom from physical disease or pain " Essentially the same information comes from medical dictionaries Blakiston, for instance, tells us that health is "that condition of bodily soundness in which the functions are performed normally, a state of well being and freedom from disease " The reference to "normal" functions is not much of a lead either Ivy,[8] in a very thoughtful paper on "What is Normal or Normality?" arrives at a description of the physiologically normal condition of the body "as that relatively steady state which results from well integrated functions supported by margins of safety in materials, structures and processes," but he adds immediately that this is not "a definite reference point from which to measure or with which to make a comparison Provocative as this physiological statement may be, it is certainly too vague to serve as a directive in the selection of therapy, and leaves us with only a general notion of what might be achieved

At this point the stress concept, as proposed by Selye, comes to our aid His definition gives the term "stress" a specific meaning[14] it is an attempt to arrive at a unified basis for various disease processes and their signs and symptoms Others before had tried such a unified approach, since the days of Hippocrates,[15] but it was Selye's contribution that he based his all-encompassing concept on findings in the field of hormonal interaction and tested it by exact laboratory experiments.

This new approach has greatly stimulated research as well as the treatment of various diseases. The stress concept was taken up by different medical specialties, foremost among them endocrinology, with psychosomatics running a close second, but there is no branch of medicine which has not profited by the discovery of stressors and the evaluation of stress-producing situations. With ever more sensitive techniques of investigation the number of stress-producing agents and situations is constantly increasing.

It would, however, seem that in paying attention to specialized applications of the stress concept Selye's basic idea of a unified theory of disease has been lost sight of. In the light of his original plan the most remarkable discoveries in the field of hormonal interaction, or in any other of the specialties, are only means of clarifying the common basis of health and disease. A frame of reference for hitherto unrelated biological events has been established. This is important for the recognition of pathologic processes, but its significance does not end there. It is only one step from a unified concept of disease to a unified concept of therapy. By improving several seemingly unrelated functions we come closer to the ultimate objective of all medicine—to promote health. The coordination of as yet separate methods or procedures into an integrated plan of treatment holds out promise of a much greater and more lasting therapeutic effect.

Research and therapeutic experience have progressed far enough for such a unified approach to be applied in the management of common ear, nose, and throat diseases. This can be best demonstrated with regard to the status of the mucous membranes of the ear and the respiratory passages, in health and disease.

Nobody will underestimate the value of topical treatment, particularly chemo- and antibiotic therapy, in combating carriers of infection, but still more important are the natural defenses of the mucous membrane, or to put it differently, its ability to deal with noxious agents of any kind. It has been convincingly shown that resistance to infection is lowered in stressful life situations.[7] Similarly endocrine and autonomic disturbances result in impairment of the protective functions of the mucous membrane.[8] Nutritional deficiencies not only interfere with smooth recovery from disease, but also change the microscopic structure of the mucous membrane and lower its ability to resist the inroads of stress.[1]

Therapy along any one of these lines at times produces spectacular results. Topical treatment is likely to afford immediate relief, endocrine therapy often leads to remarkable improvement, psychotherapy in one form or another may resolve the conflict-laden situation and thereby remove psychic stress, better nutrition not only increases all-around health but has also been found effective in lowering the incidence of upper respiratory disease.[10] The most promising approach, however, would seem to be a combination of these two last-named treatment methods with topical therapy to alleviate the immediate complaint.[4] It will be shown that dietary supplementation and psychotherapy are mutually supportive, one potentiating the beneficial effects of the other.[11,17,18]

Such an integrated plan of therapy amounts to a practical application of Selye's original concept of stress. The various stressors and stress-producing situations are interlinked, and by attacking several of them simultaneously it is possible to influence the overall reaction pattern of the patient. The whole is more than the sum-total of its parts.

Examples of how stressors and stress-producing situations are interlinked might easily be found in all fields of medicine and by critical evaluation of any therapeutic approach. Concentrating on dietary supplementation, there can be no doubt that this measure by itself is often highly effective.[2,3] Recently Watson, of W. C. Kalash Laboratories, Pasadena, Calif.,[19] obtained significant relief of mental symptoms by inclusive dietary supplementation, but dietary intake represents only one aspect in a much more comprehensive setting of internal and external conditions which determine the degree of being of the human organism. This has been well express by Dann and Darby, after surveying the many experiments and clinical observations regarding dietary deficiencies, they came to the conclusion that "the introduction and universal consumption of an ideal diet would not ensure abounding health, it would lay only one of the foundation stones on which such health might be based. A multitude of environmental factors, including as not the least important, the individual's reaction to his fellow members in human society, must be in correct adjustment before such health can ensue."

That diet should be evaluated in a setting of numerous conditions affecting the external and internal environment has been still more impressively pointed out by Kruse.[11] A clear distinction is made between "nutrition" as a bodily process and "diet," which is defined as a regimen of food supporting the bodily processes of nutrition. At first this may appear quite arbitrary, but we must remember that an increase of dietary intake is routinely prescribed under such conditions of special stress as growth, pregnancy, and hard labor.

The recognition of multiple stress-producing factors has not remained without impact on the treatment of nutritional disturbances. Jolliffe,[9] for instance, states that the successful treatment of vitamin deficiencies "involves treatment, and whenever possible, the elimination of the stress or conditioning factors. It involves symptomatic treatment, for a comfortable patient is of great aid to recovery. It finally involves nutritional therapy in sufficient amounts over a sufficient period of time to evoke maximal reversal of the nutritional syndrome."

A similar plan for a unified management of diseases involving the mucosa of ear and respiratory passages has proved very successful during the past few years. While a detailed report is reserved for a later communication, a few of the underlying principles will be discussed in the following.

According to Selye[16] "the primary object of the stress reaction is the maintenance of life and the re-establishment of normalcy during and following damage or functional activity."

Topical treatment, if necessary, combined with systemic therapy will as a rule result in repair of damage to the mucosa and re-establishment of its physiologic functions. This constitutes adequate management as long as we consider diseases of the mucosa of ear and respiratory passages as merely incidental, somewhat on the order of an unfortunate accident, but such a purely mechanistic view, attributing mucosal disease entirely to a foreign invader or to some kind of extraneous cause is no longer tenable. Mucosal disease occurs as a result of disproportion between insult and ability to deal with it. Merely topical treatment, even if combined with systemic support of local defense, leaves the underlying condition of failing resistance unchanged. The presenting acute illness is actually an exacerbation of a chronic condition of lowered physiologic responses, and it is due to this weakening of natural defenses that stressors which otherwise might have remained innocuous are able to produce disease.

As long as management is restricted to dealing with the acute episode, the patient is left in the same condition of disease proneness as before—we have ministered to disease but not to health; thus stress is regarded as an exclusively negative factor, or as Whitehorn[20] puts it, "stress has become a bad word." In a provocative paper on "The Healthful Benefits of Stress" he remarks that "perspectives have become so distorted at times that health efforts are aimed too sweepingly at the elimination of stress or anxiety." This represents the observation of a psychiatrist, but Whitehorn's advice that "doctors should think more discriminatingly about stress" applies equally to other branches of medicine.

What does all this mean in terms of the treatment of patients with diseases of the mucosa of ear and respiratory passages? Chemo- and antibiotic therapy is applied, and pain relieving drugs are administered, but management is not limited to these emergency measures, and a long-range program to build up the patient's resistance is immediately initiated. Of course, this is not possible in all cases, as many patients look upon their doctor simply as a trouble shooter; they take off a few minutes from the job, rushing into the office and rushing out again, expecting immediate relief and perhaps a pep talk, but are not open to further advice Many others, however, have begun to wonder why they catch cold so frequently or why they are bothered by recurrent attacks of ear, nose, and throat diseases Patients of this type are not satisfied with temporary relief, and expect the physician to do something about their disease proneness If approached with tact and sympathy they will cooperate in a long-range medical program Here the suggestion of a change of diet or dietary supplementation will fall on fertile soil, and the patient has no difficulty in understanding that such measures must be continued for some time before tangible results can be expected, but to suggest dietary therapy without having first gained the patient's confidence will rarely prove successful

By offering psychological support and prescribing dietary supplementation, an attempt is made to utilize the episode of acute disease as a starting point for improving the natural resistance of the body[12] At least potentially a new trend has been set up, a spiral toward health replacing the old spiral toward disease

Selye has drawn attention to the fact that any disease is a crisis involving the entire system Still more far-reaching is his distinction between various types of adaptation to threatening stimuli Even in adapting to a state of lowered resistance the human organism exhibits its fundamental tendency toward self-preservation The unified approach to therapy, combining topical, systemic, psychologic and dietary management is designed to improve adaptation to every kind of stimulus, with the ultimate aim of increasing overall fitness

SUMMARY

Re-study of clinical and experimental data in the light of Selye's stress concept has resulted in a new plan for the management of mucosal disease, particularly of ear and respiratory passages Multiple stress-producing factors call for a unified approach to therapy Topical and systemic medication is administered to afford immediate relief, but at the same time long-term management, combining psychologic support and dietary supplementation, is instituted to increase the patient's resistance to disease

D E STAUNTON WISHART, M D ,

1888-1958

Dr D E Staunton Wishart died in Toronto in April, 1958, at the age of 69 He had been in ill-health for over a year, but carried on his work until a few months before his death

Dr Wishart was the son of Dr Gibb Wishart, who was a former professor of otolaryngology in the University of Toronto, so he was steeped in the traditions of medicine and the specialty in which he spent his medical career Educated at St Andrew's College and the University of Toronto, he received a B A degree from University College in 1909, and an M B from the Faculty of Medicine in 1915 He was an honor student throughout his medical school

During the first World War, Dr Wishart served in the Canadian Army Medical Corps and transferred to the Royal Army Medical Corps later He saw service in Gallipoli, Serbia, Macedonia and Palestine and was mentioned in dispatches at Salonika in 1917 On returning from overseas he took up the study of Otolaryngology and did post-graduate work in Boston, Philadelphia and Edinburgh, and on his return to Toronto was appointed to the staff of the Hospital for Sick Children He became chief of otolaryngology at the hospital and an assistant professor in the University, both of which positions he held until his retirement to private practice in 1953 He remained a graduate lecturer in the University

In 1939 Dr Wishart was appointed to the editorial staff of THE LARYNGOSCOPE and was assigned the subject of Rhinology in Children His annual reviews of the available literature on this subject were masterpieces He had an uncanny ability to get at the gist of a paper, and to cover it briefly, but thoroughly, in his Review

Dr Wishart was a member of the American Otological Society and was one of the few Canadians to become its President, which honor was conferred upon him in 1954 He was a former President of the Canadian Otolaryngological Society, a member of the American Laryngological Society, and the Royal Society of Medicine, London He delivered the Birkett Lecture in Montreal, in 1952, an outstanding honor in Canadian otolaryngology

One of Dr Wishart's chief interests was the study of deafness, and he did much research in the problems of hard-of-hearing children He founded the Clinic for the Prevention of Deafness, sponsored by the Atkinson Charitable Foundation at the Hospital for Sick Children, Toronto

Dr Wishart's main recreation interests were trout fishing golf, and his summer home at Georgian Bay among the Thirty Thousand Islands of Ontario He looked forward each year to his holiday there with his family

He is survived by his wife, two sons and a daughter

DIRECTORY OF OTOLARYNGOLOGIC SOCIETIES

(Secretaries of the various societies are requested to keep this information up to date)

AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Erling W Hansen 90 So Ninth St., Minneapolis, Minn
Executive Secretary Dr William L Benedict, Mayo Clinic, Rochester, Minn
Meeting Palmer House, Chicago, Ill

AMERICAN BOARD OF OTOLARYNGOLOGY

Meeting Palmer House, Chicago, Ill

AMERICAN BRONCHO ESOPHAGOLOGICAL ASSOCIATION

President Dr Francis W Davison, Geisinger Memorial Hospital, Danville, Pa
Vice-President Dr George S McReynolds, 615 N Boulevard, Galveston Tex
Secretary Dr F Johnson Putney, 1712 Locust St, Philadelphia 3, Pa
Treasurer Dr Verling K Hart 106 W 7th St Charlotte, N C
Meeting The Homestead, Hot Springs, Va, March 10 11 1959

AMERICAN LARYNGOLOGICAL ASSOCIATION

President Dr Fred W Dixon, Cleveland, Ohio
Secretary Dr James H Maxwell, Ann Arbor, Mich
Treasurer Dr Francis E LeJeune, New Orleans, La
Editor, Historian, and Librarian Dr Edwin N Broyles, Baltimore Md
Meeting The Homestead, Hot Springs, Va, March 8 9, 1959

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, INC

President Dr Gordon Hoople, 1100 E Genesee St, Syracuse 10, N Y
President Elect Dr Theo E Walsh, 640 So Kingshighway, St Louis 10, Mo
Secretary Dr C Stewart Nash, 700 Medical Arts Bldg, Rochester 7, N Y
Annual Meeting The Homestead Hot Springs Va March 10 11 12, 1959 (Mornings only)

Meeting of the Sections

Eastern Savoy Plaza, New York N Y, January 8 9, 1959

AMERICAN MEDICAL ASSOCIATION, SECTION ON LARYNGOLOGY, OTOLOGY AND RHINOLOGY

Chairman Dr Victor R Alfaro Washington D C
Vice-Chairman Dr Harold F Schuknecht, Detroit, Mich
Secretary Dr Walter E Heck San Francisco, Calif
Representative to Scientific Exhibit Dr Walter H Maloney, Cleveland, Ohio
Section Delegate Dr Gordon F Harkness Davenport Ia
Alternate Delegate Dr Dean M Lierle Iowa City, Ia
Meeting Atlantic City, June 8 12, 1959

AMERICAN OTOLOGICAL SOCIETY, INC

President Dr Moses Lurie, Boston Mass
President Elect Dr R. C Martin
Secretary Dr Lawrence R Boies, University Hospitals, Minneapolis 14, Minn
Place The Homestead, Hot Springs Va., 1959

AMERICAN OTORHINOLOGIC SOCIETY FOR THE ADVANCEMENT OF PLASTIC AND RECONSTRUCTIVE SURGERY

President Dr Joseph Gilbert 111 E 61st St, New York N Y
Vice-President Dr Kenneth Hinderer 402 Medical Arts Bldg Pittsburgh, Pa.
Secretary Dr Louis Joel Feit, 66 Park Ave, New York 16, N Y
Treasurer Dr Arnold L Caron, 36 Pleasant St Worchester Mass

AMERICAN RHINOLOGIC SOCIETY

President Dr Russell I Williams 408 Hynds Bldg, Cheyenne, Wyo
Secretary Dr Robert M Hansen, 1735 No Wheeler Ave Portland, Ore
Annual Clinical Session Illinois Masonic Hospital Chicago, Ill October 1958
Annual Meeting October 1958, Chicago Ill (Definite time and place to be announced later)

AMERICAN SOCIETY OF FACIAL PLASTIC SURGERY

President Dr Trent W Smith, 327 East State St. Columbus 15 Ohio
Vice-President Dr Oscar J Becker Chicago Ill
Secretary Dr Samuel M Bloom 123 East 83 St., New York 28, N Y
Meeting November 12 1958 in conjunction with the Section on Laryngology Rhinology and Otology of the Medical Society of the County of Kings and Academy of Medicine of Brooklyn 1313 Bedford Ave Brooklyn N Y

AMERICAN SOCIETY OF OPHTHALMOLOGIC AND OTOLARYNGOLOGIC ALLERGY

President Dr Joseph W Hampsey Grant Bldg Pittsburgh 19 Pa
Secretary Treasurer Dr Daniel S DeStio 121 S Highland Ave Pittsburgh 6 Pa.
Annual Meeting Palmer House Chicago Ill October 16 17 1958

ASSOCIACAO MEDICA DO INSTITUTO PENIDO BURNIER—CAMPINAS

President Dr Antonio Augusto de Almeida
First Secretary Dr Alberto Galo
Second Secretary Dr Alfredo Porto
Librarian Treasurer Dr L de Souza Queiroz
Editors for the Archives of the Society Dr J Penido Burnier, Dr Guedes de Melo Filho and Dr Roberto Franco do Amaral
Meetings Twice every month, first and third Thursday, 8 30 P M

ASOCIACION DE OTORRINOLARINGOLOGIA Y BRONCOESOFAGOLOGIA DE GUATEMALA

Presidente Dr Julio Quevedo, 15 Calle Oriente No 5
First Vice-Presidente Dr Héctor Cruz, 3a Avenida Sur No 72
Second Vice-Presidente Dr José Luis Escamilla, 5a Calle Poniente No 48
Secretario-Tesorero Dr Horace Polanco 13 Calle Poniente No 9 D

ASOCIACION DE OTO RINO LARINGOLOGIA DE BARCELONA, SPAIN

Presidente Dr J Abello
Vice-Presidente Dr Luis Suñe Medan
Secretario Dr Jorge Perellò, 319 Provenza, Barcelona.
Vice-Secretario Dr A Pinart.
Vocal Dr J M Ferrando

BALTIMORE NOSE AND THROAT SOCIETY

Chairman Dr Walter E Loch, 1039 No Calvert St , Baltimore, Maryland
Secretary Treasurer Dr Theodore A. Schwartz

BUENOS AIRES CLUB OTOLARINGOLOGICO

Presidente Dr K Segre
Vice-Presidente Dr A. P Belou
Secretario Dr S A Aranz
Pro Secretario Dr J M Tato
Tesorero Dr F Games
Pro Tesorero Dr J A Bello

CANADIAN OTOLARYNGOLOGICAL SOCIETY SOCIETE CANADIENNE D'OTOLARYNGOLOGIE

President Dr Robert T Hayes, 42 Cobourg St St. John N B
Secretary Dr Donald M McRae, 324 Spring Garden Rd Halifax, N S

CENTRAL ILLINOIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr G C Otrich, Belleville Ill
President Elect Dr Phil R McGrath Peoria Ill
Secretary Treasurer Dr Alfred G Schultz Jacksonville, Ill

CHICAGO LARYNGOLOGICAL AND OTOLOGICAL SOCIETY

President Dr Stanton A. Friedberg, 122 So Michigan Ave, Chicago 3 Ill.
Vice-President Dr Maurice Snitman, 408 So 5th Ave, Maywood Ill
Secretary Treasurer Dr Fletcher Austin, 700 No Michigan Ave Chicago 11, Ill.
Meeting First Monday of each Month October through May

CHILEAN SOCIETY OF OTOLARYNGOLOGY

President Dr Enrique Grünwald S
Vice-President Dr Agustin Estartus
Secretary Dr Marcos Chaimovich S
Treasurer Dr Benjamin Kapkan K
Director Dr Alberto Basterrica A.

COLORADO OTOLARYNGOLOGY SOCIETY

President Dr James T Blair Denver Colo
Vice-President Dr James Rigg Grand Junction Colo
Secretary Dr Will P Pirkey Denver Colo

DALLAS ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Ludwig A. Michael, 3707 Gaston Ave Dallas, Tex.
Vice-President Dr Hal W Maxwell
Secretary Treasurer Dr Edward A Newell 1511 No Beckley, Dallas 8 Tex

FEDERACION ARGENTINA, DE SOCIEDADES DE OTORRINOLARINGOLOGIA.

Meeting October 14, 1958, Palmer House Chicago Ill

SOUTH CAROLINA SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr James H Gressette Orangeburg, S C
Vice-President Dr Robert P Jeanes, Easley S C
Secretary Treasurer Dr Roderick Macdonald 333 East Main St Rock Hill S Car
Meeting

SOUTHERN MEDICAL ASSOCIATION, SECTION ON OPHTHALMOLOGY AND OTOLARYNGOLOGY

Chairman Dr V Eugene Holcombe Charleston W Va.
Chairman Elect Dr G Slaughter FitzHugh Charlottesville Va.
Vice-Chairman Dr George M Haik New Orleans La
Secretary Dr Mercer G Lynch New Orleans La

VIRGINIA SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Benjamin Sheppard 301 Medical Arts Building Richmond Virginia.
President Elect Dr Emanuel U Wallerstein, Professional Building Richmond Virginia
Vice-President Dr Calvin T Burton Medical Arts Building Roanoke Virginia
Secretary Treasurer Dr Maynard P Smith 600 Professional Building, Richmond Virginia.
Meeting

WEST VIRGINIA ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr James K Stewart, Wheeling W Va.
Secretary-Treasurer Dr Frederick C Reel Charleston W Va.
Annual Meeting

NOTICE TO CONTRIBUTORS

THE LARYNGOSCOPE reserves the right of exclusive publication of all articles submitted This does not preclude their publication in Transactions of various Societies

Manuscripts should be typewritten, double spaced, on one side of paper only and with sufficient margins to allow for corrections

Author's name and city should appear directly under title on first page, street address at end of article

All prints or photographs to be submitted in black and white, in good sharp contrast Good halftones depend upon clear photographs Line drawings for zincs to be in black and white Colored inks or red or blue quadrille rulings will not reproduce

References should be complete author's surname, initials, title of article, Journal, volume, page, month, year

Six illustrations will be furnished for each article without cost to author Authors will please limit illustrations to six or assume the expense of additional illustrations

Proofs will be submitted to authors for corrections If these are not returned, articles will be published as corrected in this office

Reprints will be furnished at the following prices

WITHOUT COVER

	250 Copies	500 Copies	1000 Copies	2000 Copies

REVIEW OF AVAILABLE LITERATURE ON THE LARYNX FOR 1957 *

Francis E LeJeune, M D ,
and
Mercer Lynch, M D ,
New Orleans, La

ANATOMY

Pichler and Gisel,[1] who worked on 100 dissections with a dissecting microscope, caution against accepting the presence of an extralaryngeal motor ramus posterior to the recurrent nerve They observed that this branch supplied the mucosa and anastomosed with the posterior segment of the superior laryngeal nerve In their dissections the main nerve branched endolaryngeally, and a definite abductor and adductor branch could not be demonstrated These observations do not coincide with those of King and Gregg, Rustad or Morris and, therefore, present food for thought, as any definite conclusion at this time would be premature

In a study of the recurrent laryngeal nerve in cats, Murray[2] noted that the nerve supplying the intrinsic muscles of the larynx in these animals has a unimodal fiber-sized distribution He was also able to show that there are few or no proprioceptor fibers in this nerve Probably one of his most interesting observations is that in the recurrent laryngeal nerve there is a variable number of fibers of extravagal origin

---

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication Sept. 25 1958

Caparosa and Zavatsky[3] describe the anatomy of the cricothyroid space, emphasizing the paucity of vessels and vital structures They recommend this space as a site for emergency tracheotomy in the full sense of the word emergency Whenever possible, this procedure should be followed by the classical tracheotomy within eight to ten hours to prevent development of stenosis Complications are listed, and steps to prevent these are described

Clader and co-authors[4] realized that a detailed knowledge of the surgical anatomy of the superior and inferior laryngeal nerves and their corresponding thyroid arteries is essential for surgeons who undertake surgical procedures upon the thyroid gland For this reason, they undertook to dissect, study and photograph the thyroid compartment of the anterior portion of the neck of 50 recently embalmed bodies Their findings are well tabulated, and the photographs clearly show the variations of the inferior laryngeal nerve, which in one case, divided into six branches Forty-three per cent of the specimens in this series had nerves with from two to six extra laryngeal branches Their conclusions pointed out that external division of the superior laryngeal nerve is often in danger during ligation of the superior thyroid artery There is no constant relationship between the inferior thyroid artery and the inferior laryngeal nerve This is an excellent article for quick review before thyroid surgery

Gregg[5] undertook a study of the extralaryngeal nerves for the purpose of facilitating recognition of these structures when doing thyroid surgery Some of the types of vocal cord paralysis produced in dogs help us to understand what may occur in patients undergoing thyroidectomy Gregg advocates routine dissection of the recurrent laryngeal nerve in all thyroidectomies Injury to the extralaryngeal nerves with resulting paralysis may be temporary or permanent depending upon factors as yet not explained

Negus,[6] in his inimitable and thorough way presents an interesting and enlightening article dealing with the history of man from the standpoint of the nose and larynx The ease of his style and the manner of writing belie the vast amount of work and energy represented in this concise article For one who is interested in research or as a reference article this concise manuscript is invaluable

PHYSIOLOGY

The Semon lecture on the physiology of phonation was delivered in 1956 by Portmann[7] In this interesting lecture Portmann discusses at length the myo-elastic, or tonic theory, and the clonic theory, however, there is little unanimity of acceptance of either theory Those interested in this subject should read his article, which also gives much consideration to the three levels of stimulation the cortex, the diencephalon and the medulla oblongata

In order to test a hypothesis on the origin of the vibrations of the vocal folds Van Den Berg and Spoor[8] made some simultaneous recordings on the electromyogram of the thyro-arytenoideus muscle and the sound curve in a patient who had a stoma just above the larynx and whose laryngeal muscles presented themselves directly Electrodes were placed, one in the thyro-arytenoideus muscle and the other near the arytenoid The vibrations were in agreement with the results noted by Trendelenburg and Wullstein Van Den Berg and Spoor state that the microphonic effect of the larynx will manifest itself in all the recordings of the potentials of a large region of the internal laryngeal muscles They believe that this is the explanation for the synchronism claimed between the potentials in the recurrent nerve and the sound pattern

In his usual interesting, thorough manner Negus[9] presents a comprehensive article on the mechanism of the larynx which leaves little to be desired He begins with the evolution of the larynx from the simple vertebrates to man In covering the phase of evolution, he describes the physiology and anatomy of various types of animals One of the important functions of the larynx, little considered, is the assistance in blood and circulation by pump action The other functions of the larynx are fully discussed It is concluded that phonation was developed secondarily Negus emphasizes the point that when dealing with the production of sound, the larynx of man follows the general physiologic principles applicable to other vertebrates and is not subject to mechanisms of purely human design

In a discussion of the theory of the nature of the vibrations of the vocal cords, Froeschels[10] states that until recently it was almost the general opinion that the vibrations of the vocal cords are initiated by the stream of air and that the swing back is due to the elasticity of the cords The function of the recurrent nerves was considered to be the innervation of the muscles that open and close the glottis The cranial branch of the pneumogastric nerve, according to the theory, innervates the cricothyroid muscle, thus helping to elongate the vocal cords This is called the myo-elastic or aerodynamic-muscular theory Husson's neuromuscular theory is new, according to it every vocal vibration is due to a single impulse from the recurrent nerve and not to air pressure This function of the recurrent nerve is from central stimulation with acoustic center regulating the pitch Froeschels questions Husson's theory, pointing out that many patients with bilateral abductor paralysis have excellent voices In some of these the recurrent nerve had been accidentally severed during operation Froeschels has been unable to accept the facts as described in the Husson theory, but he believes that this interesting theory should be studied further before it can be fully accepted

Floyd and co-workers[11] report their observations on numerous experiments on the mechanism of phonation There are two main theories the tonic and the clonic, and the advocates of each are staunch believers in the validity of their theory Floyd and associates describe the action of the intrinsic muscles of the larynx on the function of the vocal cords They conclude that they do not agree that clonic contraction of the intrinsic muscles of the larynx is possible at rates above 110 C/S, and in consequence they give their full support to the older tonic theory

Van den Berg[12] reports that Piquet and associates took some high-speed motion pictures of the vibrations of the vocal folds during total laryngectomy without an air stream through the glottis Certain observations were recorded pertinent to the cause of vibrations of the vocal cords Their conclusions play a role in the current discussion of the myo-elastic and neuro-chronaxic theories of voice production Van den Berg discusses these at length and believes that Piquet and associates' attempts to prevent a flow of air through the glottis were unsucessful

ABNORMALITIES

Alonso and Regules[13] describe a simple procedure for treatment of congenital and cicatricial webs in the anterior portion of the larynx in children and adults They briefly review the methods now being used for amelioration or correction of the existing conditions and then describe their method, which consists of removing the web through a laryngoscope and then placing a thin polyethylene semi-circular plate with nylon thread attached to the straight edge of the plate The two ends of the nylon thread are introduced through the mouth into the larynx and brought out through the thyrohyoid and cricothyroid membranes, by this means the polyethylene plate is placed in the anterior portion of the larynx This plate is held in place by tying the nylon thread over rubber tubing The authors used this procedure only one year and, therefore, they have not performed it on many patients The procedure has much merit and will be used by many laryngologists in the due course of time

Respiratory distress in dogs may result from a number of causes Leonard[14] reports five cases of eversion of the lateral ventricles of the larynx responsible for respiratory distress In three of these dogs the protruding ventricles were removed with a tonsil snare All recovered and were free from respiratory distress

DIAGNOSIS

In an article on the radiologic investigation of diseases of the ear, nose and throat, Samuel[15] states that radiologic examination of the larynx cannot be regarded as complete until the cervical esophagus has been filled with barium and its outlines demonstrated. He describes the technique used in obtaining these radiographs and extols the merits of films of good quality. Malignant growths of the larynx will obliterate normal workings. The lateral view is of great value in assessing subglottic extension of such neoplasms.

Pirozok and associates[16] propose a method for rapid histologic diagnosis of infectious avian laryngotracheitis. All agree that this infection is highly contagious and fatal. Gross pathologic examination usually yields inconclusive results and other diagnostic methods are time-consuming. The method of obtaining reliable histologic sections mounted on slides described by Pirozok and associates requires three hours. They use Carbowax$^{\mathrm{W}}$® as an embedding medium for sectioning tracheas in the differential diagnosis of laryngotracheitis.

Powers and co-workers[17] present the results of their anatomic study of the larynx in which they used a contrast medium to obtain radiographs. Experiments proved that use of Dionosil,® introduced slowly into the hypopharynx and larynx after topical anesthetization, offered the best results for interpretation of existing disease, and functional and anatomic abnormalities.

INSTRUMENTS

Martin[18] presents a new type of pharyngolaryngoscope with a wide proximal end tapering to the distal end and containing an electric bulb for proper illumination. The wide proximal end permits binocular vision of the base of the tongue and vocal cords. There are three sets of tapered tubes that fit on one handle. The instrument is best employed with use of a general anesthetic, as Martin says it is not always practical to use a topical anesthetic.

Pitman[19] presents a new instrument for examination of the larynx of patients having extremely sensitive throats and anatomic difficulties. This instrument, modeled after the pattern of a nasopharyngoscope, is called by Pitman a *naso-laryngoscope*. It is introduced through one nostril after proper cocainization of the nose, by means of proper lenses, prisms and light, it is possible to obtain a view of the larynx when the tip of the instrument is placed through the nostril into the nasopharynx, and the illumination is directed downward for visualization of the larynx.

The tubular portion of the Jackson laryngoscope has been modified by Heinberg,[20] so that it is no longer a closed tube as in Jackson's instrument. The modification consists of an opening about one-half inch wide along the tubular wall whereby such things as instruments and suction tubes may readily be passed in or out of the laryngoscope.

DISEASES

In an excellent article, Jones and Camps[21] report results of a study of 29 cases of acute epiglottitis. The clinical picture is well described. The diagnosis is suspected by recognition of upper respiratory obstruction and is confirmed by the appearance of the epiglottis. Early recognition and immediate hospitalization are most important. The treatment "par excellence" is tracheotomy. The specific infecting organism in their patients was the hemophilus influenza, Type B, which responded favorably to treatment with chlortetracycline, the drug of choice for this condition.

In a brief, uninformative article Chia[22] reports a case of a patient having two diseases simultaneously. He believed that the patient suffered from tuberculosis of the cervical glands and larynx, and from an osteogenic sarcoma of the tibia with a secondary deposit in the first rib.

Heinberg[23] states that many changes in the concept of laryngeal obstruction in children have occurred during the past three decades. The medical profession has realized that infections other than diphtheria can cause obstruction of the airway. Chemotherapy and the antibiotics have resulted in management of these cases by the family physician or pediatrician, however, when the laryngitis becomes obstructive, the laryngologist is called. Heinberg pleads for early teamwork to prevent anoxia and toxemia. He discusses the various causes of laryngeal obstructiton and outlines the therapy.

Contact ulcer has been attributed to excessive use of the voice and exposure to irritants Ulcers due to emotional strain have been reported Rubenstein[24] presents such a case of an ulcer that persisted for many years despite all methods of surgical and medical treatment Finally, the conditions producing the severe emotional strain were removed, and immediately the ulcer healed spontaneously

In a brief but interesting article Pearson[25] describes a case of rheumatoid arthritis of the larynx in a 61-year-old man who had had rheumatoid arthritis for more than 30 years Dyspnea, due to limited abduction on respiration, developed necessitating tracheotomy Death was due to respiratory infection and consolidation Histologic sections of the larynx showed changes in the crico-arytenoid joints characteristic of rheumatoid arthritis If laryngeal stridor occurs in a case of rheumatoid arthritis, the most likely cause is involvement of the crico-arytenoid joints by the pathologic process

In discussing rheumatoid arthritis of the crico-arytenoid joints, Copeman[26] states that it is strange that no article in the English language appears to have been written on this subject He describes the crico-arytenoid joints in minute detail The outstanding symptom besides partial or total ankylosis of the joint is local tenderness on pressure over the larynx between the thyroid and cricoid cartilages laterally or centrally Copeman reports in detail three cases of rheumatoid arthritis of the larynx He states that the differential diagnosis in these types of cases appears to lie only between rheumatoid arthritis involving the crico-arytenoid joints and paralysis of the recurrent laryngeal nerves

Baker and Bywaters[27] report a case of laryngeal stridor in rheumatoid arthritis due to involvement of the crico-arytenoid joint Classical rheumatoid arthritis had exisited for four years Dyspnea and dysphagia gradually developed The left cord became fixed in a position of adduction and the right cord showed progressive loss of abduction The patient responded favorably to Cortisone therapy The authors stated that in retrospect the laryngeal picture resembled that of bilateral abductor paralysis

Muñoz MacCormick[28] discusses the three distinct types of leprosy, namely, the lepromatous, the tuberculoid and the indeterminate from the standpoint of pathology and clinical manifestations Lesions involve the mucous membranes, especially the nose, in 90 per cent of cases In the lepromatous or malignant type, the larynx is involved in 28 per cent of cases The laryngeal pathology is discussed, and the differential diagnosis between this disease, tuberculosis and syphilis is discussed Lastly, the known treatment is briefly considered with emphasis on investigative studies of drugs like isonicotinic acid and corticotropin This is a most interesting and thorough discussion of this seldom seen disease in this country

Obregon[29] reminds us that pemphigus of the larynx, although rare, is of great importance to the laryngologist, because the larynx may be the first site of the disease He considers four main types foliaceus, erythematosus, vegetans and vulgaris He concludes that pemphigus vulgaris is the type most frequently found in the larynx and reports two such cases Use of the Tzanck or Cantharides tests confirmed the diagnosis Corticosteroid therapy gave excellent results in both cases

Coleman[30] calls attention to the fact that apparently benign dysphagia associated with chronic hypochromic anemia in what is commonly known as the Plummer-Vinson syndrome must be regarded as a precancerous state, as it may progress to post-cricoid carcinoma The syndrome is almost exclusively confined to women Coleman reports the unusual case of a man in whom hypochromic anemia developed after partial gastrectomy The syndrome progressed to post-cricoid carcinoma, which is fairly common in women but hitherto unrecorded in a man

In a most interesting article Silcox[31] describes the powerful effect of corticosteroids in otolaryngological conditions Its anti-inflammatory action is fully discussed as well as its action on connective tissue permeability Use of corticosteroids for brief periods is reported as beneficial in acute edema of the larynx, contact ulcers and laryngeal polyps Silcox stresses the fact that corticosteroid therapy alone is never curative and always potentially dangerous

DIVERTICULA

According to Walls,[32] the diagnosis of laryngocele presents no difficulty provided the condition is kept in mind, since the lesion is rare The various types of laryngocele are described The symptoms will depend upon the extent of development and the location of the dilatation Usually the tumor enlarges when the intraglottic air pressure is increased Walls reports a case of bilateral laryngoceles of considerable size which were surgically removed with excellent results In his bibliography Walls fails to mention Felix LeBorgne of Montevideo, who presents many roentgenograms of laryngoceles in his excellent book on radiography of the larynx

Kodicek[33] reports a case of bilateral external laryngoceles in a man 77 years of age who had been blown up by a shell during the first World War His voice was extremely hoarse, and the large bilateral swelling in his neck was a source of much interest to his friends Palpation of the neck during quiet respiration revealed no abnormality When he was asked to phonate, an air-filled cyst appeared on each side of his neck in front of the sternocleido-mastoid muscle and extended from just below the angle of the lower jaw to about the level of the cricoid Kodicek describes three types of laryngocele and presents a diagram outlining these cysts He points out that these cysts of the laryngeal ventricle and saccule show great similarity to the ventricular air sacs present in some monkeys and apes

Price and associates[34] review briefly the early history of laryngoceles and the anatomy of this region The etiology, diagnosis and complications are discussed briefly, and the surgical technique for extirpation of a laryngocele is described in detail Two cases of successful operation are reported

PARALYSIS

Sometimes in hemiparalysis of the vocal cord an extreme lateral position of the cord is assumed Goodyear and Hogg[35] transplanted a section of cartilage from the superior border of the thyroid cartilage to correct this condition. This was inserted the length of the cord after the cord had been elevated following thyrotomy. When the patient was seen 21 days later, her voice was satisfactory and she was to return to work as a telephone operator the next day.

Reaves[36] states that the main factor in the differential diagnosis of bilateral abductor paralysis of the larynx and bilateral crico-arytenoid ankylosis is the fact that mirror laryngoscopy shows typical bowing of the anterior two-thirds of the cords on inspiration. The basic facts to be kept in mind are that in one there is permanent loss of muscle function, and in the other the laryngeal muscles are temporarily impaired in their action owing to immobile arytenoids. Reaves advocates bilateral arytenoidectomy for correction of bilateral crico-arytenoid ankylosis.

Neurologic complications have been described after injections of such antisera as tetanus, gas gangrene, diphtheria, pneumococcus, streptococcus, typhoid and rabies. The site of injection appears to be unimportant. Radiculitis affecting the fifth and sixth cervical roots is the most common anatomic site of neurologic complications of prophylactic inoculations. Bauer and Ellis[37] report a most interesting case in which a 31-year-old man received antitetanus serum into the right arm because of a cut on a finger. One week later development of neurologic symptoms necessitated hospitalization. Later paralysis of the right vocal cord developed, but four months later it spontaneously subsided. Bauer and Ellis concluded that the paralysis of the recurrent laryngeal nerve was undoubtedly a part of a generalized disease, and they express the hope that for prevention of tetanus, active immunization in the form of toxoid be used in preference to passive immunization by antitoxin, as it is less likely to cause neurologic complications.

In a most excellent, interesting article Arnold[38] presents the current concept of laryngeal paralysis. He prefaces his paper with the statement that whereas the advent of new drugs or bacteriologic advances have radically altered most aspects of medical practice, the problems of normal and diseased laryngeal innervation remain the same Arnold attempts to define the major problems of laryngeal paralysis by analyzing the representative bibliography from the following viewpoints value of animal experiments, chronologic changes in the concepts of laryngeal disease, discussion of central pathways and the peripheral course of the laryngeal nerves, *variability of terminal ramification of the recurrent* nerves and the present interpretation of the position of the paralyzed cords Semon's law is discussed at great length, and numerous opinions are quoted The conclusion reached is that Semon's rule of the greater vulnerability of the abductor fibers represents a clinical observation that signifies either an incipient sign of a progressive lesion or a terminal sign of subsiding paralysis

Melampri[39] presents a brief review of the occurrence of laryngoplegias in pseudobulbar paralysis, labioglossopharyngeal paralysis, multiple sclerosis, syringomyelia and tabes dorsalis observed between 1942 and 1956 On the basis of his personal findings and those of the reviewed literature the frequency of laryngoparalysis in the diseases mentioned appears unvaried with the exception of tabes dorsalis, which has shown a progressive reduction in incidence This may be the result of more efficient social prophylaxis, particularly introduction of the recently discovered treatments

Thornell[40] states that paralysis of the *vocal cords may* result from a variety of causes The most frequent cause of bilateral paralysis of the vocal cord is injury to the recurrent laryngeal nerves during thyroidectomy Bilateral paralysis in which the vocal cords are fixed in the median line is an extremely critical condition Emergency tracheotomy is usually necessary because the airway is inadequate In order to create an adequate airway Thornell devised intralaryngeal arytenoidectomy, which is performed with the aid of the Lynch suspension laryngoscope This ingenious procedure provides satisfactory results in the majority of cases We *thoroughly concur in* Thornell's warning against laceration of the mucous membrane on the medial aspect of the cartilage, as this will nullify the attempt to increase the glottic space

The findings of unilateral recurrent laryngeal nerve paralysis in an infant 11 months old aroused considerable interest, and because of its rarity, Ross and Chambers[41] report the case Two weeks before admission to the hospital the child cried with a hoarse voice Laryngoscopic examination revealed abduction paralysis of the right vocal cord No cause for the paralysis could be found at the time Two months later the condition became worse and bilateral papilledema developed At necropsy a tumor of the right side of the pons and medulla was found

Asherson[42] informs us that achalasia of the cricopharyngeus invariably accompanies bilateral recurrent laryngeal nerve paralysis In six of eight cases reported, some obstruction to swallowing of fluids could be demonstrated clinically In this form of achalasia there is little or no obstruction in swallowing solids Asherson reports a case of achalasia of the cricopharyngeus developing after bilateral abductor paralysis caused by bronchogenic carcinoma

Occurrence of postoperative laryngeal paralysis does not necessarily imply that the recurrent laryngeal nerve has been severed Ross and Sukis[43] carefully explain that there are many other causes for laryngeal paralysis and dysfunction, which are discussed in this excellent article The anatomy and variations of the recurrent nerve and its branches are well described The superior laryngeal nerve and its two branches are prone to injury in certain surgical procedures The importance of preoperative examination of candidates for thyroidectomy is stressed and repeated postoperative examinations are necessary because of the amazing changes that occasionally occur in the larynx When paralysis is unilateral, the patient can be encouraged by assurance that one-half of these paralyses are transient

STENOSIS

Tschiassny[44] discusses the various experiments producing laryngeal stenosis by bilateral division of the recurrent nerve with relief by inactivation of the cricothyroid muscle The experiments were conducted on animals and later on man with identical results These results brought forth a vigorous discussion relative to the validity *of Semon's law, and much* consideration is given to this problem Factors responsible for the cadaveric position of the vocal cords are considered, and results obtained by neurotomy of the superior and inferior laryngeal nerves are reported Superior laryngeal neurectomy resulted in the vocal cord's assuming the cadaveric position with a good airway In an extensive and interesting discussion Tschiassny presents factors responsible for failure and success of crico-arytenoid elimination and dwells at length on the mechanism responsible for opening the glottis as well as factors interfering with this opening He concludes that cricothyroid *elimination* cannot replace *modern and* the more complex methods of arytenoidectomy, lateropexy, or both, but that this technique may be used advantageously when restricted to its own territory

Milne[45] reports that introduction of an intubation tube *into a patient's larynx for induction of anesthesia* produced sufficient irritation in the subglottic region at the level of the cricoid cartilage eventually to cause dyspnea It is supposed that in this patient there occurred gradual development of stenosis at the level of the cricoid cartilage as a result of chronic but not pronounced inflammation, and passage of the tube produced acute exacerbation of the condition with narrowing of the lumen There is nothing in this report, however, to substantiate this supposition The stenosis was corrected by laryngofissure and Thiersch graft

SURGERY

In a unique article Bofenkampf[46] describes a relatively simple corrective operation for relief of aphagia after poliomyelitis The anatomy and physiology of the cricopharyngeus muscle are described Two cases of aphagia of three years' duration after poliomyelitis treated by denervation of the cricopharyngeus muscle are reported Through an incision *on the side of the neck the thyroid and cricoid* cartilages are exposed and rotated laterally and outward The cricopharyngeus *muscle is identified, and a small section* is removed from its posterior aspect In both patients thus treated normal swallowing occurred within 24 to 36 hours, and normal swallowing has persisted

In a most interesting and informative article on laryngeal and tracheal emergencies in the newborn, Miller[47] indicates the procedure for proper diagnosis Obstruction of the airway in the newborn or extremely young infant is a real emergency requiring accurate diagnosis to institute life-saving measures This at times can be difficult in these tiny patients

Miller enumerates the various problems that may contribute to obstruction of the airway, and concludes that many conditions other than atelectasis of the newborn and laryngeal obstruction must be considered in the very small infant presenting respiratory distress that requires emergency treatment All laryngologists should review accurate and concise articles such as this one in order to refresh partially forgotten facts

Lewis, Smitman and Loewy[48] describe and illustrate each stage of the reconstruction methods employed by them after laryngopharyngectomy Reconstruction of the hypopharyngeal-esophageal tube is undertaken as soon as the original wound has completely healed The various problems arising when doing this type of work are thoroughly discussed The illustrations of the methods of reconstruction make a difficult problem seem easy

In addition to cordal carcinoma DeBord[49] reports use of the laryngofissure approach for removal of foreign bodies, cysts and benign tumors, and for arytenoidectomy in patients with bilateral abductor paralysis For such conditions this approach provides better vision and enables manipulation and careful approximation of the mucosa postoperatively

Howie[50] reminds us that the operation of laryngofissure has many uses It is the only way to remove impacted foreign bodies in the larynx that have resisted removal by direct laryngoscopy Injuries and trauma to the larynx may require laryngofissure to readjust displaced fragments of cartilage or stenosis occurring from various causes enumerated in this article The main object of the laryngofissure operation is management of early cordal cancer, and the ideal type of lesion is a tumor of low gradation in which both extremities of a mobile cord are free Howie quotes statistics of British and American laryngologists on percentage of cures by laryngofissure and mentions use of radiation and teleradium in a provocative vein The conclusion reached is that laryngofissure used in proper cases gives excellent results This paper was freely discussed by Sir Victor Negus, Capps, Macbeth and many others who generally agreed with Howie and added nothing new to the original article

Clinical studies dealing with the psychologic reaction of the patient to laryngectomy, and those studies that evaluate the progress made by laryngectomized patients in programs for speech rehabilitation, should include all patients referred to a given program In this excellent article on evaluation of rehabilitation programs Lueders[51] advocates that a team comprised of the laryngologist, the speech therapist and the psychologist would appear to be best fitted for the task of evaluating the factors inherent in the non-cooperating group of patients Broadly, he states that the purpose of this team would be to determine by physical and psychologic examinations and by clinical experience whether esophageal voice training or a speech prosthesis (electro-larynx) is indicated to achieve maximum rehabilitation

In a discussion of the pseudoglottis in laryngectomized patients Micheli-Pellegrini[52] rejects the possible existence of pharyngeal elements capable of vibrating like vocal cords He does not believe that any esophageal element, and in particular the cricopharyngeus, is able to simulate a vibrating glottis Views of the various contributers on the subject of the so-called pseudoglottis in laryngectomized patients are discussed, mostly to disagree Michelli-Pellegrini believes that air flowing through a narrow section would produce sound, and that the most probable site for such a narrowing space would be between the base of the tongue and the posterior pharyngeal wall He states that the esophageal mouth constituted by the cricopharyngeus seems to represent those structures at which level fundamental sound is produced in the laryngectomized patient From reading this article it is evident that no unanimity of thought exists concerning the production of sound in a laryngectomized patient

Simon[53] is of the opinion that any operation on the thyroid gland, no matter how trivial, endangers the recurrent laryngeal nerve He believes that the incidence of nerve injury in thyroid surgery is much higher than present statistics indicate Non-functioning recurrent nerves are a terrific handicap and frequently blight the patient's life Simon maps out a triangle for protection of the recurrent nerve The triangle is bounded laterally by the common carotid artery, superiorly by the inferior thyroid artery and medially by the body of the recurrent nerve on the lateral border of the trachea Location and visualization of the nerve in this triangle practically assure that it will not be injured provided adequate care and gentle technique are observed

Mettler[54] reports a case of a mediastinal abscess that apparently lay dormant for seven months after laryngectomy It was diagnosed by roentgenography with use of barium, opened and drained

VOICE THERAPY

It has been noted that patients with simple conduction deafness tend to speak softly Cantor[55] suggests that in advising a patient to rest his voice a conduction deafness can be produced artificially by means of ear stoppers or ear muffs

The first part of Briess' article[56] deals with the history of voice therapy dating from the discovery of the laryngoscope by Garcia in 1854 This is followed by a discussion of the theory of voice production and the interplay of the laryngeal muscles in accomplishing this

Next is brought out the classification of the voice therapist and the order of testing depending upon the condition of the patient, whether there is a lesion on the cords, and the pathologic type of lesion The methods are then considered, and the techniques of carrying out these tests are explained This is the first part of a subsequent series of articles in which the means of correcting muscle pairs that are functioning out of balance will be described

Gartland[57] reports a case of injury to the thyroid cartilage without fracture producing a hematoma of the false cord and swelling of the arytenoid with fixation of the cord They used interrupted galvanic current under direct laryngoscopy to determine whether paralysis of the cord was due to nerve injury or to dislocation of the arytenoid The voice recovered for every day needs, but the cord remained immobile

Livesey[58] reports the case of a 20-year-old soldier who fell and struck his neck on a tent-peg Aphonia, coughing, hemoptysis and some pain developed immediately followed by dyspnea later The next day emergency tracheotomy was necessary Subsequent examination of the larynx showed a large hematoma on the left side Livesey warns that any heavy blow on the larynx may result in severe dyspnea and such accidents should never be considered too lightly

FOREIGN BODY

Zoller and Bowie[59] state that several cases have been reported in the literature in which calcifications of the neck were confused with foreign bodies of the food passages Calcification of the neck occurred in three successive cases of suspected foreign body of the esophagus in which the patient gave a history of swallowing a chicken bone and on esophagoscopy no foreign body was found These patients presented the problem of calcification of normal laryngeal cartilages These cases prompted Zoller and Bowie to review the literature and launch an investigation of this problem Numerous radiographs appear in the article showing normal calcifications of isolated portions of the laryngeal cartilages giving the impression of a foreign body It is acknowledged, however, that 98 per cent of foreign bodies of the esophagus are below the lower border of the cricoid cartilage

Feldman and associates[60] report a case of a piece of wooden tongue depressor breaking and being aspirated by the patient during a convulsive seizure A plea is made for care in the use of wooden tongue depressors under similar circumstances, and the danger is emphasized

BENIGN TUMORS

Epstein and Winston[61] express the opinion that intubation granuloma is a rare complication of endotracheal anesthesia There is no doubt that this condition is far more common than the 55 published cases would suggest Epstein and Winston state that intubation granulomas are invariably found on the vocal processes of the arytenoids We agree that the vocal process is by far the most frequent site of occurrence, but in our series of 25 unreported cases, we have had two patients in whom the granuloma occurred in the middle third of the vocal cords The histologic picture of these granulomas is simply that of nonspecific granulation tissue Various theories have been postulated in an attempt to explain their cause and site Evidence is offered to incriminate the role of static pressure rather than direct trauma as the most important etiologic factor

In an editorial[62] further emphasis is placed on the fact that greater care should be exercised in the introduction of the endotracheal tube at the time of induction of anesthesia in order to avoid the occurrence of granulomas

Figi and Berman[63] state that although primary amyloid deposits occur in many parts of the body, they are found most frequently in the laryngotracheal region Nine cases of amyloid tumors occurring in the larynx and trachea were seen during a period of six years, one of which is reported in detail Hoarseness was the chief complaint of all patients, and the treatment found most effective was surgical removal

Szpunar[64] correctly states that papillomatosis of the larynx in children represents a different morbid process from papilloma of the larynx of adults Whereas hyperkeratotic papilloma in the adult is considered a precancerous lesion, malignant degeneration of papillomatosis occurs rarely in children It is now thought that laryngeal papillomatosis in children does not undergo malignant degeneration unless irradiated For this reason, there is belief that irradiation and radical surgical excision should be banned in the treatment of laryngeal papilloma in children. Szpunar comments on the varied unsuccessful treatments used for papilloma of the larynx and then describes the treatment he used in 80 cases of multiple papillomatosis from 1946 to 1956 with good results. This consisted of injection of 0.1 to 0.5 ml. of stilbesterol into the larynx. Only one side of the larynx was injected at one time, as occasionally moderate swelling develops.

Studies in tissue growth of laryngeal papilloma were conducted by West and co-workers[65] using the suspended cell methods patterned after techniques suggested by Hanks. Observations suggested growths occurred more rapidly from laryngeal papilloma obtained from the larynx of both children and adults, than any other adult tissue cultured, either benign or malignant.

Woodman[66] presents a follow-up report of a case of a woman, aged 35 years, with multiple obstructive papillomas treated by a surgical technique in which a laryngofissure approach was used with submucosal dissection of the growth followed by insertion of an acrylic mold. The patient has remained free of recurrence for three years.

Capps[67] made a survey of the treatment of papilloma of the larynx by circulating a questionnaire to a number of colleagues in charge of clinics, he received 80 replies. He rightfully concluded that no accepted therapy will control these growths. The various treatments advocated are listed. The probable cause of stenosis in these cases is injury to the vocal cords and violation of the anterior commissure. In the treatment of such stenosis Capps advocates thyrotomy with excision of scar tissue and Thiersch grafts.

Huizinga[68] brands laryngeal papilloma as a mysterious tumor and from the present outlook fears that it will remain mysterious. Microscopically, there is no difference between papilloma in the child and in the adult, or between single papilloma and multiple papillomas. Huizinga admits that little is known about the etiology of multiple papillomas. He calls attention to the increase in incidence of multiple papillomas in Finland and the Netherlands after World War II, which he attributes to bad hygienic and social conditions We have been of the opinion for years that multiple papillomas occur predominantly in underprivileged children

Ono and associates[69] present a masterly discussion of the etiology of multiple papillomas and describe experiments unsuccessfully conducted for determination of the etiology Papilloma is the most common benign tumor of the larynx with the exception of the polyp, which is an inflammatory hyperplastic lesion The striking features of this tumor are its frequent occurrence in children, its resistance to treatment, its tendency to transplant itself, its tendency to recur and its spontaneous regression and disappearance after its existence for a number of years Among the possible etiologic factors discussed are hormones, chronic irritation and virus infections The thought is expressed that clinical and experimental observations point to the fact that virus is most likely a major causative agent This is an excellent presentation, which should be read in its entirety by those interested in this subject

Vettorato[70] reports a survey of 38 cases of papilloma of the larynx in children and adults and describes his therapy

Bjork and Hakosalo[71] conducted a study on the mitotic activity in benign and malignant papillomas of the larynx in adults, because it offered additional possibilities for evaluation of intra-epithelial anaplasia Pathologic mitosis is extremely rare in benign papillomas but fairly common in malignant papillomas The frequency of mitosis, and of pathologic mitosis in particular, is an important criterion in consideration of the possibility that papillomatous formations in the larynx are malignant.

In an interesting, informative article Bjork and Terr[72] report results of the comparative clinical and histologic study of benign and malignant papillomas of the larynx in adults Many authorities agree that the diagnosis of malignant tumor is often difficult to make in the case of papillomas Ullman is quoted as stating that single papillomas in adults show a tendency to malignant degeneration, and Altman is quoted as saying that intra-epithelial anaplastic changes are conclusive evidence of malignant growth in non-papillomatous laryngeal tumors, whereas the same signs in papillary tumors are less significant, however, Bjork and Teir consider intra-epithelial anaplastic changes to be of utmost significance in determining malignant degeneration Critical distinction is necessary in evaluating epithelial changes since benign papillomas can show some degree of atypia

Ciacovaner and Chodosh[73] report two most interesting cases One presented unusual symptoms and the other unusual therapeutic requirements The first patient suddenly noted a "fleshy mass" in his mouth On mirror examination of the larynx a large pedunculated mass was noted in the left pyriform fossa, the pedicle arose from the inferior portion of the left posterior pillar The possibility of glottic obstruction was appreciated, and surgical removal was accomplished without difficulty The second patient had a ventricular polyp which had to be removed by a laryngofissure approach Other polyps were encountered on the cords Seldom is it necessary to resort to such a procedure to remove polyps from the larynx, but large ventricular polyps present problems which at times, such as in this case, require a laryngofissure approach

Plasmocytoma is an uncommon tumor of the soft tissues of the upper respiratory tract, and as an intrinsic tumor of the larynx it is extremely rare Clark[74] reports such a case that caused recurrent hoarseness, dyspnea and dysphagia for two or three years On indirect laryngoscopy a large, soft polyp was seen between the vocal cords and appeared to originate from the right ventricle After removal, the pathologic diagnosis was plasmocytoma

Epiglottic cysts complicating anesthesia are rather uncommon Norris[75] reports two such cases which presented problems to the anesthesiologist Cysts of the epiglottis are not considered rare by the laryngologist, and frequently when found, they are symptomless Only when they assume large proportions, do they present problems Norris discusses the origin and classification of cysts of the epiglottis and the method of handling such cases when administering an anesthetic The difficulties and dangers resulting from unsuspected epiglottic cysts encountered during general anesthetization are well discussed

Asherson[26] states that a cyst of the epiglottis is usually considered to be a benign lesion, but this classification belies its deadly nature and is misleading if the cyst is large The most lethal of such cysts, despite their relatively small size and rarity, is the congenital juxta-laryngeal cyst that is a common cause of laryngeal obstruction in the neonate, 15 out of 20 resulting in death from asphyxia within a few weeks of life Even in the adult, large cysts of the epiglottis become dangerous as they increase in size and a pedunculated cyst may become impacted in the glottis with resultant asphyxia and death Asherson describes the various types of cysts and attempts an interesting classification of them He advises peroral removal of all cysts occurring in the epiglottis and upper portion of the larynx with the aid of the Davis tonsil mouth gag and removal of the plunging intra-laryngeal cyst by the external approach It is strange to the reviewers that Asherson does not mention utilization of suspension laryngoscopy for removal of laryngeal cysts, which to us is the ideal method

Epstein and co-authors[27] agree that in spite of much writing on vocal cord polyps, considerable confusion still exists in the literature as to nomenclature and histologic interpretation Their objective in this presentation was to analyze and assess the clinicopathologic significance of vocal cord polyps They analyzed 283 cases of vocal cord polyps histologically and clinically and discuss the pitfalls of nomenclature Polyps and their clinical variants are not neoplasms, consequently, use of such terms as fibroma, angioma or myxoma is not correct True benign neoplasms of the vocal cord, with the exception of papillomas, are excessively rare This is a most excellent article and should be studied by the laryngopathologist

In an excellent, thorough article on benign tumors of the larynx, Capps[28] excluded from discussion nodes, polyps, cysts and some fibromas, which are probably the result of trauma or inflammation He states that compared with malignant growths of the larynx, benign tumors are rare Papillomas are outstanding and account for nearly all growths occurring in infancy The therapy of multiple papillomas is discussed generally with the expected conclusion that there is no specific remedy available This latter fact is brought out forcibly by quoting numerous articles on multiple papillomas Capps reports one case of a fibroma simulating carcinoma Two cases of angiomas and one lymphoma are included Five chondromas were seen, and the literature of recorded cases is reviewed

In a discussion of benign tumors of the larynx Salkeld[79] reports a case of a non-specific granuloma of the larynx in a 68-year-old man, which was removed by laryngofissure with recurrence in four months Radiation partially controlled the growth The lesion was studied by several pathologists, who concurred that it was an inflammatory granulomatous tumor with abundant plasma cells At the time of their report the patient was receiving extensive corticosteroid therapy

Following the shock of an air raid 13 years before, a patient became hoarse, and six months later when examined, paralysis of the right vocal cord was found In 1953 Salmon[80] investigated the larynx because of recurring hoarseness and found a large, rounded mass expanding the right aryepiglottic fold Roentgenograms were characteristic of an ossifying chondroma of the right arytenoid Utilizing a curved lateral incision and making use of the Woodman arytenoidectomy approach he removed the tumor, and the diagnosis was confirmed

Stewart[81] discusses the histopathology found in a series of 104 cases of benign tumors of the larynx Polypoid-like growths occur in the larynx with relative frequency, and these inflammatory polyps are regarded as formations of mesenchymal origin as the forerunners of fibromas and angiomas Stewart considers the fibroma as the most common of the differentiated benign tumors occurring in the larynx These, together with angiomas, are described thoroughly from a histopathologic aspect and microphotographs are presented to substantiate the diagnosis

MALIGNANT TUMORS

Pirkey[52] reports a case of a metastatic laryngeal lesion of a proved case of multiple myelomatosis This is extremely rare, particularly because metastasis to the larynx scarcely ever occurs Of interest in this case was the rapid favorable response of the lesions to administration of urethane Although the patient died, as long as urethane could be given improvement was steady, however, use of the drug had to be discontinued because it caused severe leukopenia

In a lengthy article Lane[53] reports ten cases of polypoid or fungating oral, faucial and laryngeal lesions The features they had in common were the presence of an intramucosal or invasive squamous cell carcinoma associated with an anaplastic stroma of sarcomatous appearance Only two of the ten patients had a history of radiation to the region in question Pathologic study of these cases suggested that only the carcinomatous portion had truly malignant neoplastic properties Lane suggests that the sarcomatous component of these growths is probably not a malignant neoplastic tissue, and for this reason proposes the tentative designation of "pseudosarcoma"

Kuhn and associates[54] present a detailed, extensive statistical report on 602 cases of carcinoma of the larynx They classified their cases not only as to age, sex and duration of symptoms but also as to site and grade They concluded that the findings of their study "indicate that among various items of information available at the time of treatment, the site of the tumor, the histologic grade of the tumor and the microscopic infiltrative nature of the tumor, each significantly affects the likelihood of occurrence of cervical metastases from patients with squamous cell carcinoma of the larynx" They considered their findings determinants of the indications for radical procedures designed to remove cervical areas of metastatic spread in this disease This is an excellent reference article

Quinn and McCabe[85] found only eight cases of laryngeal metastases from distant organs in a review of the literature from 1916 to 1951 To this group they added two cases of carcinoma of the prostate gland that were metastatic to the larynx These cases are well described, and the route by which neoplastic emboli reached the larynx is discussed

In a most interesting and valuable contribution on pharyngolaryngectomy with primary "sleeve graft" reconstruction, Shaw and Omerod[86] describe their technique for successful handling of these difficult cases Much stress is placed on the importance of using the proper type of self-retaining Latex stents originally devised by Sir Victor Negus It is agreed that total pharyngolaryngectomy with primary closure by skin tube must be used when resection of the primary tumor in the hypopharynx or cervical esophagus necessitates excision of more than 70 per cent of the mucosal circumference The incision and resection are matters of skill and surgical judgment A rectangular split skin graft of sufficient size (4x6 inches) to create a "sleeve" type tube for the upper gullet is used This graft is applied to the operative defect, raw surface outward, and is sutured to the lower edge of the posterior pharyngeal wall and the upper edge of the posterior esophageal wall The Latex stent is placed in position, and the graft is carefully sutured around the hourglass stent Complications and postoperative treatment are discussed Those interested in this type of surgical reconstruction should read the entire article, which is much too long to cover adequately in such a review as this

Marchetta and co-authors[87] present the end-results of a study of 158 documented cases of carcinoma of the larynx seen from 1935 to 1953 They concluded that the smoking history in this series was of little significance They divided their cases into three categories the first category included 56 cases in which the lesion was confined to the vocal cords without evidence of fixation Half of these were treated by excision and half by radiation Twenty-four months after treatment 75 per cent of the surgical group were free of disease, whereas only 50 per cent of those treated with radiation were without recurrence The second group consisted of 60 patients with lesions limited to the cords with fixation indicating deeper infiltration of the structures of the larynx. Eighty-three per cent of the patients treated surgically showed no evidence of recurrence at the end of 24 months, whereas only 22 per cent of those treated by irradiation were free of disease at the end of this time. In the third category were 42 patients with lesions that involved the ventricular band in addition to the true cords. All seven treated surgically were alive at the end of 24 months, but only 11 per cent of the remaining 33 who received irradiation were alive at the end of this time. Surgical treatment consisted of laryngofissure, laryngectomy or laryngectomy with radical neck dissection. Salvage efforts were instituted whenever possible. This presentation is of great interest, and only the outstanding statistics have been presented because of the length of the paper.

Jackson and associates[58] report the results of a survey of 25 years' experience with treatment of 1,066 patients with carcinoma of the larynx by operation and irradiation. Treatment consisted of partial laryngectomy in 384 patients, total laryngectomy in 374 patients, laryngectomy with radical neck dissection in 48 patients and irradiation in 260 patients. The five-year survival rate, as would be expected, was highest in those having partial laryngectomy (87 per cent) and lowest in those treated by irradiation (42 per cent). Metastasis and recurrence are discussed, and their management is outlined.

In a study of 170 case histories of patients suffering from cancer of the larynx Fior[59] was able to show that 32 relatives had suffered from some form of malignant lesion. These findings are discussed, and the importance of extrinsic factors which, by acting on the larynx, might enhance the hereditary cancer potential already existing in these subjects, is pointed out.

Foxwell[60] reports two interesting cases of carcinoma of the larynx in which he questions whether redevelopment of carcinoma 15 and 17 years later was a recurrent or a secondary primary lesion. The first patient was a laryngofissure in 1935 when the right vocal cord, which was fixed and had "an irregular white mass," was removed. Fifteen years later a growth developed on the left vocal cord and required laryngectomy. In the second case laryngectomy was performed in 1938, and a mass developed above the tracheal stoma in 1955. We concur that the first case was a second primary carcinoma, but we cannot understand the rationale of laryngofissure in the face of fixation of the cord. The choice was undoubtedly the proper one, for there was no recurrence on the side of operation. In the second case recurrence is a possibility.

There is universal agreement with Morfit and associates[91] that cancers arising in the laryngopharynx, extrinsic larynx, and upper cervical esophagus present difficult therapeutic problems. The main method of treatment in the past has been irradiation. Cancer therapists are now turning with greater frequency to surgical excision to improve results. Eleven patients were subjected to laryngopharyngectomy partial esophagectomy and neck dissection. The lesions were so extensive that after removal, primary closure was impossible and continuity was established with polyethylene. The method of doing this is well described. Morfit and associates conclude that when the growth can be extirpated by combined neck dissection, laryngectomy, partial pharyngectomy and primary closure obtained, the end-results indicate this is worthwhile. If the growth is so extensive that auxiliary measures must be employed, little or no increase in the salvage rate can be expected.

Snitman and Loewy[92] state that adequate surgical treatment of carcinoma of the larynx implies resection of the primary tumor and its path of direct and lymphatic spread with a true margin of safety. Laryngofissure techniques are satisfactory for restricted lesions, however, it is important to evaluate the indications carefully and adhere to them. For more extensive lesions of the vocal cord with relatively poor lymphatic-spread potentials, total laryngectomy is proper treatment. The various types of lesions occurring in the larynx and adjacent tissue are discussed. In all of these cases Snitman and Lowey comment on the type of operation considered adequate for the particular lesion. Laryngectomy in continuity with neck dissection is in frequent demand for certain types of lesions When indicated, they believe that laryngectomy should be of the widefield type, including the bloc from the hyoid to the trachea This is a most interesting and informative article replete with sound judgment and good advice

Thompson[93] reports that carcinoma of the larynx represents 4 per cent of all malignant lesions and more than 16 per cent of all laryngeal tumors It is most prominent in the fifth to seventh decades of life but has been reported in children as young as 11 years The ratio of men to women is ten to one and of Negro to whites per population is 1 to 1 5 per cent Thompson presents a series of cases illustrating the types of laryngeal carcinoma and methods of treatment

In an excellent article on laryngeal cancer Snitman and Loewy[94] deplore the inadequate type of operation in which lymphatic spread has not been covered They believe that the treatment of advanced carcinoma of the larynx is fundamentally surgical Relatively few patients with advanced carcinoma of the larynx demonstrate absolute contraindications to surgical management when they first seek medical aid In the past patients with advanced tumors were referred for radiation therapy, not in the hope of cure but for presumed palliation Many patients can now expect useful extension of their life span if given the benefit of adequate surgical excision This article is well worth reading

In an excellent article Holinger and associates[95] discuss the symptoms of laryngeal cancer with particular emphasis on persistent hoarseness As the condition develops, other symptoms appear Most of these tumors are squamous cell carcinomas Their location is described, and the symptoms resulting are given The diagnosis is made by indirect and direct laryngoscopy and biopsy Treatment consists of laryngofissure, and laryngectomy alone or with radical neck dissection The preoperative care and especially the postoperative nursing care are described in detail This is an excellent article for floor nurses as well as private duty nurses caring for this type of patient

Ormerod[96] defines pharyngolaryngectomy as total excision growth developed on the left vocal cord and required laryngectomy In the second case laryngectomy was performed in 1938, and a mass developed above the tracheal stoma in 1955 We concur that the first case was a second primary carcinoma, but we cannot understand the rationale of laryngofissure in the face of fixation of the cord The choice was undoubtedly the proper one, for there was no recurrence on the side of operation In the second case recurrence is a possibility

There is universal agreement with Morfit and associates[91] that cancers arising in the laryngopharynx, extrinsic larynx, and upper cervical esophagus present difficult therapeutic problems The main method of treatment in the past has been irradiation Cancer therapists are now turning with greater frequency to surgical excision to improve results Eleven patients were subjected to laryngopharyngectomy, partial esophagectomy and neck dissection The lesions were so extensive that after removal, primary closure was impossible and continuity was established with polyethylene The method of doing this is well described Morfit and associates conclude that when the growth can be extirpated by combined neck dissection, laryngectomy, partial pharyngectomy and primary closure obtained, the end-results indicate this is worthwhile If the growth is so extensive that auxiliary measures must be employed, little or no increase in the salvage rate can be expected

Snitman and Loewy[92] state that adequate surgical treatment of carcinoma of the larynx implies resection of the primary tumor and its path of direct and lymphatic spread with a true margin of safety Laryngofissure techniques are satisfactory for restricted lesions, however, it is important to evaluate the indications carefully and adhere to them For more extensive lesions of the vocal cord with relatively poor lymphatic-spread potentials, total laryngectomy is proper treatment The various types of lesions occurring in the larynx and adjacent tissue are discussed In all of these cases Snitman and Lowey comment on the type of operation considered adequate for the particular lesion Laryngectomy in continuity with neck dissection is in frequent demand for certain

Fluoroscopy confirmed the fact that air did not enter the esophagus because of inability to relax the sphincter of the esophagus Educational methods soon brought results A large esophageal bougie was used daily to dilate and relax the cricopharyngeal sphincter The patient gradually succeeded in swallowing air and pressing it out of the esophagus, and within two months a satisfactory conversational voice had developed

In an interesting article Haas[100] presents his recent work, although limited, on the betatron treatment of carcinoma of the larynx This presentation offers food for thought and again brings up the old argument of radiation vs excision as curative therapy for carcinoma of the larynx The advantages of the betratron are greater penetration, lesser surface dose, insignificant side scattering and, therefore, less osseous absorption and risk of necrosis of bone and bone marrow depression This type of treatment employs less radiation and causes less discomfort to the patient both during and after radiation Only ten cases of carcinoma of the larynx are reported, three of the ten patients are dead, and at the time of the report only one has been living for more than five years

McReynolds[101] considers carcinoma of the larynx an interesting and challenging problem in which the ideal treatment is yet to be found He reviews 244 cases of laryngeal cancer seen at the University of Texas Medical Branch during the past 15 years He reviews the modes of therapy employed and discusses at length and accurately the significance, potentialities, method of treatment and prognosis of leukoplakia Although his percentage of reported cures seems slightly low, his advice and surgical management are sound

Struben[102] comments on the difficulty of classifying laryngeal carcinoma, as evidenced by the divergent classifications proposed by various laryngologists He presents a classification proposed by the joint staffs of the Radiotherapeutic Institute of Rotterdam and the Netherlands Cancer Institute of Amsterdam, which is much the same as that suggested by the International *Committee for stage-grouping in cancer in* 1953 A universally accepted classification would make it of the larynx with at least half of the pharyngeal tube He adequately describes the pathology and surgical procedure, but dwells more on the methods of repair after this formidable operation His method of suturing and repairing the pharyngeal defect is well presented He points out that the condition of these patients is much improved by this drastic surgical procedure, the discomfort occasioned by the presence of a large septic malignant lesion in the pyriform fossa where air and food passages cross, being exchanged for the well being and comfort of a healed and clean alimentary tract

The immediate effects of too much Roentgen-ray irradiation on the skin, subcutaneous tissue and cartilage are well known Reports of late damage to the deep tissues of the pharynx, larynx and upper esophagus are not common Henry[97] reports two cases of damage from prolonged irradiation for noncancerous lesions ten to 15 years before Severe dyspnea and dysphagia developed in one patient, and in the other carcinoma of the larynx developed Henry voices the opinion that when cancer occurs several years after prolonged roentgenotherapy for a noncancerous lesion at the site of irradiation, it may be termed an irradiation cancer

The prognosis of carcinoma of the epiglottis is much worse than that of the vocal cords There seems to be a wide variation in the surgical management of this condition McCall and associates[98] believe that the solution lies in use of more radical excision They advocate total laryngectomy, including the epiglottis and radical neck dissection (unilateral if the growth is localized to one side, but bilateral in two stages if the growth is in the midline) To substantiate this procedure the lymphatic supply of the epiglottis and larynx is illustrated Statistics during a period of ten years show a higher incidence of recurrence in patients having less radical operations Helpful advice in performing bilateral radical neck dissections is offered

In an interesting and unusual paper Damsté[99] describes improvement of the voice of a patient after total laryngectomy by changing the site of the pseudoglottis For two years the laryngectomized patient spoke with a weak pharyngeal voice radiation offers hope in the treatment of carcinoma of the true cords, but it fails completely to improve unsatisfactory survival rates of patients with carcinoma in other parts of the larynx or laryngopharynx Shaw advocates the classical method of radical *en bloc* dissection of the larynx and cervical glands, together with removal of the sternocleidomastoid and omohyoid muscles, the internal jugular vein and the submaxillary gland Early diagnosis and early adequate surgical treatment remain the most powerful weapons for attacking cancer Radical surgical excision will never be the ultimate answer, but is the most effective single method available until biochemical control can be achieved

In an interesting and thorough article Goolden[106] states that the carcinogenic properties of ionizing radiation have been recognized for many years Radiation tumors that have developed in the pharynx and larynx are discussed Most radiation-induced tumors are squamous cell carcinomas Five cases of radiation cancer of the larynx have been reported in the literature These patients had irradiation for tuberculous adenitis and exophthalmic goiter In addition to these, 12 cases of postcricoid carcinoma after irradiation for thyrotoxicosis are reported Goolden classifies postcricoid carcinoma under pharyngeal tumors, but in our opinion, they could be equally as well classified as occurring in the larynx The latent interval between treatment and development of carcinoma ranged from ten to 35 years Goolden points out that with the new type of therapy now being used in irradiation there is less chance of development of post-radiation tumors

Henken[107] does not consider the primary diagnosis of carcinoma nor does he attempt the differential diagnosis He compares the current nomenclature of laryngeal carcinoma in the United States and the Netherlands The nomenclature is surprisingly similar basically in the large medical centers of both countries Based on classification the surgical indications are practically the same except more postoperative roentgenotherapy is administered abroad, and in some of the centers all patients are given a trial of roentgenotherapy preoperatively The comparative statistics are much more favorable in the United States than in the Netherlands, but the main possible to compare statistics and results and map out modes of treatment for various carcinomas of the larynx more accurately than we now can. Struben believes that carcinoma of the larynx should be treated only in special clinics in order to enable the staff to enlarge their experience and thus provide the patient with the best treatment possible.

The rare incidence of fibrosarcoma of the larynx, says Johnston,[103] can best be appreciated by comparison with the incidence of other cancerous tumors of the larynx. Figi reported four cases of sarcoma at the Mayo Clinic from 1910 to 1933 as contrasted with 713 cases of carcinoma of the larynx. Johnston reports three cases of fibrosarcoma and 686 cases of carcinoma seen between 1947 and 1956. The ratio of sarcoma to carcinoma is 1:117. Fibrosarcomas rarely metastasize, but when they do, extension is through blood vessels or infiltration. The tumor is usually smooth and rounded, and the diagnosis is made by microscopic examination of the tissue. Complete surgical removal is necessary for cure. Sarcomas are radioresistant. Johnston describes the therapy instituted in his cases with appropriate comments.

In a series of two articles Davis[104] presents first a lengthy historical sketch of carcinoma of the larynx followed by a detailed discussion of the incidence, etiologic factors, classification, pathologic processes and diagnosis. He emphasizes the necessity of repeated biopsies on clinically malignant-appearing lesions. In the second part of this article management of carcinoma of the larynx is well presented. The indications and technique for laryngofissure and laryngectomy are considered. Davis believes that there is a place for irradiation in the treatment of carcinoma of the larynx and quotes the views of numerous radiotherapists. In this article Davis has accomplished his objective to describe the essential facts of carcinoma of the larynx in such a way that the physician who is not a specialist in laryngology, encountering a patient with symptoms indicating the disease, would know how to proceed.

In a most comprehensive article Shaw[105] discusses all phases of cancer of the extrinsic larynx and laryngopharynx. Teletion fails, or there is a recurrence, surgical treatment is undertaken In the presence of cervical metastasis, surgical excision is advocated The result of this policy is that most patients who require surgical treatment have had full courses of deep Roentgen-ray therapy and devitalization of the skin The radical type of excision necessary in these patients creates such a defect that reconstruction is difficult Woods suggests insertion of a polyethylene sponge in a pocket created between skin flaps and prevertebral fascia A thick split skin graft is sewn around this polyfoam sponge The results obtained in such reconstruction of the pharynx have been most satisfactory

Hara[111] reports results of a study of the five-year survival rate of 38 patients with carcinoma of the larynx The symptomatology, diagnosis and pathology are considered, but only the essential features of the operative procedure are discussed This report is well presented and Hara makes a plea to endeavor to make people more conscious of the dangers of persistent hoarseness

10 Froeschels E The Question of the Origin of the Variations of the

reason is that during the war years, Europe did not have the benefit of group comparisons and conferences This is an excellent article

Foxen[108] presents the results of a survey of 206 cases of carcinoma of the endolarynx treated by surgeons and radiotherapists during the past 23 years He briefly considers the anatomy, symptomatology, site of the disease, mobility, histology, treatment and prognosis Lack of mobility generally constitutes a firm surgical indication in operable cases Teleradiotherapy is the method of choice in mobile glottic cases Most patients in this series received some form of irradiation as their first and chief form of therapy Foxen reports that midcord carcinomas respond favorably to teleradiotherapy, however, cases of reduced mobility, and supraglottic and bilateral lesions give disappointing results with this type of therapy Foxen believes that laryngectomy unaccompanied by neck dissection is never indicated Apparently he does not appreciate the value of laryngofissure for limited cordal lesions, for he definitely states that "a laryngofissure operation is now considered most suitable for nonmalignant and premalignant conditions"

Trible[109] discusses the effect of preoperative *radiation on* subsequent operation in carcinoma of the larynx He believes that radiation has a place in the treatment of early lesions of the vocal cords but that all other lesions should be removed surgically Roentgen-ray in conventional dosage administered by the Coutard method does not adversely affect performance of laryngectomy, however, radiotherapy delays wound healing, increasing the duration of hospitalization, and frequently necessitates plastic procedures After higher doses of roentgen-ray radionecrosis may develop Comparison of the postoperative duration of hospitalization in a series having laryngectomy alone and a group having previous radiotherapy showed an average stay of 28 days for the former and 40 days for the latter The impression gained from reading this paper is that Trible is opposed to preoperative radiation

Woods[110] prefers a full course of deep Roentgen-ray therapy for all patients with carcinoma of the hypopharynx If radia-

EXPERIMENTAL STUDIES IN FIXATION OF THE STAPES AND FENESTRA OVALIS *†

CESAR FERNANDEZ, M.D.,
GEORGE W. ALLEN, M.D.,
and
JOHN R. LINDSAY, M.D.,
Chicago, Ill.

Stapes mobilization, as put forward by Rosen[1] and further developed by many followers,[2-8] has been an important contribution to the surgical treatment of otosclerosis.

In cases of failure to mobilize the footplate of the stapes, Rosen[9] proposed the fenestra ovalis operation. Essentially, the procedure consists of creating an opening in the margin or body of the footplate of the stapes as close to the posterior crus as possible. Removal of the incus facilitates exposure of the footplate and creation of the fenestra. Rosen[10] has reported that normal or near-normal hearing was obtained in many cases, both when the ossicular chain remained intact and when the incus was removed. Consequently, Rosen[11] stated: "The Helmholtz concept of the transformer action of the intact ossicular chain is a *sufficient* but not a *necessary* condition for normal and near-normal hearing."

The concept that an intact physiological ossicular chain is a *necessary* condition for normal hearing prompted this investigation. The principles of the transformer action of the middle ear mechanism and the effects which follow injury of the ossicular chain, are fully explained in the comprehensive work of Wever and Lawrence,[12] Bekesy and Rosenblith,[13] Stuhlman,[14] Stevens and Davis,[15] and others.

The investigation to be reported here was undertaken for

---

*This investigation was supported in part by funds provided under Contract B-682 (C3) with U. S. Public Health Service and in part by the Central Bureau of Research of the American Otological Society, Inc.

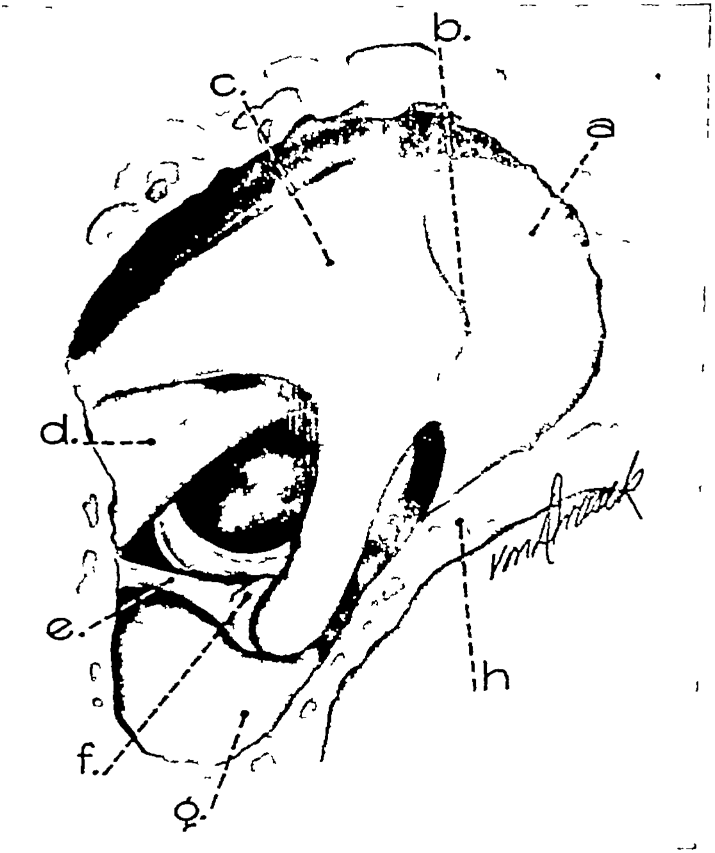

Fig 1 Freehand drawing of ossicular chain as seen after opening the attic a. malleus b malleoincudal articulation c incus d facial canal e tendon of stapedius muscle f head of the incus g tympanic cavity h. ridge of superior external canal

(CM) were measured by octaves from 125 to 8,000 c p s sine waves Thresholds are here defined after Pestalozza and Davis,[20] and maximum voltage as the voltage of CM for a predetermined set of the attenuator The input was fixed at an intensity sufficient to give an output of CM near the point of non-linearity Stimuli at higher intensity may produce, in the long process of measurements, undesirable fatigue effects For observing changes in action potentials (AP) 8,000 c p s tone pips were used the purpose of studying the effect of the fenestra ovalis, as described by Rosen,[10 11] on the transformer action of the middle ear mechanism in experimental animals This study may also help in the understanding of the results claimed by Rosen[10] but denied by others [8,16]

Thresholds and maximum voltage of both cochlear microphonics and action potentials were used as indices of the transformer action It is understood that the electrophysiological method of measuring sensitivity at the peripheral level is related but differs from the over-all sensitivity as determined by behavioral methods in animals or audiometric tests in human beings The electrophysiological method of recording cochlear responses is specific for the study of the mechanism of the peripheral ear, including the transformer action The behavioral or audiometric method is more suitable for studying the auditory system as a whole, which includes peripheral and central neural mechanisms

The decision to use thresholds and maximum voltage of cochlear microphonics as an index of the transformer action is justified by previous experience [12 17,18 19] Measurements of action potentials were included in this study, because they represent the final event of the peripheral mechanism

METHOD

The experiments were carried out on 19 cats anesthetized with pentobarbital sodium, 37 5 mg per kilo body weight, in a single dose

The operation was performed in three stages first, following removal of the mastoid cells and bone of the posterior and superior walls of the external canal, the round window niche was exposed An electrode of silver wire, enameled except for the flat tip, was allowed to rest on the membrane of the round window The opening in the bulla was sealed with dental cement An ear speculum coupled to a PDR-10 transducer by a plastic tube 80 mm long, was tightly attached to the external canal

Thresholds and maximum voltage for cochlear microphonics

250 c p s) improved by an average of 10 db while the other frequencies sometimes showed variations of a few decibels Sensitivity of AP was not modified

Commentary These experiments confirmed the results of Wever, Lawrence and Smith,[21] that is, opening of the middle ear cavity causes only minor changes in transmission For this reason we decided to use the cochlear responses given by the initial opening of the attic as the reference level, thus, in the course of this paper the results are generally expressed in terms of losses or gains in decibels relative to that reference

B *Injury to the Ossicular Chain*

The effect of injury to the ossicular chain has been fully explored in the past,[12] however, we reproduced those lesions which pertained to our aims

1 Disarticulation of Incudostapedial Joint Separation of incus from stapes was done by applying traction on the long process of the incus with a Shambaugh hook When traction was released, the incus always returned to contact with the stapes if the malleoincudal joint and posterior ligament had not been damaged Restoration of contact between the two bones was facilitated by sound stimuli To obtain a permanent gap it was necessary to rupture the posterior ligament and capsule of malleoincudal joint

A gap of 1 mm or more between incus and stapes produced a large impairment of thresholds and maximum voltage of both CM and AP A representative case is illustrated in Fig 2 *Curve A* represents the threshold shift of CM after disarticulation Low frequencies could not be differentiated from the background noises even at the highest intensity input In the middle range the losses were 40 to 60 db and for higher frequencies 30 to 40 db

Impairment of maximum voltage of CM also increased from high to low tones, the losses being between 20-30 db for high frequencies, and 30-40 db for the middle range This change in amplitude of CM for 2,000 c p s sine waves can be estimated from Record 2 The loss was 27 2 db , which represents about 95 per cent of the reference (Record 1)

The second stage of the operation consisted of exposing the attic so that incus and stapes with its footplate were widely visualized Fig 1 shows a freehand drawing of the ossicular chain, as seen under a Zeiss microscope (16X) The cochlear responses were measured again Some animals were used to study modifications of cochlear responses after various types of injury of the ossicular chain

The third stage of the operation was attachment of a device for mechanical fixation of the stapes and creation of the fenestra ovalis The device consisted of a small pulley with a thread which had a thin steel hook on one end and a scale pan for holding weights on the other end The hook was anchored to the neck of the stapes Cochlear responses were measured after adding to the scale pan weights from 10 to 40 gm Fenestration of the footplate was made with a sharp needle as close to the posterior crus as possible The effect of the fenestra ovalis was studied in four types of preparations

1 Normal ossicular chain

2 Injury of ossicular chain

3 Normal ossicular chain plus mechanical fixation of stapes

4 Injury of ossicular chain plus mechanical fixation of stapes

RESULTS

A *Cavity Effects*

The technique for fixation of stapes, making fenestra ovalis and other surgery of the ossicular chain required opening the attic This eliminates the volume elasticity of the middle ear cavity The question was raised as to whether there is a corresponding change in the cochlear responses The answer to this question is important in the final assessment of our results

Comparison of the results obtained before and after opening the attic showed that the opening produced modifications in thresholds of CM Low frequency sensitivity (125 and shown in Fig 2 *Curve B* represents the losses in sensitivity of CM after reconstruction, and Records 3 and 6 the recovery in voltage of CM and AP respectively The degree of recovery of these parameters only varied slightly from one animal to another

Commentary The results of these experiments showed that disarticulation of the incudostapedial joint was accompanied by a considerable loss in both sensitivity and amplitude of cochlear potentials This finding is particularly interesting, because as Wever and Lawrence[12] stated, "The loss just described is considerably greater than we should expect simply from the elimination of the transformer action of the middle ear mechanism, which we have found to average 28 db " The authors[12] gave two reasons for this effect one is that incus, malleus and tympanic membrane "are in the path of the incoming sound and cause both reflection and absorption of this sound to no good purpose" Wever, Lawrence, and Smith[21] measured the sensitivity of CM before and after disarticulation of the incudostapedial joint, and again after removal of incus, malleus and tympanic membrane After removal of the latter three structures, there was a recovery of about 15 db in the middle range of the threshold shift, produced by the incudostapedial disarticulation These experiments were repeated in two animals of the present series with the same qualitative result The other factor, which Wever and Lawrence[12] cited, is that "the sounds have more nearly equal access to both oval and round windows Their stimulating effects upon the inner ear tend to be counteractive" The contribution of this factor, as determined by Wever,[22] is about 12 db A third additional factor impairing responses is the loss of the lever ratio which, in the mechanical advantage of the ossicular chain of the cat, amounts to a factor of 2 5 [12]

2 *Removal of Incus* This injury produced similar, and in some animals a larger impairment of cochlear responses than disarticulation of the incudostapedial joint A representative case is illustrated in Fig 3 Threshold shift of CM was 42 db or more and that of AP was 55 db Amplitude of CM lost 23 db , which represents a reduction of 93 per cent of the

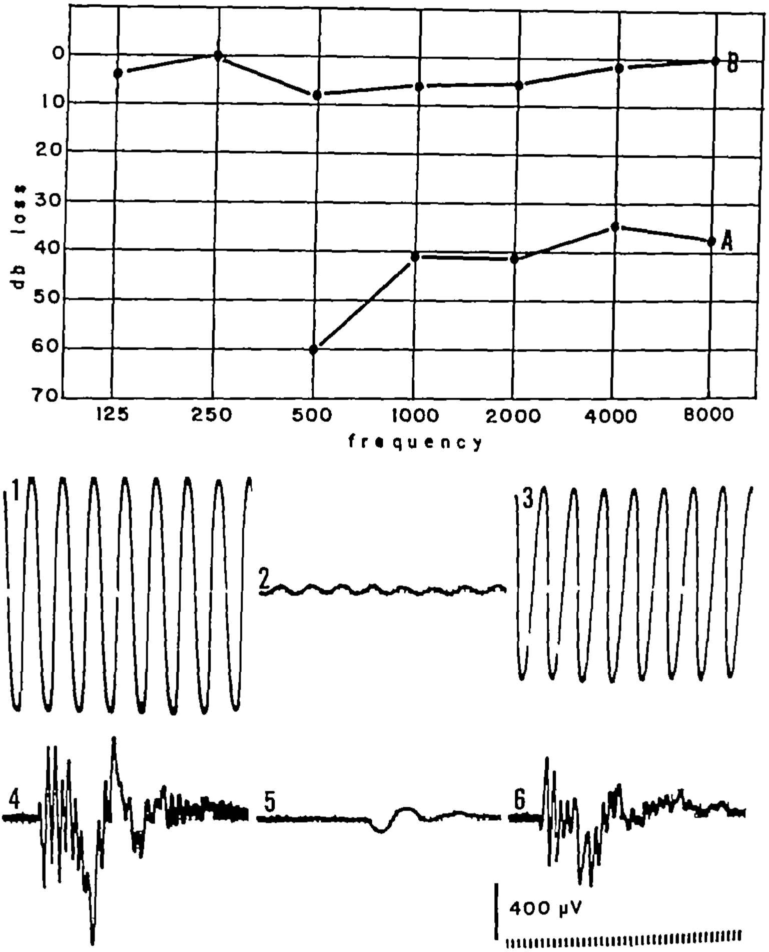

Fig 2 Cat A-479 Effect of disarticulation of incudostapedial joint followed by reconstruction Changes in thresholds of CM are represented by Curves A disarticulation of incudostapedial joint and B reconstruction Changes in amplitude of CM for 2000 c p s sine waves at 59 db above threshold are shown by Record 1 reference Record 2 disarticulation and Record 3 reconstruction The corresponding changes in amplitude of AP for 8000 c p s tone pips at 67 db above threshold are represented by Records 4 5 and 6 In this and following figures time calibration is 10 000 c p s

Changes in AP were considerable Threshold shifted as much as 55 db and amplitude was reduced to 30 per cent or less of the reference level, as Record 5 illustrates

A careful reconstruction of the ossicular chain by returning the incus to its normal position may produce nearly complete recovery of cochlear responses These findings are also

Wever et al,[21] which are supported by the experiments reported here, it is assumed that a gap in the ossicular chain of a human ear must produce equal or similar results

If the incus be removed and the malleus and tympanic membrane remain in their normal positions, they bring about one condition under which the transformer action of the middle ear mechanism cannot be fully restored In the fenestra ovalis operation, as proposed by Rosen,[10 11] the malleus and tympanic membrane are usually left in their normal positions, where they act as an attenuator of the incoming sound, the attenuation being of the order of 15 db [21] This loss cannot be recovered as long as the malleus and tympanic membrane remain in position and a gap exists between them and the inner ear

The recovery of cochlear responses after reconstruction of the ossicular chain (see Fig 2) is significant in two ways first, it supports the rationale of stapes mobilization[1-8] and similar operations[23] for otosclerosis, and also of tympanoplastic surgery The efficiency of these procedures depends upon success in reconstructing the transformer action of the ossicular chain as it normally exists, second, the posterior ligament of the incus and capsular ligaments of the incudostapedial and malleoincudal articulations seemed to play a minor role in transmission of sound All these ligaments can be broken and the incus displaced, upon reconstruction, however, the cochlear responses may return to the reference level This indicates that the functional properties of the incus during transmission of sound depend more on its contiguity with the malleus and stapes than on their attachments The importance of these attachments, as conceived by Helmholtz,[24] Dahmann[25] and others, seems to have been overemphasized

3 *Removal of Incus and Stapes* These experiments were done because they represent a modification of the fenestra ovalis operation, as proposed by Rosen [11] Removal of the stapes is equivalent to making a fenestra ovalis in the human being as large as the oval window

The results showed that the impairment of cochlear re-

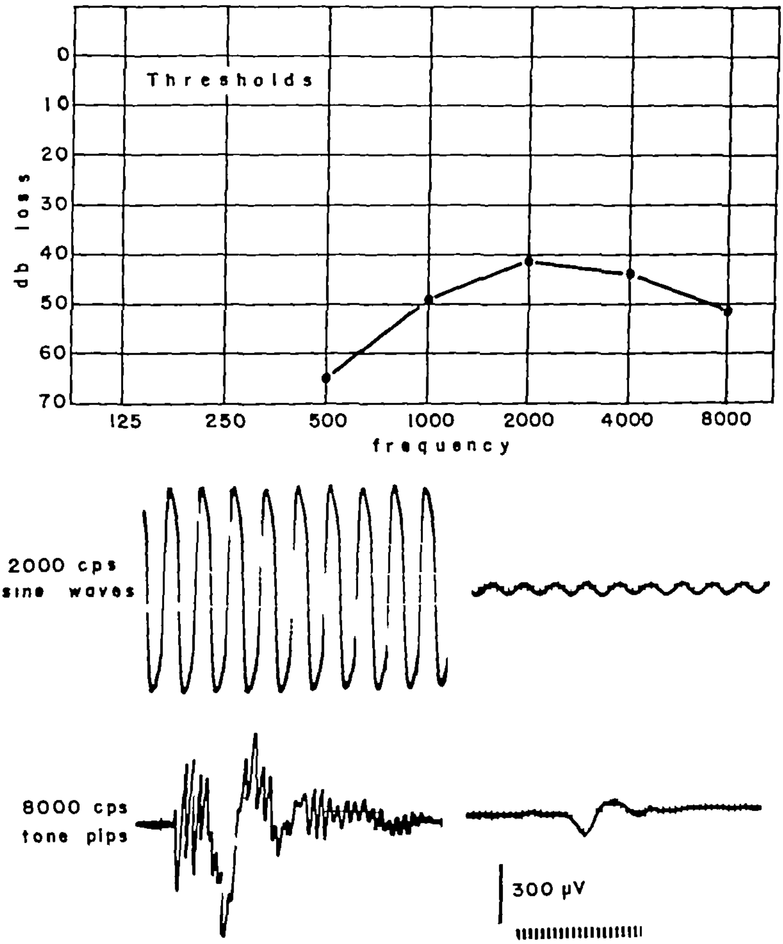

Fig 3 Cat A-455 Effect of removal of incus Thresholds of CM lost 42 db or more The records in the left column are references 2000 c.p s sine waves at 74 db above threshold of CM and 8 000 c p s tone pips at 76 db above threshold of AP The losses after removal of incus were 93 and 84 per cent respectively This can be estimated from the records on the right column

reference level Changes in amplitude of both CM and AP can be estimated from the records shown on the right column of Fig 3

Commentary The impairment of responses following removal of the incus is due to the same factors that produce a threshold shift when the incudostapedial joint is simply disarticulated From the results of Wever and Lawrence,[12] and

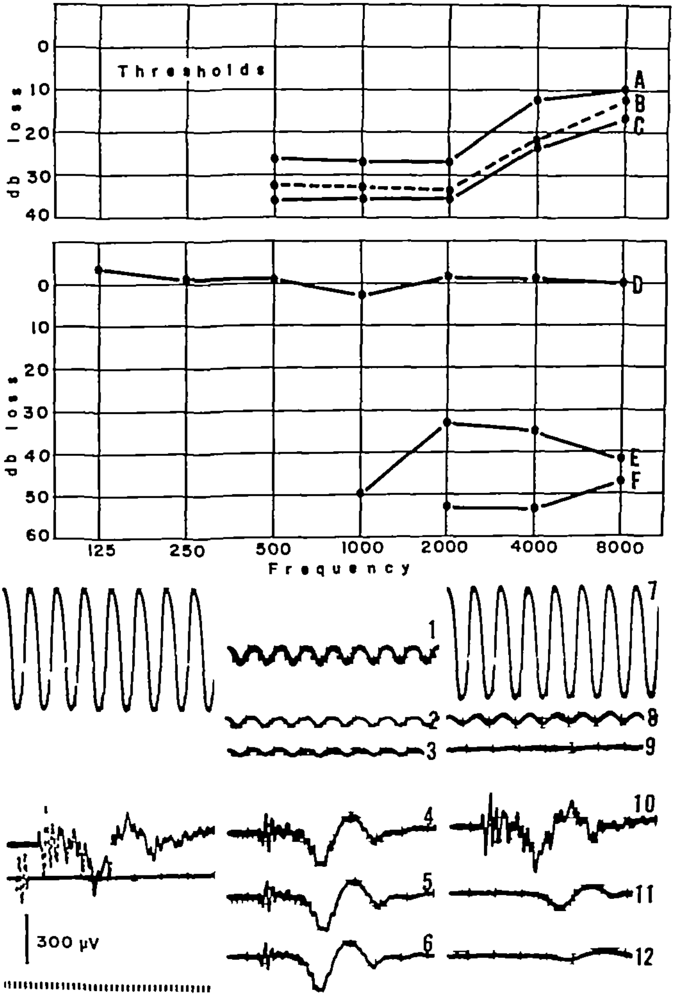

Fig 4 Cat A-454 Effect of simple mechanical fixation of stapes Records in left column are reference for amplitude of CM and AP for 2 000 c p s sine waves at 66 db above threshold and 8 000 c p s tone pips at 67 db above threshold respectively Curves and other records represent the following Fixation of stapes with 10 gm Curve A and Records 1 and 4 Fixation with 20 gm Curve B and Records 2 and 5 Fixation with 30 gm Curve C and Records 3 and 6 Removal of weight. Curve D and Records 7 and 10 Removal of incus without fixation of stapes Curve E and Records 8 and 11 Finally fixation of stapes without incus Curve F and Records 9 and 12

sponses due to ablation of incus and stapes together was of the same order of magnitude as removal of incus alone

Commentary These experiments indicate that a fenestra ovalis of the size of the oval window, leaving malleus and tympanic membrane undisturbed, produces a loss in cochlear responses larger than simple elimination of the transformer action At least some of the reasons for this impairment are those just mentioned

This or similar procedures had been used in the past for surgical treatment of otosclerosis The approach proved to be unsatisfactory and was abandoned The reasons for its failure are now understood

C Mechanical Fixation of Stapes

The mechanical device for fixation of the stapes was arranged in such a manner that the direction of the pulling force acted approximately parallel to the main axis of the anterior crus Avoiding contact of thread and/or hook with surrounding tissues reduced frictional forces to a minimum Because of the anatomical arrangement and direction of acting force, we assumed that the anterior region of the footplate was retracted appreciably

The weight of hook, thread and scale pan was 0 8 gm Attachment of this mechanical device produced minor losses in both thresholds and maximum voltage of cochlear responses Most of the experiments in mechanical fixation made use of a maximum weight of 30 gm This criterion was adopted because of limitations imposed by resistance of the stapes which usually broke with a weight of 40 gm

Addition of weights in steps of 10 gm each produced a characteristic pattern in cochlear responses, as Fig 4 illustrates *Curves A, B and C* represent threshold shifts of CM after adding 10, 20 and 30 gm respectively The impairment increased from high to low tones Fixation with 30 or 40 gm produced a loss of 15 to 20 db for high frequencies, 35 to 40 db for the middle range, and no responses were seen for the low frequencies Changes in maximum voltage of CM are illustrated in Records 1, 2 and 3, which correspond to the fixation of the stapes with incus removed represents the combined action of several factors

a. Removal of incus eliminates the transformer action of the middle ear mechanism which accounts for 28 db

b Malleus and tympanic membrane absorb and reflect acoustic energy This shifts the sensitivity curve to about 40 db loss

c Mechanical fixation of stapes increases stiffness reactance and frictional resistance which add to the previous factors

d The lever ratio of ossicular chain is definitely lost

e Mechanical fixation of the stapes produces a blocking effect in the oval window and consequently the sound pressure is applied only in one window, *i e*, the round window Since there is now no point of pressure discharge, the mass displacement of cochlear fluids necessary for stimulation of sensory organs either cannot take place or is largely reduced

Combination of all these factors produces the residual hearing illustrated by *Curve F* (sensitivity of CM) and Records 9 (amplitude of CM) and 12 (amplitude of AP) of Fig 4

This interpretation may be considered to be a restatement of that given by Wever[22] after several experiments on blocking the round and oval windows

D The Fenestra Ovalis

Exposure of the footplate of the stapes in the cat is a minor surgical problem A wide view of it can be obtained by removing the attic bone as close to the posterior ligament of the incus as possible and drilling down the facial canal

The fenestra ovalis was made with a steel wire which was sharpened with sand paper to a diameter of about 100 microns at the tip The holes were irregular in shape and of a size larger than the stylet Sometimes the fenestration produced fractures which occasionally extended to the margins of the footplate The fenestra ovalis was preferably made near effect of fixation upon CM for 2,000 c p s with 10, 20 and 30 gm , respectively The losses were 5 to 10 db for high frequencies and 25 to 30 for the middle range

The average loss in thresholds of AP after fixation with 30 gm was 16 db Changes in amplitude can be estimated by the Records 4, 5 and 6, which correspond to the effect of 10, 20 and 30 gm , respectively Notice that the amplitude of AP was little affected by the increasing weight

All the curves and records shown in Fig 4 belong to one animal, which was considered to be representative of this series Slight variations in both sensitivity and maximum voltage of cochlear responses were found from animal to animal

The question whether fixation of the stapes may have some traumatic consequences was explored in many cases by removing weight and mechanical device After this the responses fully recovered the reference level, as Fig 4 illustrates *Curve D* corresponds to sensitivity of CM, Record 7 to maximum voltage of CM at 2,000 c p s and Record 10 that of AP at 8,000 c p s

The impairment produced by fixation of the stapes with 30 gm increased considerably after removal of the incus The losses in sensitivity and amplitude of both CM and AP were consistently larger than 50 db These findings are shown in Fig 4 *Curve E* (sensitivity of CM), and Records 8 (amplitude of CM) and 11 (amplitude of AP) correspond to the effect of removal of incus only Subsequent impairment of fixing stapes with 30 gm is shown by *Curve F* and Records 9 and 12

Commentary The results on simple mechanical fixation of the stapes without other lesions of the ossicular chain, confirmed the findings of Smith[20] The increasing impairment from high to low tones is due to "the fact that fixation of stapes adds a great amount of stiffness as well as frictional resistance to the moving system "[12]

The profound impairment in sensitivity of CM following

Commentary These observations are interesting because they showed that the footplate is very brittle The perforation with a stylet may produce fractures which extend to the margins, and both size and shape of the hole are unpredictable It is possible that in human subjects the fenestra ovalis may produce fractures which act as a stapes mobilization

The fact that the fenestra ovalis produced a stream of perilymph which filled the oval window niche is important because this fluid and the fluid of the inner ear make a continuous medium through the fenestra The significance of this observation will be presented in a following paragraph

E Effects of Fenestra Ovalis

1 Normal Preparations

The fenestra ovalis performed in a normal ossicular chain in general produced minor changes in cochlear responses In some animals the reference level was not modified during 1 to 2 hours of observation, while in others sensitivity of CM may lose 10 db at some frequencies These changes were observed in low and middle tones while high frequencies consistently remained unchanged

Commentary These preparations are important because they showed that a careful performance of the fenestra ovalis was not accompanied by immediate damage to the sensory organs This is true only for acute preparations The loss of as much as 10 db, which was observed in some frequencies of some animals, may be related to fracture of the footplate and accumulation of fluid in the oval window and tympanic cavity

2 Injury of Ossicular Chain Without Fixation of Stapes

The procedure consisted of creating a fenestra ovalis first and then severing the ossicular chain in several ways, or vice versa

The results were essentially the same as in the series in which the ossicular chain was damaged without fenestration of the footplate A case is illustrated in Fig 6 Curves *A* and *E* represent thresholds and maximum voltage of CM after the posterior crus, but in some animals it was located in the center In many experiments it was enlarged once or twice in order to correlate its size with cochlear responses The fenestra ovalis was always followed by a stream of perilymph which filled the oval window niche and sometimes ran into the attic and/or tympanic cavity In our experiments it was not possible to keep the oval window niche free of perilymph longer than a few seconds

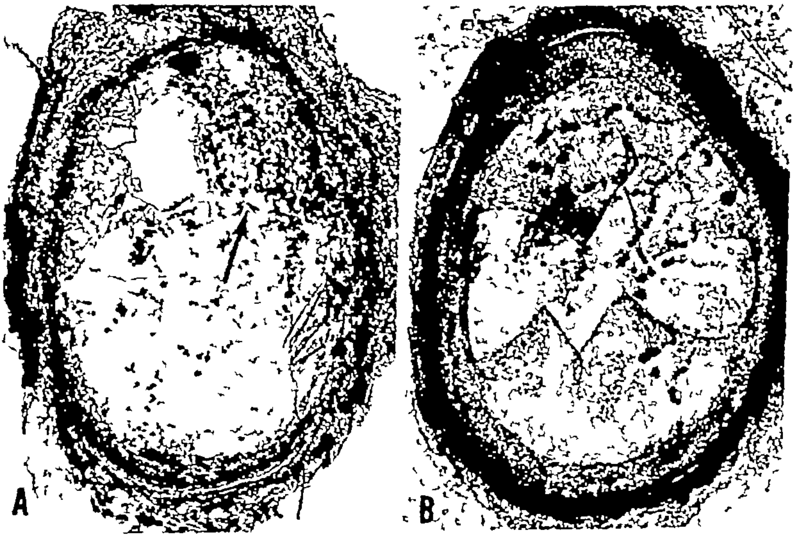

Fig 5 Samples of fenestra ovalis made in the footplate of stapes in the cat A Small fenestra after perforating the footplate just once Arrow points to a fracture which extends to the margin Enlargement of fenestra ovalis produced generally holes of the same shape but associated with several fractures B This unusual fenestra ovalis was found in one case The hole was enlarged twice Unstained X50

In six animals the temporal bones were removed at the end of the experiment and fixed in Heidenhain-Susa solution Subsequently the stapes and frame of the oval window were carefully dissected and mounted in thick Canada balsam for photographic reproductions and microscopic measurements of the fenestra ovalis Fig 5 shows two different footplates with two kinds of fenestrae, as seen from the vestibular side The area of the fenestra ovalis varied from 0 075 mm^2 (Fig 4-A) to 0 320 mm^2 (Fig 4-B) ovalis in a mobile stapes did not restore the transformer action which had been altered by injury to the ossicular chain Even after removal of the malleus and tympanic membrane, the losses exceeded those produced by simple elimination of the transformer action of the middle ear mechanism The cause of impairment following injury of the ossicular chain has already been explained

3 Ossicular Chain Intact with Fixation of Stapes

These conditions are shown in Fig 7 The freehand drawing from a preparation shows undamaged ossicular chain, the hook anchored on the neck of stapes and a simplified fenestra ovalis near the posterior crus

The impairment of thresholds and maximum voltage of both CM and AP produced by mechanical fixation of the stapes remained essentially unchanged after the fenestra ovalis Some animals showed improvement of about 5 db for thresholds of CM, others, like the one illustrated in Fig 8, presented losses of as much as 10 db *Curve G* represents threshold shift of CM after fixation of the stapes, and *Curve H* the further shift following the fenestra ovalis The corresponding changes in maximum voltage of CM for 1,000 c p s are shown on Records 4 and 5, and those for 4,000 c p s in Records 6 and 7 Records 8 and 9 illustrate changes in AP Notice in Fig 8 that cochlear responses recovered the reference level after removal of weight This is shown by *Curve I* and Records 10, 11 and 12

The size and location of the fenestra ovalis did not produce changes which were different from those already described

After fixing the stapes with 30 gm and creating the fenestra ovalis, the attic was closed with dental cement in several animals The results showed impairment similar to that seen with attic open

Commentary This series clearly demonstrated that the fenestra ovalis did not restore the losses produced by fixation of the stapes, thereby indicating that the transformer action of the middle ear mechanism is a necessary condition for normal hearing as measured at the peripheral level

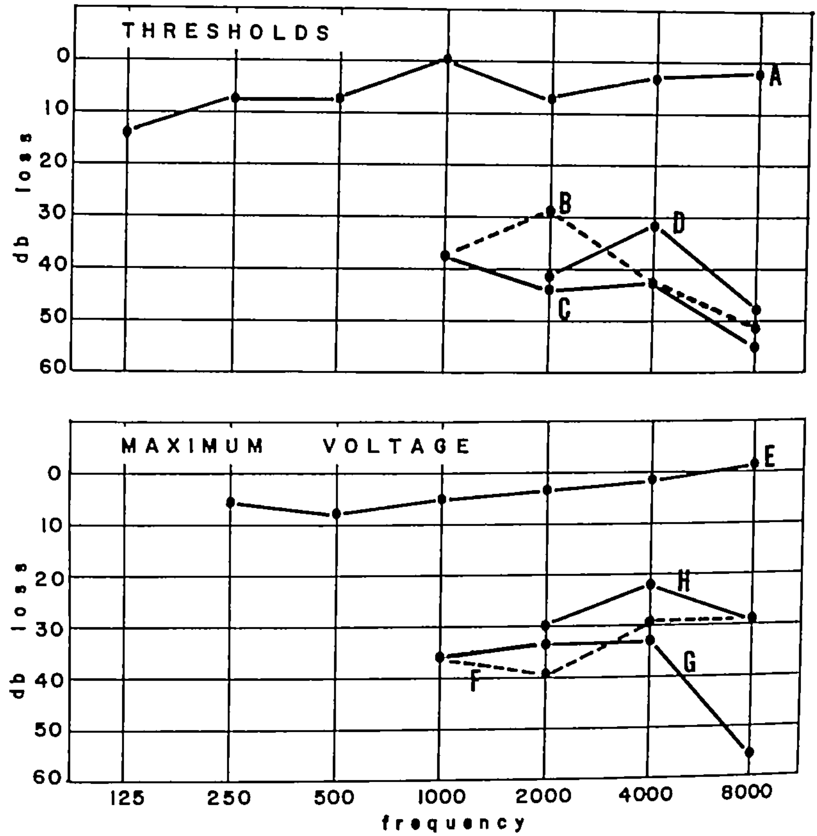

Fig 6 Cat A-403 Effect of fenestra ovalis with injury to the ossicular chain Stapes not fixed Curves A and E represent thresholds and maximum voltage of CM after fenestra ovalis alone Disarticulation of incudo-stapedial joint produced losses represented by Curves B and F respectively Removal of incus Curves C and G and removal of remaining malleus and tympanic membrane Curves D and H

the fenestra ovalis alone Disarticulation of the incudo-stapedial joint produced a threshold shift of CM of about 40 db or more for most frequencies (*Curve B*) These losses increased when the incus was removed (*Curve C*) Finally, when malleus and tympanic membrane were extirpated thresholds improved (*Curve D*), however, the final loss exceeded 40 db The corresponding changes in amplitude of CM are shown in *Curves F, G* and *H* Sensitivity and amplitude of AP followed a similar pattern

Commentary This series demonstrated that a fenestra

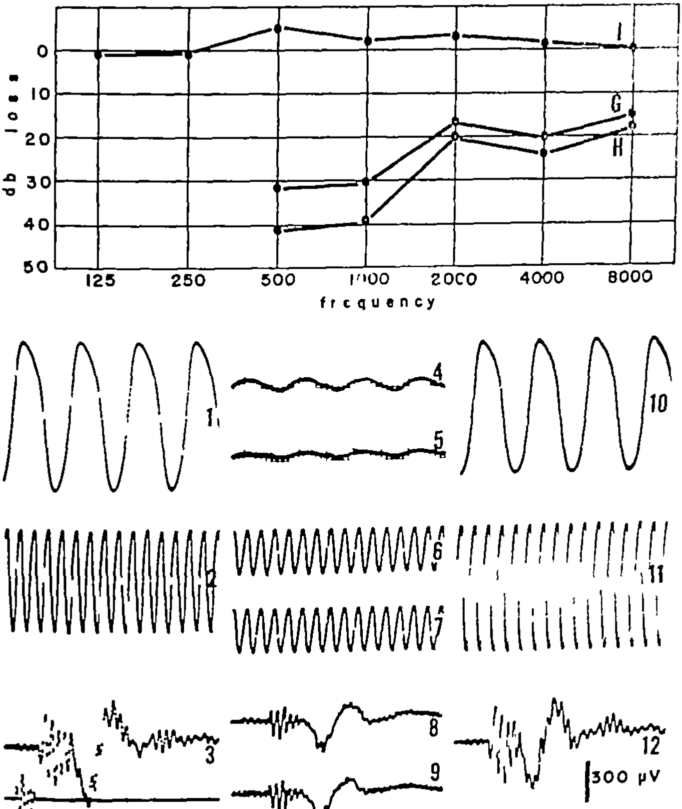

Fig 8 Cat A-458 Effect of fenestra ovalis following fixation of stapes with 30 gm Ossicular chain was not damaged Record 1 reference amplitude of CM for 1 000 c p s sine waves at 67 db above threshold Record 2 reference for 4 000 c p s at 59 db above threshold and Record 3 reference of AP for 8 000 c p s tone pips at 71 db above threshold Curves for thresholds of CM and other records represent the following Fixation of stapes with 30 gm Curve G and Records 4 6 and 8 After fenestra ovalis Curve H and Records 5 7 and 9 Removal of weight, Curve I and Records 10 11 and 12 Notice that amplitude of CM for 4 000 c p s is larger than the reference by 1 8 db

4 *Removal of Incus and Fixation of Stapes*

Fig 9 is a freehand drawing of the ossicular chain after removal of incus and creation of the fenestra ovalis As demonstrated before, removal of incus alone produced a considerable loss in thresholds and maximum voltage of both CM and AP After removal of incus and fixation of stapes, the impairment exceeded 50 db loss for all frequencies In

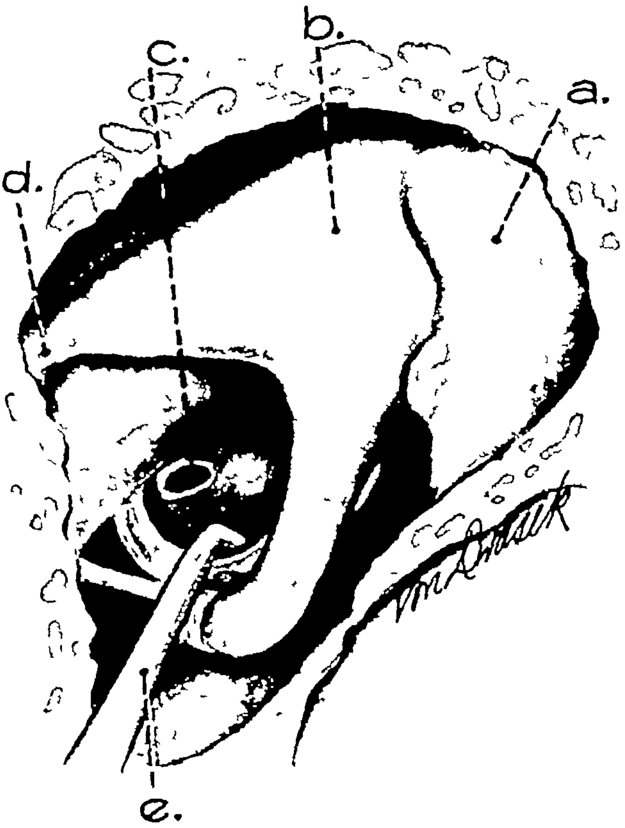

Fig 7 Freehand drawing of the ossicular chain showing the placement of hook for mechanical fixation of stapes and a simplified fenestra ovalis. A. malleus b incus c fenestra ovalis d posterior ligament of incus e hook for mechanical fixation of stapes

The question of whether fixing the stapes and creating the fenestra ovalis may produce some injury in the conductive mechanism and/or sensory organs was ruled out because cochlear responses recovered the reference level after removal of weight

Factors such as attic open or attic closed did not modify the impairment already established Similarly size and location of fenestra ovalis seemed not to be critical factors in this type of preparation

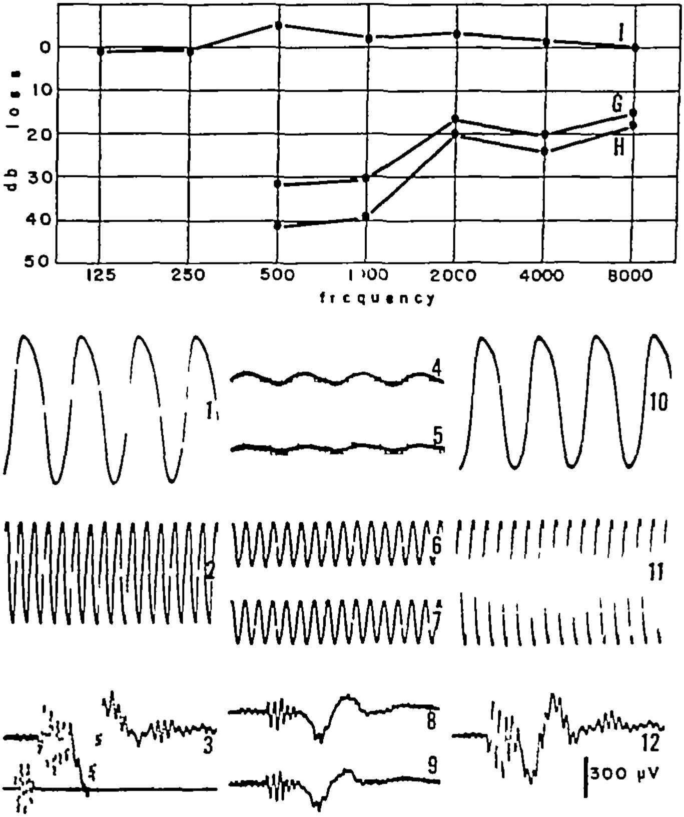

Fig 8 Cat A 458 Effect of fenestra ovalis following fixation of stapes with 30 gm Ossicular chain was not damaged Record 1 reference amplitude of CM for 1 000 c p s sine waves at 67 db above threshold Record 2 reference for 4 000 c p s at 59 db above threshold and Record 3 reference of AP for 8 000 c p s tone pips at 71 db above threshold Curves for thresholds of CM and other records represent the following Fixation of stapes with 30 gm Curve G and Records 4 6 and 8 After fenestra ovalis Curve H and Records 5 7 and 9 Removal of weight Curve I and Records 10 11 and 12 Notice that amplitude of CM for 4 000 c p s is larger than the reference by 1 8 db

4 *Removal of Incus and Fixation of Stapes*

Fig 9 is a freehand drawing of the ossicular chain after removal of incus and creation of the fenestra ovalis As demonstrated before, removal of incus alone produced a considerable loss in thresholds and maximum voltage of both CM and AP After removal of incus and fixation of stapes, the impairment exceeded 50 db loss for all frequencies In

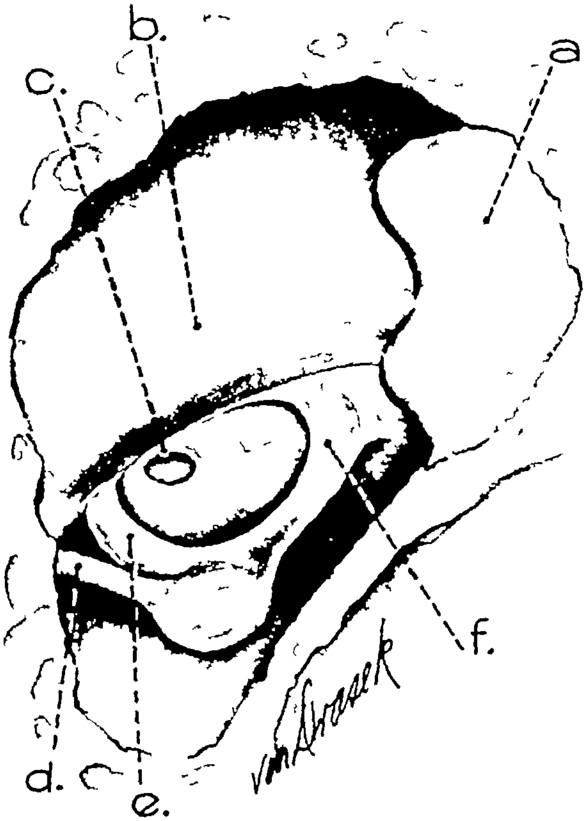

Fig 9 Freehand drawing of ossicular chain after removal of incus For simplicity hook for mechanical fixation was not included a malleus b facial canal c simplified fenestra ovalis d tendon of stapedius muscle e posterior crus of stapes f anterior crus of stapes

general, this result was favorably modified by the fenestra ovalis

Changes in thresholds of CM of a representative case are illustrated in Fig 10 *Curve J* shows the threshold shift after fixation of stapes alone, and *Curve K* that after removal of incus alone When removal of the incus was followed by fixation of the stapes thresholds shifted to *Curve L* After the fenestra ovalis was created, thresholds improved to *Curve M*, and when the fenestra was enlarged, thresholds showed

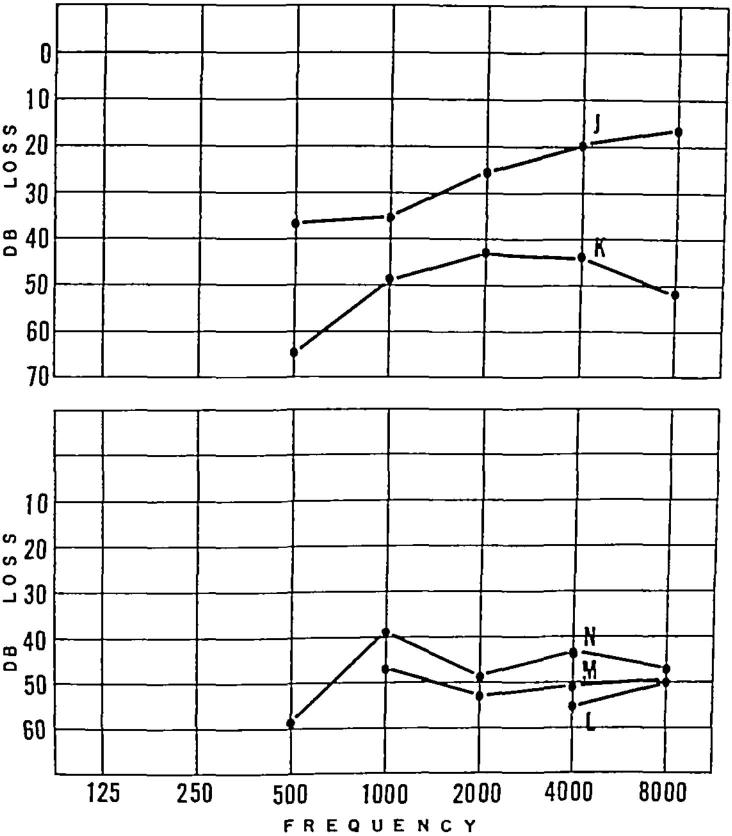

Fig 10 Cat A-455 Effect of fenestra ovalis on thresholds of CM after fixation of stapes and removal of incus. Fixation of stapes with 30 gm. Curve J Incus removed without fixation of stapes Curve K. Incus removed plus fixation of stapes with 30 gm Curve L Curve M, fenestra *ovalis plus incus removed and stapes fixed Curve N the fenestra was* enlarged twice

further improvement, *Curve N* Final losses exceeded the 40 db level

Threshold shift of AP produced by fixation of the stapes and removal of the incus was also favorably modified, but the final loss was about the 60 db level

Changes in amplitude of both CM and AP can be estimated from the records presented in Fig 11 The fenestra ovalis improved the losses produced by fixation of the stapes and

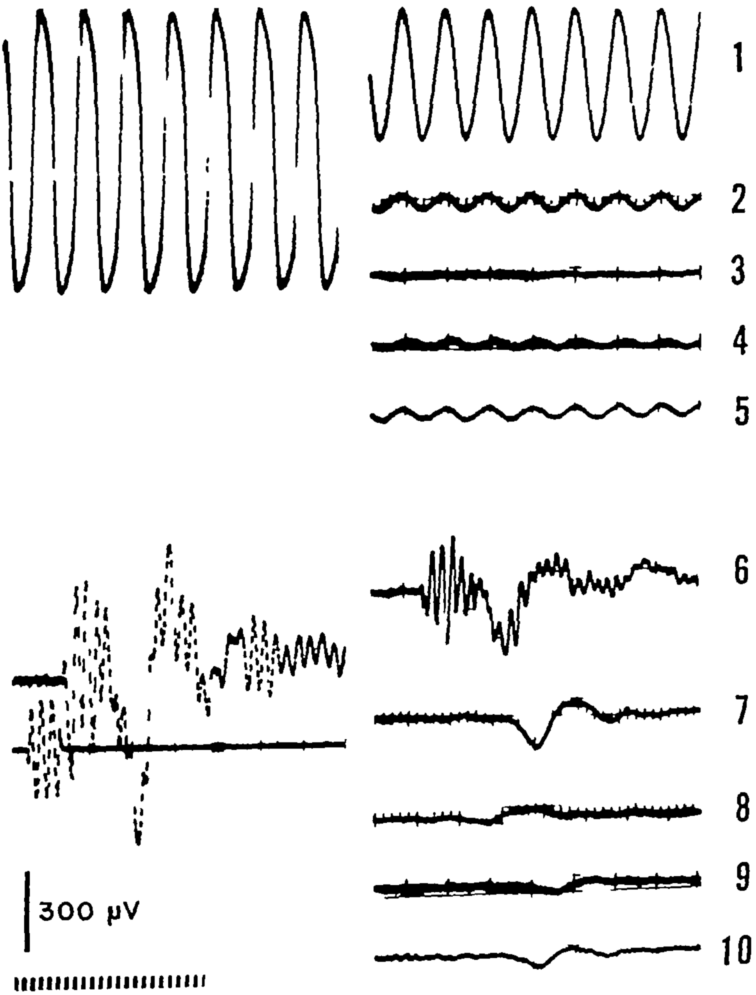

Fig 11 Cat A-455 Effect of fenestra ovalis on amplitude of CM and AP The records on left column are reference 2 000 c p s sine waves at 74 db above threshold and 8 000 c p s tone pips at 76 db above threshold Records 1 and 6 fixation of stapes with 30 gm Records 2 and 7 removal of incus without fixation of stapes Records 3 and 8 removal of incus and fixation of stapes The hump in Record 8 is an artefact Records 4 and 9 fenestra ovalis plus incus removed and stapes fixed Records 5 and 10 the fenestra ovalis was enlarged twice

removal of the incus by a few decibels Nevertheless, the losses were 90 per cent or more of the reference

When the sound stimuli were applied through the attic instead of the external ear the losses already described were sometimes decreased by a few decibels A similar effect was obtained by removing both malleus and tympanic membrane or by creating a perforation in the tympanic membrane

Commentary The losses produced by fixation of the stapes and removal of the incus were definitely decreased by a fenestra ovalis, however, the final loss remained larger than 40 db As in the previous series these findings do not support the proposition of Rosen[10,11]

The further improvement that was observed after removal of malleus and tympanic membrane, or after creating a perforation in the tympanic membrane, or when sound was introduced through the attic is due to the same condition that is, elimination of attenuating effect produced by the presence of malleus and tympanic membrane

The improvement of cochlear responses by the fenestra ovalis after fixation of the stapes and removal of the incus is more difficult to explain When the stapes is fixed and the incus removed, incoming sound has access mainly to the round window In other words, stiffness and frictional resistance are added to the stapes and, furthermore, mobilization of inner ear fluids is largely reduced because of the blocking effect[illegible] Now, the fenestra ovalis produces a stream of perilymph which fills the oval window niche, thereby the surface of perilymph reestablishes the area of this window Inner ear fluids and fluid in the oval window niche make a continuous medium through the fenestra ovalis[illegible] As a consequence the blocking of the oval window is eliminated, and stiffness and frictional resistance no longer play a role at this level The fenestra ovalis seemed to produce the same effect as in the series where the incus was removed, but the stapes was not fixed In both series the incoming sound has access to both windows and their counteractive effects will largely depend upon their phase relation

In the series where the stapes was fixed and ossicular chain remained intact the fenestra ovalis has no favorable effect, because sound is mainly conducted through on intact but overloaded ossicular chain This overloading is not modified by the fenestra ovalis former action of the middle ear mechanism has been altered, therefore, the proposition of Rosen,[10,11] that "the transformer action of the intact ossicular chain is a sufficient but not a necessary condition for normal and near-normal hearing," is not supported by these experiments

OTOLOGIC EVALUATION IN CLEFT PALATE PATIENTS *†

EMANUEL M. SKOLNIK, M.D.,
Chicago, Ill.

The increasing concern for the complex and many faceted needs of the child with a cleft lip and palate, particularly in the domain of speech disorders, has necessitated the organization of a carefully designed integrated program of diverse professional talents striving toward a common goal—effective care on a longitudinal basis to obtain superior functional results. The otolaryngologist, in particular, is possessed of the proper grounding in the surgical anatomic and physiologic nature of the contiguous structures to render a most valuable service in the total rehabilitation of such a patient.

Since good hearing is essential to learning to speak, it is obvious that any hearing loss due to diseases of the ear is an obstacle to the patient's acquisition of good speech and is of primary concern to all who are engaged in the care of the cleft palate patient. The split in the velum alters physiologically the muscles related to the Eustachian tube, thus making the child vulnerable to frequent attacks of otitis media.

The tonsil and adenoid problem, so often the subject of controversy in the case of a normal child, deserves judicious evaluation when the child has a cleft palate since the lymphatic structures are an integral component of the velopharyngeal mechanism for the development of normal speech.

Congenital deformities of the external ear and nose with resultant nasal obstruction, as well as the type of cleft and status of the patient, may play a significant role in the final analysis of the auditory state; however, the management of the multiple phase problem of auditory deficiency relative to

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication April 24, 1958.

‡Figures and photographs are from the files of the Cleft Palate Center of the University of Illinois College of Medicine.

the condition of a cleft palate is mainly one of hearing loss It is essential to know whether the loss of hearing is progressive and whether the speech development will be restricted by the hearing deficit

The purpose of this paper is to report the results of a survey of the ear pathology and audiological findings in patients with clefts of the lip and palate, and to analyze the factors related to the pathogenesis of ear disease in this congenital anomaly

HISTORICAL

In 1878, Alt[1] reported on the "Cure of Deafmutism by Successful Treatment of Otorrhea and Congenital Cleft Palate" Thorington,[2] in 1892, reported a case of "almost total destruction of the velum palati corrected by an artificial soft palate, producing not only greatly improved speech, but an immediate increase of audition" Then in 1904, "drainage of milk through the ear in an infant with congenital cleft palate" was reported by Variot [3]

The importance of good hearing in the phonetic rehabilitation of cleft palate patients was recognized early In 1893, Gutzmann[4] observed that about half of his cleft palate patients had hearing disturbances which accounted for a frequent failure of speech therapy Lannois[5] was probably the first to approach the problem of the status of the middle ear relative to cleft palate in 1901 Brunck,[6] in 1906, emphasized the need for a thorough otolaryngological examination in the phonetic correction of cleft palate patients because of the high percentage of inflammatory changes involving the upper airways and middle ear of these patients Introducing the term "submucous cleft palate," and making a thorough investigation of this congenital anomaly, Kelly,[7] an otolaryngologist, in 1910 reported that 15 of 19 cases had ear difficulty associated with nasal catarrh Rendu[8] associated cleft palate with congenital atresia of both external auditory canals and rudimentary auricles in 1912 Borel,[9] in her study on the physiology of phonation and speech therapy in cleft palate patients, discussed otogenic phonetic disturbances, their correction and auditory re-education

Pagnamenta[10] made an analysis of 150 postoperative cleft palate patients, and found that 30 per cent had hearing loss, however, he also observed that the severity of the cleft was parallel to the increase in severity of hearing loss Seeler[11] stressed the importance of systematic speech therapy in cleft palate patients directed toward improving the efficiency of the palatal and tubal musculature, and the avoidance of persistent closure of the tube Segre[12] studied the pressure changes in the middle ear of cleft palate patients during respiration and deglutition and maintained that in these patients the tubal opening has a paradoxical behavior—usually opens and closes during swallowing Opposite conclusions were reached by Meissner,[13] who made an analysis of 213 cleft palate patients whose ages varied between 10 and 35 years He found hearing disturbances in 27 per cent of his cases, but only 17 per cent of them had perfectly normal ears The basis for these findings is a persistent closure of the Eustachian tube due to physiopathologic changes in the velotubal musculature No relationship was found by Meissner between ear pathology and the severity of the cleft

✓Beatty,[14] in dealing with pre- and postoperative management of cleft palate patients, recognized that seven per cent of his patients had infections of the ear or sinuses while under surgical observation He pointed out how remarkable is the small percentage of ear and sinus disease in these patients, considering the disturbance of normal physiology of the nasal and oral cavities, often in association with malnutrition, dehydration and improper feeding methods

More recently, Sataloff and Frazer[15] analyzed 30 children with cleft palate, and related the very high incidence of ear pathology and hearing loss (90 per cent) to hyperplasia of tonsils and adenoids They suggested early adenoidectomy in infancy to preserve the hearing Nassy,[16] of the Netherlands, studied 70 children and 40 adults with cleft palate and found that 61 per cent of them had hearing disorders and ear pathology He suggests a disturbance of the function of the

Eustachian tube and that the frequency of ear disorders depends on the size of the cleft He made a plea for early closure of the cleft, speech training and regular treatment of ear, nose and throat pathology Halfond and Ballenger[17] analyzed the audiological and otological findings of 69 cleft palate patients and found that 50 per cent or more have hearing loss, however, no definite relationship could be established between hearing loss and the type and width of the cleft, surgical or non-surgical closure, nasal pathology, or hyperplasia of lymphoid tissue

METHOD OF APPROACH TO ANALYSIS

This study was carried out over a period of eight years and the data were derived from a study of hundreds of patients with clefts of the lip and palate Four hundred and one of these individuals received a complete otolaryngological examination, and constitute the basis for this investigation and presentation

The otolaryngological examination included the following survey

A History pertaining to

1 Previous ear disease

2 Age of first attack and frequency of ear infection

3 Frequency of upper respiratory infections

4 Frequency of sore throat (tonsillitis)

5 Relationship of upper respiratory infection and sore throat to ear infection

6 Surgical removal of tonsils and adenoids, age of operation and significance relative to ear infection

7 Presence of allergic factors of the upper head space

8 Relationship of growth of individual to ear infection

9 Contagious diseases and their relationship to ear infection

10 Closure of the palate and the relationship to ear infection

11 Insertion of a speech aid and the relationship to upper respiratory infections, sore throat and ear infection

12 Hearing loss, onset and course

B Otological evaluation

1 Configuration of auricles

2 Patency and configuration of external auditory canals

3 Tympanic membranes—

a Landmarks and light reflex
b Evidence of retraction
c Scarring
d Perforations (site and size) and
e Nature and amount of secretion

C Rhinological evaluation

1 External configuration (dorsum, alae, columella, nares)

2 Condition of the vestibule

3 Septal deformity (deviations, ridges, spurs)

4 Color of mucosa and size and resilience of turbinates

5 Presence of abnormal secretions

6 Patency of airway

D Pharyngolaryngological evaluation

1 Type of cleft palate, width, and condition of adjacent tissues

2 Neuromuscular function of velum and pharynx

3 Presence, size, site, and condition of tonsils and adenoids

4 Relationship of tonsils to movement of soft palate

5 Relationship of tonsils to dimension of oro-pharynx

6 Relationship of nasopharyngeal lymphoid tissue and nasal obstruction

7 Evidence of laryngeal anomalies

8 Size and position of tongue (glossoptosis)

9 Configuration, color and movement of pharyngeal and laryngeal structures

10 The airway

E Laboratory procedures

1 X-ray studies of mastoids (Schuller-Law, Stenver, Towne and Mayer's view) and sinuses (Caldwell, Water and laterals) was carried out when pathology was suspected

2 Laminographic studies of the nose and nasopharynx when indicated

F Functional examination

1 Vestibular evaluation performed in presence of severe or perceptive hearing loss

2 Hearing evaluation in patients with—

- *a* Congenital anomalies of the ear
- *b* History of recurrent ear infection
- *c* Evidence of middle ear pathology
- *d* History of contagious diseases that might relate to the ears
- *e* Clinical evidence of inner ear dysfunction

3 The hearing evaluation included—

- *a* Conversational and whispered voice
- *b* Tuning forks
- *c* Pure tone audiometry
- *d* Speech reception threshold and discrimination tests (binaural in free field and monaural with ear phones) when advisable

Hearing evaluation in preschool children was performed by conditioning the child to execute a certain movement when pure tones, the name of toys, or low ("go") and high pitched ("sh") sounds were transmitted to him through a loudspeaker or ear phones By transmitting these sounds at different loudness levels a fairly accurate hearing evaluation could be made If a child was severely deaf, reflexes were studied when producing very loud noises (tom-tom, bells, whistles, etc) In instances of severe mental retardation, or in brain injured children, the responses to auditory stimulation during electroencephalography were observed The psychogalvanic skin resistance test was employed only as a control when advisable

To further document data referable to growth and development of the head associated with this anomaly, cephalometric roentgenography is employed The instrument for oriented cephalometric roentgenography consists of a firmly-based head-positioning device and two X-ray tubes in fixed relationship to the head-positioner (see Fig 1) This arrangement provides a constant position of the head in relation to the source of X-rays, therefore, it becomes possible to reproduce the same lateral and postero-anterior views of the head at desired intervals The resultant films are then placed on a trans-illuminated tracing table and covered with thin tracing paper The bony structures visible on the film, as well as the outlines of the soft tissue profile, the pharynx, soft palate and the tongue are traced onto the paper Where it is desired

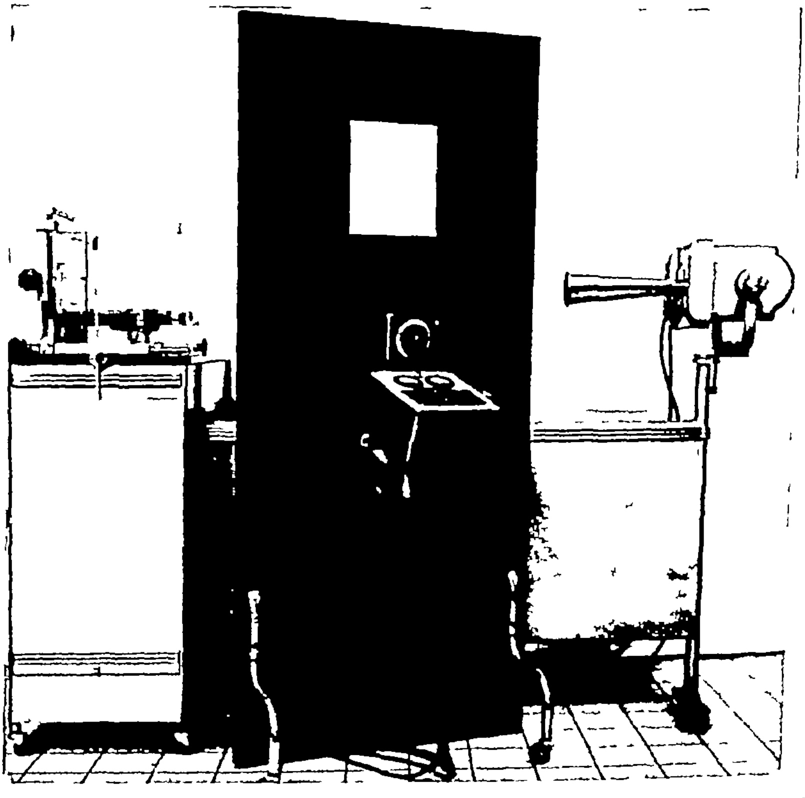

Fig 1 Specially designed cephalometer The X-ray tube for the frontal film is concealed within the cabinet beneath the head holding device

to study the changes incident to growth or the movements during phonation, one tracing is superimposed on the other The roentgenographic studies are facilitated by sedating the younger children

This survey does not represent a research project to prove a certain thesis The objective is to report the ear pathology and audiological findings in 401 individuals with cleft lips and palates observed in a period of eight years, furthermore, the study was not strictly limited to observations of diseases of the ear, nose and throat According to the concept of *total patient care*, and in order to stimulate interprofessional understanding of the defect, the ear pathology was related to the genetic heritage, metabolic climate, growth and development pattern, and to the surgical and non-surgical modalities of rehabilitation

ANOMALIES OF THE EAR IN CLEFT PALATE PATIENTS

The association of cleft palate and other physical malformations, particularly due to arrested development, has been frequently observed, however, as far as the congenital anomalies of the ear are concerned, very few cases have been reported, and no impression of its average incidence of occurrence has been given

Fogh-Andersen[18] in a study of 1013 patients with cleft lip or cleft palate reported severe malformations in more than ten per cent, with three or more rare abnormalities present in a great number of infants He observed also a patient with cleft lip and palate associated with cranioschisis and atresia of the auricles, a child with cleft palate, atresia of the auricles and syndactilism, and a case of cleft lip with malformation of the auricles Ivy[10] reported about 11 per cent of other congenital anomalies in the cleft lip or cleft palate patients observed in Pennsylvania

Among the 401 patients processed through this study, 62 (15 per cent) exhibited other congenital anomalies (Scheme I) The number of instances of mandibular micrognathia and upper and lower limb malformations is considerable Twelve of the patients presented the syndrome of Pierre

Robin (hypoplasia of mandible, cleft palate, glossoptosis, respiratory difficulty and malnutrition)

The patients with mandibular micrognathia and the majority of the other malformations presented a cleft of the hard and soft palates (53 per cent of 62 cases) Fogh-Andersen[18] divided his cases into "hereditary" and "solitary," according to a hereditary link that could be substantiated In his analysis he also pointed out that the majority of patients with lip involvement are supposed to be hereditary, while "in the isolated palatal cleft there is a considerable admixture of non-hereditary cases" In our series, although numerically not so large, it was observed that only exceptionally were

SCHEME I

CONGENITAL ANOMALIES IN CLEFT PALATE PATIENTS

	Anomaly	Cases	Types
1	*Anomalies of the Head*	2	*Acrocephaly, microcephaly*
2	Asymmetry of the Face	3	
3	Anomalies of the Eye	6	Corneal opacity, microphtalmia, iris colobomata, retrolental fibroplasia, optic atrophy, ptosis of eye-lids, atresia of naso lacrimal duct, strabism
4	Anomalies of the Ear ..	8	See Scheme II
5	Choanal Atresia ..	1	
6	Mandibular Micrognathia	16	Pierre Robin's syndrome was seen in 12 of these cases
7	Tracheal Stenosis	1	
8	Anomalies of the Neck	3	Klippel Feil syndrome, branchial cyst
9	Anomalies of the Heart	4	Absence of interventricular septum, patent ductus arteriosus
10	Anomalies of the Rectum ..	1	
11	Anomalies of Genitalia	5	Hydrocele cryptorchidism, phymosis
12	Anomalies of Upper Limb	9	Adactilism, syndactilism, webbed fingers, ankylosis of interphalangeal joints, club hands
13	Anomalies of Lower Limb	13	Adactilism, syndactilism webbed toes, club feet, metatarsus varus calcaneous valgus, absence of left foot
14	Hemangiomas	4	Observed on the tongue, chest back and buttock
15	Mongolism	3	

other anomalies associated with cleft palate cases in which a hereditary relationship could be demonstrated. This corresponded to Fogh-Andersen's observations.

Anomalies of the ear were noted in eight of the cleft palate patients, or 2 per cent of all the cases, or 13 per cent of the associated anomalies. Mild anomalies, such as pointed ear, lop ear, Darwin's tubercle were not included. The degree of involvement in the cases ranged from a moderate malformation of the auricle, atresia of the external auditory canals, to the more severe configurations of microtia, melotus, asymmetry of face, or peripheral facial paralysis (Scheme II).

SCHEME II

ANOMALIES OF THE EAR IN CLEFT PALATE PATIENTS

	Anomalies of the Ear	Associated Anomalies
1	Deformity of the Auricles	Cleft of the hard and soft palates Klippel Feil syndrome anomalies of the heart and rectum
2	Deformity of the auricles and stenosis of external auditory canals	Cleft of the hard and soft palates, mandibular micrognathia
3	Deformity of the auricles and displacement of the right external auditory canal	Cleft of the hard and soft palates mandibular micrognathia with Pierre Robin syndrome
4	Microtia and stenosis of external auditory canal right	Unilateral cleft of the lip and palate right
5	Microtia displacement and stenosis of external auditory canal right	Unilateral cleft of the lip and palate left asymmetry of the face right anomaly of the heart
6	Microtia and atresia of external auditory canal right with stenosis of external auditory canal, left	Cleft of the soft palate
7	Microtia displacement and atresia of external auditory canal right with stenosis of external auditory canal left	Cleft of the soft palate asymmetry of the face right peripheral facial paralysis right.
8	Atresia of external auditory canals	Bilateral cleft of the lip and palate optic atrophy

It is of interest that three cases were associated with clefts of the hard and soft palates and two with clefts of the velum. The problem of the pathogenic relationship between cleft palate and anomalies of the ear deserves more consideration

Development

Independent of the exact mechanism of development of cleft lip and palate, the importance of the mandibular arch is fully recognized According to the classical theory of fusion of nasal and maxillary processes, or the theory of mesodermal penetration, it seems that an arrest of development is significant in the pathogenesis of clefts of the lip and palate In particular, the theory of non-fusion of the palatine processes is for most investigators still valuable to account for the origin of the clefts of the hard and soft palates On the other hand, it is known that the external auditory canal develops from the first branchial groove and the auricle from the adjacent mandibular and hyoid arches The Eustachian tube and tympanic cavity develop from the first pharyngeal pouch, while the malleus and incus are formed from Meckel's cartilage, and the stapes from Reichert's cartilage

Among the cases with cleft palate, two patients are observed with unilateral microtia and homolateral asymmetry of the face (due to under development of the hemimandible), and two patients with bilateral deformity of the auricles and mandibular micrognathia This association of mandibular, palatal and auricular anomalies seems to indicate an arrest of development involving primarily the first branchial arch In fact, there is a definite parallelism between the formation of the mandible and the development of the auricle in its movement craniodorsally from its original caudo-ventral position

✓ Canick[20] has recently analyzed the embryology, pathologic anatomy, and etiology of cleft lip and palate He concluded that the mechanism of embryogenesis is complex and that several factors, both inherent and environmental, influence the development of multiple anomalies Genetic factors, dominant, recessive, incompletely sex-linked, and of reduced penetrance, have been considered Environmental factors, such as vitamin and nutrient deficiencies, maternal diseases and age seem to play a part in teratogenesis Duration, intensity and time of action of any agent seems to be of greater importance than the type of agent

✓ In the case of palatal and auricular anomalies, the normal development of the first branchial arch remains incomplete or deviates Hereditary factors and environmental agents may be the cause of this altered development, however, the observation that "solitary" cases of cleft palate and lip are more frequently associated with other anomalies, the greater incidence of association of anomalies in clefts of the hard and soft palates, the pathogenesis of which has often been related to micrognathia and nasal displacement of the tongue, the statistical data of no definite increase of other anomalies in relatives of cleft palate patients indicates the possibility of exogenous causes interfering with the early embryonic development It is possible that induced mutations determine a disturbance of growth with the consequent occurrence of multiple anomalies due to arrest of development

EAR PATHOLOGY AND HEARING DISTURBANCES IN CLEFT PALATE PATIENTS

Several factors were seen to be clearly related to the pathogenesis of ear disease in cleft palate patients

In Scheme III, the cleft palate patients are classified according to six groups, five of which are typical The atypical group includes four cases of bilateral cleft lip and unilateral cleft palate, seven cases of unilateral cleft lip and bilateral cleft palate, two cases of unilateral cleft lip and cleft velum, one case of median cleft lip, bilateral alveolar ridge and cleft velum, four cases of unilateral cleft lip and submucous cleft palate and four cases of unilateral cleft hard and soft palate

There is a male preponderance in the types of clefts involving the lip and a female preponderance in those involving only the hard and soft palates The group of submucous cleft palate is too limited for any sex distribution In the unilateral cleft lip and palate there is a definite prevalence on the left side

The number of cases with ear pathology, unilateral or bilateral, totaled 184, or 45 8 per cent Of these cases, 16 8 per cent were unilateral and 83 2 per cent bilateral The *distribution of ear disease as to sex strictly corresponded to*

that of the cleft palate patients The total number of cases with definite hearing loss is 158, or 39 4 per cent

In Scheme IV a more detailed analysis of the type of ear pathology and hearing loss is noted Ear pathology is classified according to congenital anomalies, surgical procedures and severity of infection The latter is divided according to the presence of dry or discharging perforations (evidence of previous or present purulent otitis media), scarring (evidence of repaired suppurative otitis media), retractions (evidence of repeated severe catarrhal otitis media), and alterations of luster (evidence of mild catarrhal otitis media) Each ear is reported only once relative to the greatest degree of pathology

Perforations were noted in 27 6 per cent, scarring in 23 4 per cent, retraction in 28 4 per cent, alteration of luster in 16 1 per cent of the cases It seems, therefore, that there is no significant preponderance of catarrhal or purulent otitis media in cleft palate patients Central perforations prevailed as far as the site is concerned

Not all of the cases with ear pathology could be tested audiometrically because of age, mental retardation or uncooperativeness In some the audiogram was not reliable Among 288 pathologic ears accurately tested, 11 1 per cent did not show any hearing loss, 56 2 per cent showed a mild hearing loss (less than 30 db), 28 4 per cent showed a moderate hearing loss (between 30 and 60 db), and 4 3 per cent showed a severe hearing loss (over 60 db)

Perceptive loss of hearing was noted in five cases, all others were of the conductive type In one case a severe unilateral perceptive hearing loss and a moderate mixed type of hearing loss in the opposite ear was observed in a patient who had mumps previously In a brain injury child, the audiogram revealed a bilateral moderate hearing loss without any ear pathology The same finding was noted in a deaf child due to previous meningitis, the vestibular test failed to reveal any response In one case unilateral complete deafness, due to previous labyrinthitis secondary to middle ear disease was noted, no response was elicited to the vestibular test In an-

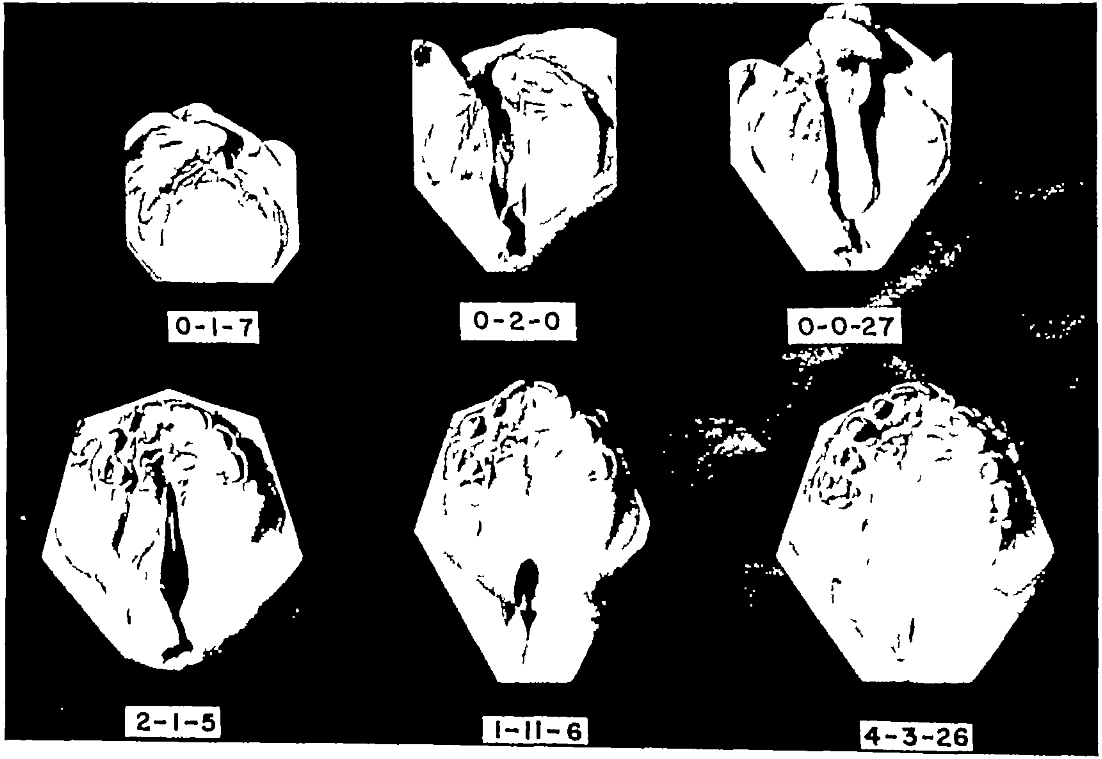

Fig 2 Plaster cast reproductions of several varieties of unoperated clefts of the lip and palate

other child a unilateral severe perceptive type of hearing loss was noticed, but no etiologic basis could be evinced

The majority of cases revealed a conductive type of hearing loss with predominant loss in the low frequencies and usually bilateral with a similar pattern in both ears A close relationship was noted between the degree of middle ear disease and degree of hearing loss The severest cases of hearing loss were either perceptive or due to surgical procedures of the mastoid Since conductive hearing loss, if not curable, is at least partially preventable, the role of the otologist in the follow-up of cleft palate patients is paramount

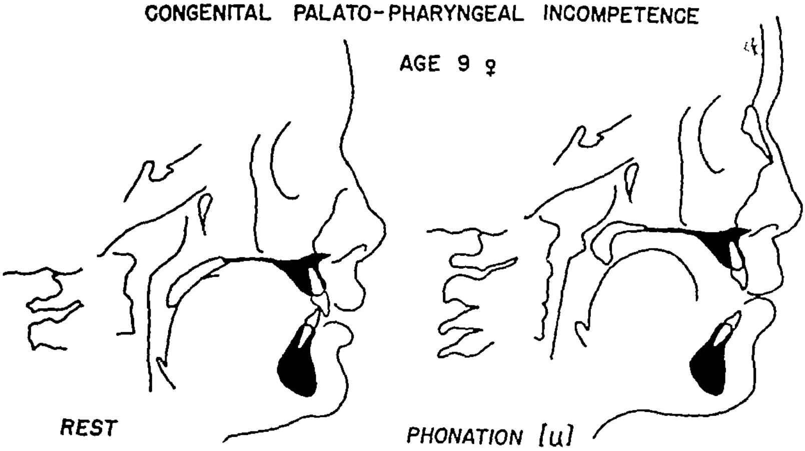

Fig 3 Palatopharyngeal incompetence as evidenced by cephalometric roentgenographic analysis from lateral films obtained at rest and during phonation of the vowel u as in boom Note congenital shortening of the palate and inability of the velum to make contact with the posterior pharyngeal wall The formation of Passavant's bar on the posterior wall of the pharynx is indicated in the stippled area.

INCIDENCE OF EAR PATHOLOGY ACCORDING TO AGE GROUP

In subdividing the cases according to their age, expressed in years, it was apparent that the incidence of middle ear pathology followed a different pattern according to four groups which appeared strikingly uniform in their structure Diagram I is very demonstrative

In the group of cases below one year of age only 6 per cent were found to have middle ear pathology A definite increase to 27 per cent of ear disease was noticed in the group of pre-school children (between one and four years of age) A more amazing increase of ear disease was observed in the school children (between five and 13 years of age) subdividing the latter group into two (five to eight years and nine to 13 years) the incidence did not change substantially In the limited number of cases over 13 years of age, the frequency of ear disease did not vary significantly It seems, therefore, that a gradual increase of ear disease exists up to the school age and then persists at a plateau level

In analyzing the cases that were followed over a long period of time there was a comparable increase of ear pathology in passing from the pre-school age to the school age The contagious diseases, as well as the increased incidence of upper respiratory infections, are factors that tend to raise the percentage of ear pathology and hearing loss in a patient with previously altered anatomic and physiologic relationships, as exists in a child with a cleft of the palate, a repaired cleft or a cleft fitted with a prosthesis

Beatty[21] reported that in his experience the majority of "well fed and well cared for" infants do not develop ear infection prior to the age for surgical closure of the palate

The frequency of ear disease in school age children observed in this study is most significant and expresses in figures the higher incidence of ear pathology in cleft palate patients compared to the normal child The values obtained in the School Surveys of the Hearing Conservation Program, which throughout the country average between 8 and 10 per cent, are used as controls Values of 60 per cent of hearing impairment in cleft palate children in school age measure this difference beyond discussion, as evidenced in the charts (Scheme III and Diagram I)

INCIDENCE OF EAR PATHOLOGY ACCORDING TO TYPE OF CLEFT

An analysis of Scheme I reveals that a different incidence of ear pathology exists for each type of cleft (see Fig 2) Maximum frequency prevails for submucous cleft palate (73 per cent) and a minimum for clefts of the hard and soft palates (31 per cent), however, as was mentioned in the preceding paragraph, a definite difference of incidence, according to the age group, was seen and it is obvious that no comparison can be made between different types of clefts without considering the age factor

In Scheme V the incidence of ear pathology in cleft palate patients according to the type of cleft in the pre-school and school age is noted The atypical cases are not considered, because the structure is not uniform

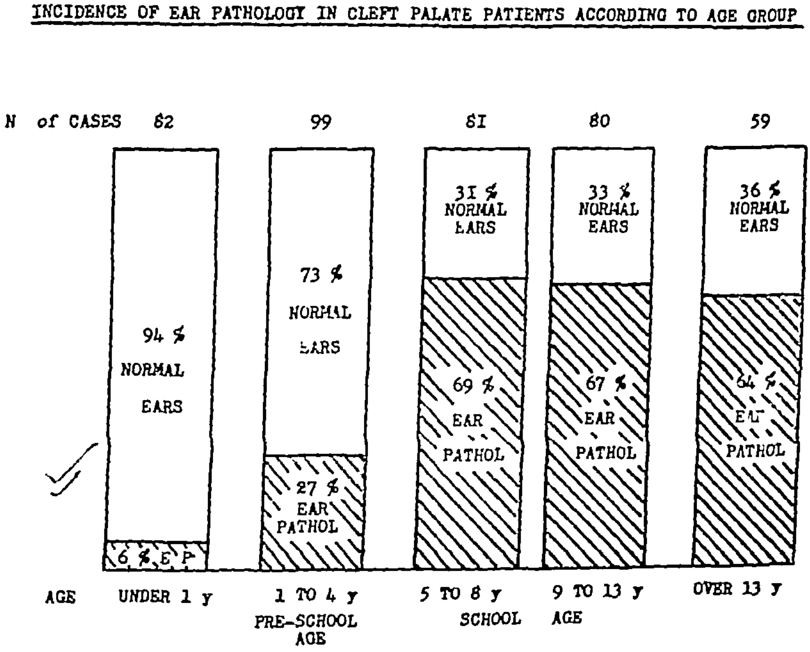

DIAGRAM I

It is quite significant that in the school age group the incidence of ear pathology, notwithstanding the small number of cases, is relatively uniform for each type of cleft The average value being 68 per cent, variations exist between 62 per cent for clefts of the hard and soft palates and bilateral clefts of the lip and palate and 74 per cent for clefts of the soft palate

The figures reported in the pre-school age group are too small to deserve consideration, however, one is justified in emphasizing the small incidence of ear pathology in this group for the clefts of the hard and soft palates (12 per cent of 33 cases) The reason for this relatively small frequency of ear pathology is not clear This is probably related to a less distorted anatomical configuration of the head spaces and relatively greater intactness of the neuro-muscular mechanism of the Eustachian tube

SCHEME V

INCIDENCE OF EAR PATHOLOGY IN CLEFT PALATE PATIENTS ACCORDING TO TYPE OF CLEFT

Type of Cleft	Pre-School Age (From 1 to 4) Total Number of Cases 91		School Age (From 5 to 13) Total Number of Cases 156	
	Cases with Ear Pathology	Cases with Normal Ears	Cases with Ear Pathology	Cases with Normal Ears
Average Values	27 %	73 %	68 %	32 %
1. Bilateral Cleft Lip and Palate	2 (25%)	6 (75%)	16 (62%)	10 (38%)
2. Unilateral Cleft Lip and Palate	11 (30%)	27 (70%)	35 (71%)	14 (29%)
3. Cleft Hard and Soft Palates	4 (12%)	29 (88%)	24 (62%)	15 (38%)
4. Cleft of the Soft Palate	6 (55%)	5 (45%)	14 (74%)	5 (26%)
5. Submucous Cleft Palate	—	1	17 (73%)	6 (27%)

Among the 62 cases of unilateral cleft lip and palate, 21 (33 per cent) showed unilateral or definitely more pathology in the ear opposite the side of the cleft, seven on the same side and the remaining, uniform, bilateral pathology Of the 21 cases with greater contralateral pathology, six were untreated and 15 were postoperative. No definite relationship was noted in these cases with unilateral nasal obstruction

RELATIONSHIP OF EAR PATHOLOGY TO WIDTH OF THE CLEFT

According to Nassy,[16] the frequency of middle ear disorders in cleft palate patients depends on the size of the cleft This

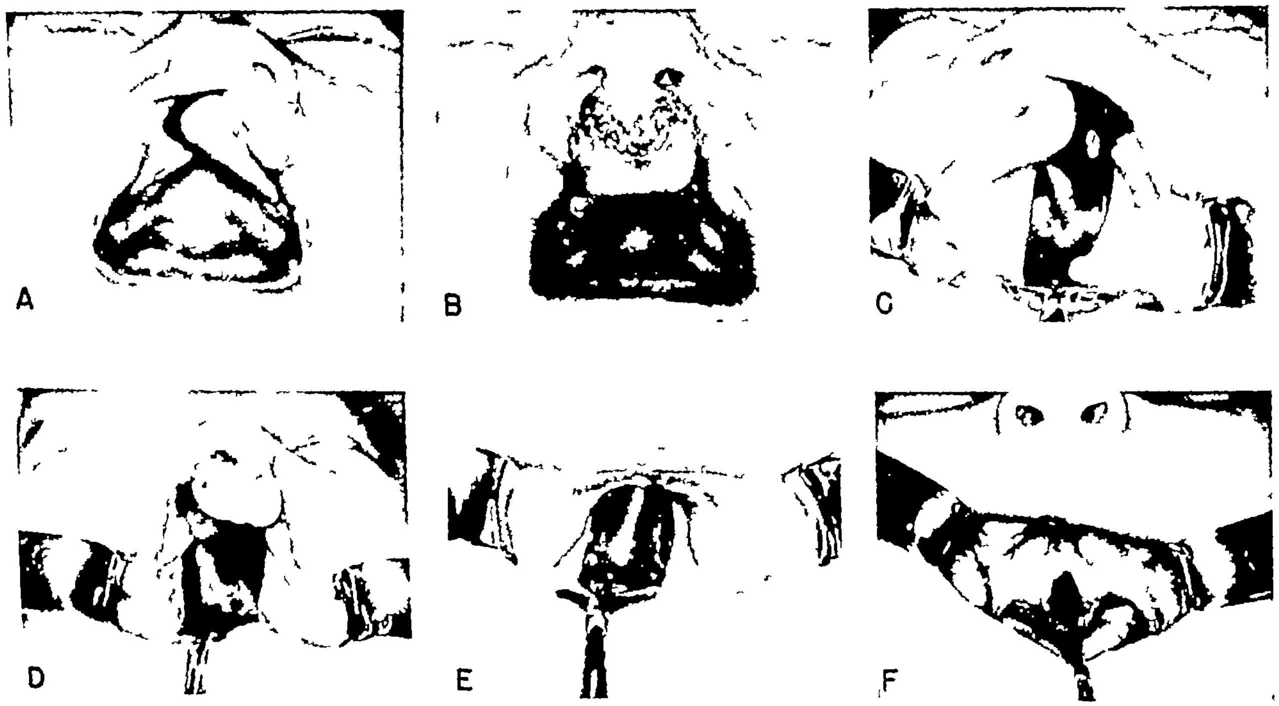

Fig 4 Varieties of clefts of the hard and soft palates A.—Unilateral cleft of the alveolar process with intact hard and soft palates B—Incomplete bilateral cleft of the lip with intact hard and soft palates C—Complete unilateral cleft of the lip hard and soft palates D—Complete bilateral cleft of the lip hard and soft palates E—Cleft of the hard and soft palates without involvement of the lip or alveolar process F—Cleft limited to the soft palate

was not observed in an analysis of a group of school children with cleft palates in this study

As the concept of width is purely subjective and variable with the *dimensions of time, the closure of lip and orthodontic* treatment, it is necessary to analyze children of a certain age group and with untreated palates Borderline cases between "wide" and "narrow" were not considered The different types of clefts are considered together as was demonstrated in the preceding paragraph In the school age group the difference in frequency of ear pathology between the different types of clefts is insignificant

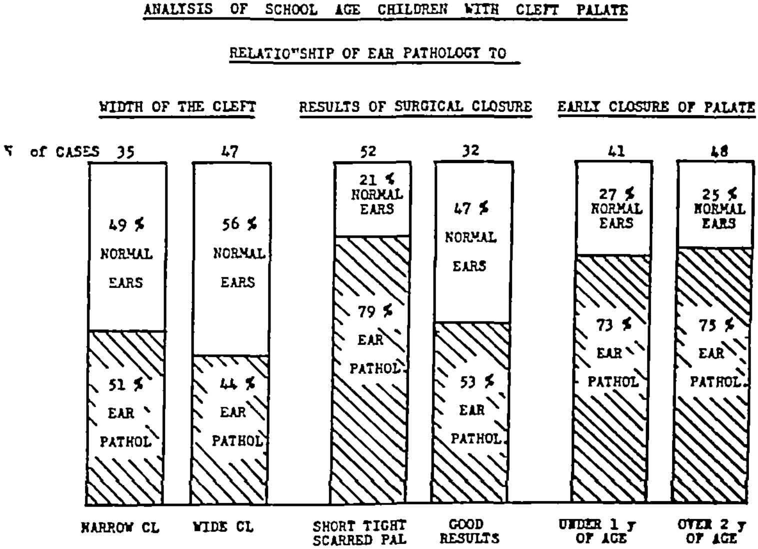

DIAGRAM II

Among 47 definitely wide clefts (not amenable to surgical closure, see Fig 4) 21 (44 per cent) showed ear pathology and 26 (56 per cent) normal ears (see Diagram II) In the same age group among 35 narrow clefts (immediately prior to surgical closure) 18 (50 per cent) showed ear pathology, and 17 (49 per cent) normal ears, therefore, it does not seem that the width of the cleft has a definite relationship to the frequency of middle ear disorders in cleft palate patients in the school age

RELATIONSHIP OF EAR PATHOLOGY TO SURGICAL REPAIR OF CLEFT PALATE

In Diagram III the relationship of surgical or prosthetical closure of cleft palate in pre-school and school children for the most important four typical clefts is evaluated

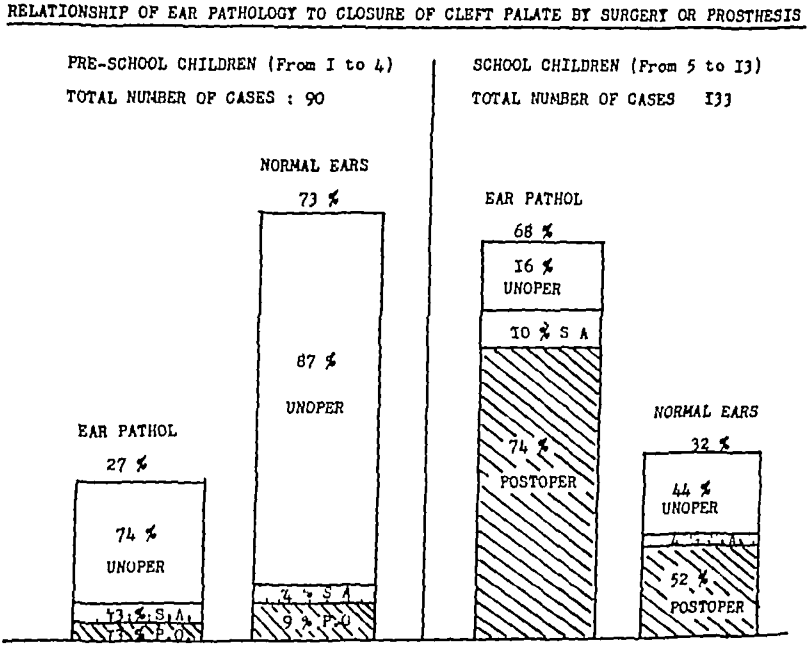

DIAGRAM III

Both in the pre-school and school age groups there is a higher percentage of postoperative cases in the pathologic group than in the normal, however, the most significant finding is the definite increase of ear pathology in passing from the pre-school age to the school age group parallel to the increased number of postoperative cases In the school age children with *surgically closed palates*, approximately 74 per cent had ear pathology (see Diagram III)

As other factors are involved in the difference of frequency of ear disease in the two age groups, further analysis of the importance of surgical closure in relation to ear pathology is made. Among the cases followed over a period of time, 16 developed otitis media in the school age after surgical repair and two after being fitted with a speech aid. Only six other untreated cases developed otitis media in the school age group. An analysis of the results of surgical repair among 52 cases in the school age with a palate that was short, tight and scarred, 41 (79 per cent) showed ear disease, and 11 (21 per cent) had normal ears. Among the 32 cases in the school age group with a good surgical repair, 17 (53 per cent) showed ear pathology, and 15 (47 per cent) had normal ears (see Diagram III). Twelve of the school age cases had more than five palatal operations: 8 (66 per cent) of them had ear pathology and 4 (34 per cent) showed normal ears.

The influence of early surgical closure was also considered. 41 of the cases of school age had palatal closure before one year of age, 30 (73 per cent) had ear pathology, and 11 (27 per cent) had normal ears. The percentage of ear pathology in children with a cleft palate closed after two years of age (when, according to Subtelny,[22] a leveling off of the dimensions of the cleft, maxillary and nasopharyngeal development has been reached) was approximately the same—over 48 cases, 36 (75 per cent) had ear pathology and 12 (25 per cent) had normal ears (see Diagram III).

Surgical closure of the palate appears to be an extremely important factor in the pathogenesis of middle ear disorders. The mechanism seems to be related to a process of atrophy, scarring and sclerosis of tubal muscles after surgery. The higher incidence of ear pathology in the cases with a scarred, tight palate compared with the good operative results accounts for this interpretation.

It has been said that simple anatomical closure of a palate without the formation of a velopharyngeal sphincter makes surgical treatment unsatisfactory. Certainly, the inadequacy of tubal musculature after surgery should be considered in the evaluation of a surgical repair of the palate; furthermore, the opinion that early closure of the palate avoids secondary atrophy of palatal muscles and prevents otitis media, is not supported by this study The dangers of early closure in relation to interference with centers of bone growth, and consequent serious disturbances of development of the bones of the jaw and face, and the high incidence of middle ear pathology, factors which are probably directly or indirectly related to each other, questions the validity of surgery at an early age, in many cases

RELATIONSHIP OF EAR PATHOLOGY TO CLEFT PALATE PROSTHESIS

Several otolaryngologists have the conviction that there is a relationship of cleft palate prosthesis with upper respiratory health and audition No definite statement on the association of ear pathology to cleft palate prosthesis has ever been made

Twenty-four of the cases in this study that were fitted with a speech aid were observed Twenty of them were unoperated and four postoperative The four postoperative and 13 of the unoperated cases showed ear pathology

Clinical experience reveals a frequent association of inflammatory changes of the upper airways, lymphoid hyperplasia and middle ear pathology with cleft palate prosthesis In most of these cases, however, an ill-fitting appliance or poor hygiene of the speech aid was noted It is known that the size and shape of the segments of the appliance are highly individualistic The contour of the palatal extension must conform strictly to the natural contour of the velar tags, and the bulb must adapt to the proportions of the patient's nasopharyngeal port The level at which the bulb is placed in the nasopharynx is of utmost importance The bulb must be reduced in size with the development of the patient's muscles It must be pointed out that when a prosthesis is defective or the hygiene of the appliance is unsatisfactory, there is a disturbance of the physiology of the nose and nasopharynx with consequent dysfunction of the Eustachian tube

RELATIONSHIP OF EAR PATHOLOGY TO NASAL DISTURBANCES IN CLEFT PALATE PATIENTS

That nasal physiology in cleft palate patients is severely disturbed, is quite apparent The malformations of the alar cartilages with stenosis of the nares, the septal deflections with obstruction of the airway, and the abnormal communication of oral and nasal cavities are the main causes of this disturbance The inspiratory and expiratory air currents, the air pressures, the humidifying, heating and purifying action of cilia and mucous blanket, the pH and bacteriology, must surely be modified in cleft palate patients as compared with the normal As a consequence of altered physiology these children are more prone to frequent upper respiratory infections and vasomotor changes

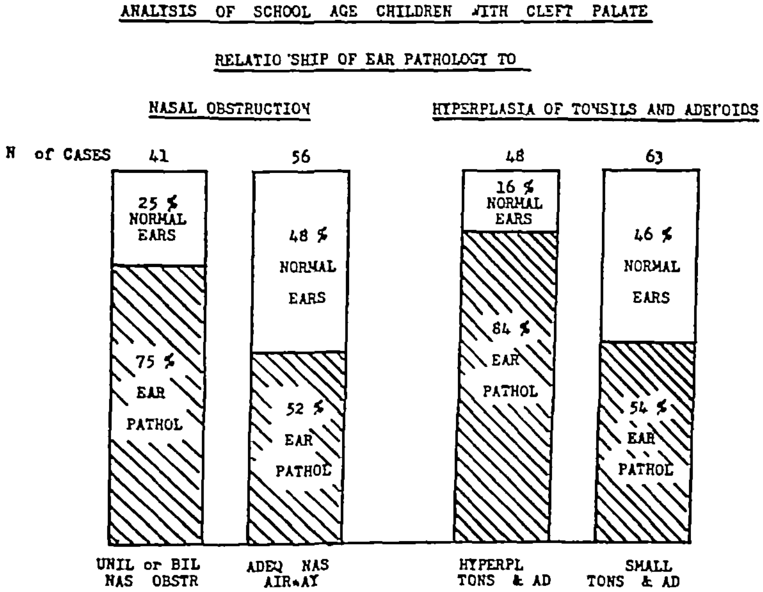

DIAGRAM IX

In an analysis of ear pathology related to nasal disturbances, a group of 41 school-age children with complete unilateral or bilateral obstruction of the nasal airway on an anatomical, catarrhal or vasomotor basis were studied Thirty-one of them (75 per cent) showed ear pathology, while the opinion that early closure of the palate avoids secondary atrophy of palatal muscles and prevents otitis media, is not supported by this study The dangers of early closure in relation to interference with centers of bone growth, and consequent serious disturbances of development of the bones of the jaw and face, and the high incidence of middle ear pathology, factors which are probably directly or indirectly related to each other, questions the validity of surgery at an early age, in many cases

must surely be modified in cleft palate patients as compared with the normal As a consequence of altered physiology these children are more prone to frequent upper respiratory infections and vasomotor changes

In an analysis of ear pathology related to nasal disturbances, a group of 41 school-age children with complete unilateral or bilateral obstruction of the nasal airway on an anatomical, catarrhal or vasomotor basis were studied Thirty-one of them (75 per cent) showed ear pathology, while

10 (25 per cent) had normal ears In a control group of 56 school children with an adequate bilateral nasal airway, 29 (52 per cent) had ear disorders and 27 (48 per cent) had normal ears (see Diagram IV)

RELATIONSHIP OF EAR PATHOLOGY TO HYPERPLASIA OF TONSILS AND ADENOIDS IN CLEFT PALATE PATIENTS

The importance of adenoid growth and enlarged tonsils in the etiology of catarrhal and purulent otitis media in children has been stressed On the other hand the significance of tonsils and adenoids for an adequate velopharyngeal closure in cleft palate patients is paramount Inflammatory changes of lymphoid tissue in these patients should receive immediate conservative treatment and be controlled as promptly as possible

In a group of 48 school-age children with hyperplasia of tonsils and adenoids, 40 (84 per cent showed ear pathology and eight (16 per cent) had normal ears A control group of 63 school children with operated or unoperated clefts and with small tonsils and scanty amount of adenoid tissue, showed 34 cases (54 per cent) with ear pathology and 29 (46 per cent) with normal ears (see Diagram IV)

RELATIONSHIP OF EAR PATHOLOGY TO GENERAL FACTORS IN CLEFT PALATE PATIENTS

Prematurity, malnutrition, dehydration, improper feeding methods and acute exanthemata appeared to be important factors in the development of severe purulent otitis media in cleft palate children On the contrary, no definite relationship could be found between the incidence of ear pathology and multiple congenital anomalies

DISCUSSION

In an analysis of 401 patients with various types of clefts of the palate, it has been observed that a multiplicity of factors are responsible for the large percentage of patients with middle ear disorders and hearing disturbances

Apart from congenital anomalies and a few general factors, such as genetic predisposition to ear pathology, resistance to infection and nutritional status, it is apparent that Eustachian tube dysfunction, primary or secondary to nasal and nasopharyngeal pathology, or surgical and non-surgical means of cleft palate closure, is the pathogenic basis of the greater majority of ear disorders in cleft palate patients than in normals

A considerable emphasis has been placed on the fact that the inactivation of the velopharyngeal closure in the open cleft palate allows the food to enter the nasopharynx, and that atypical tongue habits cause continuous irritation and bathe the Eustachian tube openings with irritants

The disturbed physiology and hygiene of the air spaces of the head is surely a factor in the pathogenesis of otitis media in cleft palate children It is noteworthy how a relatively small percentage of these children under one year of age suffer from ear pathology Lysozime and inhibitory activity of saliva and nasal secretions on bacterial growth must play an important role in these children who are free from infection, as well as the absence of environmental contact

In no cases was any fluctuation noted of the tympanic membrane during respiration, as one would expect in a persistent patent Eustachian tube, rather, the kind of pathology that is described (alteration of luster, retractions and scarring) and the improvement obtained by inflation indicate that the physiopathology of the Eustachian tube in cleft palate patients is based on a persistent closure of the orifice

It is of extreme importance to analyze the anatomy and physiology of a normal velum in order to understand the physiopathology of a cleft palate in relation to the function of the Eustachian tube (see Figs 5 to 8)

The soft palate is a muscular hinge which is attached anteriorly at the posterior border of the hard palate by means of an aponeurotic structure and moves freely posteriorly The muscles enter from the sides and interlace in the midline, 10 (25 per cent) had normal ears In a control group of 56 school children with an adequate bilateral nasal airway, 29 (52 per cent) had ear disorders and 27 (48 per cent) had normal ears (see Diagram IV)

A considerable emphasis has been placed on the fact that the inactivation of the velopharyngeal closure in the open cleft palate allows the food to enter the nasopharynx, and that atypical tongue habits cause continuous irritation and bathe the Eustachian tube openings with irritants

The disturbed physiology and hygiene of the air spaces of the head is surely a factor in the pathogenesis of otitis media in cleft palate children It is noteworthy how a relatively small percentage of these children under one year of age suffer from ear pathology Lysozime and inhibitory activity of saliva and nasal secretions on bacterial growth must play an important role in these children who are free from infection, as well as the absence of environmental contact

In no cases was any fluctuation noted of the tympanic membrane during respiration, as one would expect in a persistent patent Eustachian tube, rather, the kind of pathology that is described (alteration of luster, retractions and scarring) and the improvement obtained by inflation indicate that the physiopathology of the Eustachian tube in cleft palate patients is based on a persistent closure of the orifice

It is of extreme importance to analyze the anatomy and physiology of a normal velum in order to understand the physiopathology of a cleft palate in relation to the function of the Eustachian tube (see Figs 5 to 8)

The soft palate is a muscular hinge which is attached anteriorly at the posterior border of the hard palate by means of an aponeurotic structure and moves freely posteriorly The muscles enter from the sides and interlace in the midline,

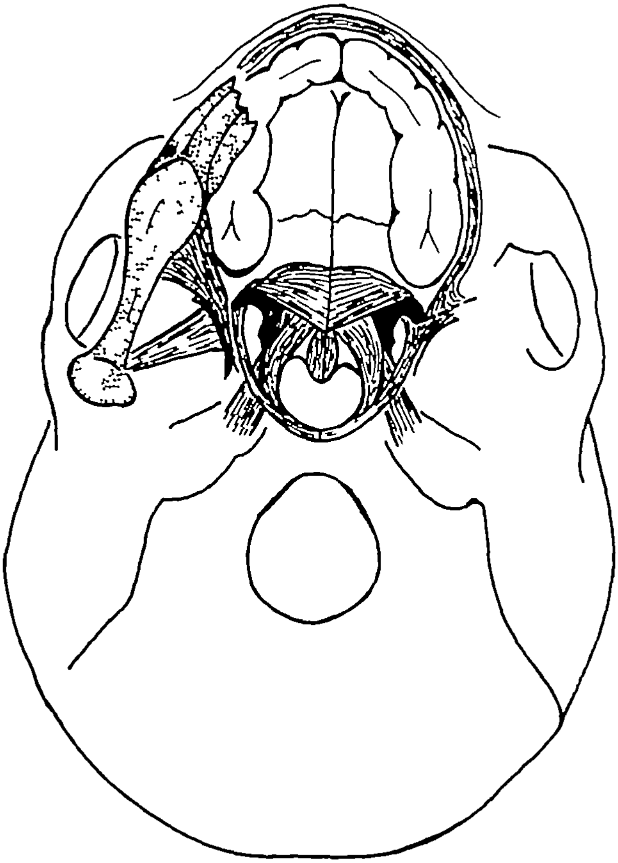

Fig 5 Drawing of the inferior view of a skull illustrating the harmonious balance of intact musculature Completeness of the musculature of the soft palate restrains the outward pull of the pterygoid muscles

each pair forming a sling arching either upward or downward The musculus uvulae fastens longitudinally all of these muscles in the midline without forming a real raphe

Three pairs of muscles arch upward the levator palati, the tensor palati and the pterygopharyngeus of the superior constrictor muscle of the pharynx The levator veli palatini arises from the apex of the petrous bone and from the medial lamina of the cartilage of the auditory tube, enters the velum with its fibers spreading downward and medialward, and blending with those of the opposite side The tensor veli palatini arises from the scaphoid fossa and the spina angularis of the sphenoid and from the lateral wall of the cartilage of

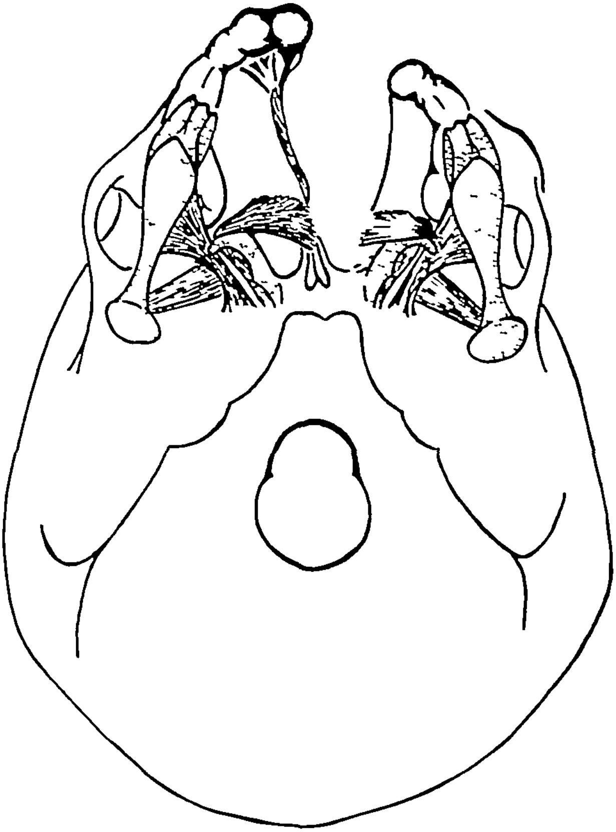

Fig 6 Drawing of the inferior view of a skull to illustrate the loss of continuity of muscle structure as a result of a congenital cleft. There is decreased restraint on the outward pull of the pterygoid musculature

the auditory tube, its tendon, after winding around the pterygoid hamulus, is inserted into the palatine aponeurosis and the posterior border of the palatine bone The pterygopharyngeus muscle arises from the pharyngeal raphe approximately 1 5 centimeters below the pharyngeal tubercle of the occipital bone It runs outward toward the pterygoid plate of the sphenoid bone, one part being inserted on it, and the hamular process and the remaining fibers running medially to be inserted into the palatal aponeurosis

Two pairs of muscles arch downward the glossopalatinus in front forms the anterior pillars and the pharyngopalatinus behind forms the posterior pillars The glossopalatinus arises from the anterior surface of the soft palate, where it is continuous with the muscle of the opposite side and is inserted into the side of the tongue The pharyngopalatinus arises from the soft palate and divides into two fasciculi The an-

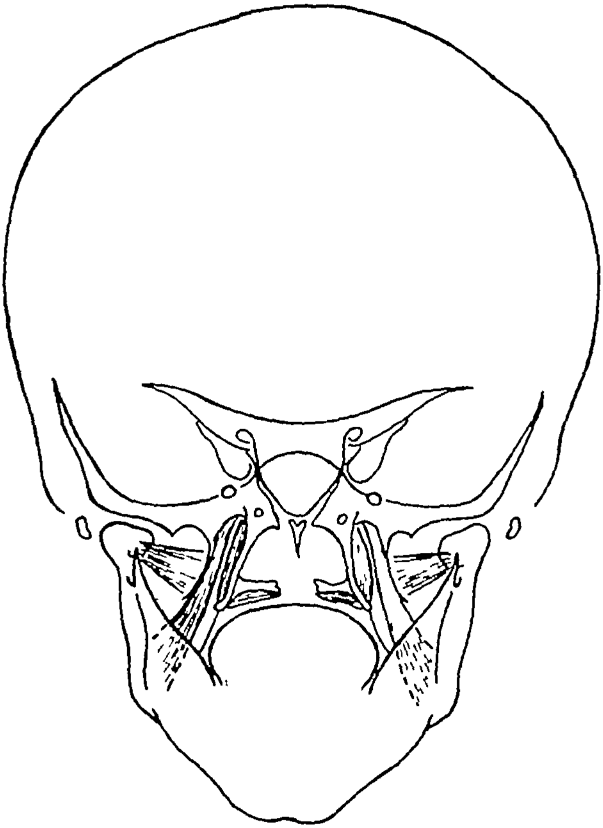

Fig 7 Frontal view of the nasopharyngeal area illustrating a loss of continuity of the tensor veli palatini muscles as a result of the cleft the outward pull of the internal and external pterygoid muscles the patent embryonic suture on both sides of the body of the sphenoid the tongue *represented by the stippled area the pterygo mandibular raphe extending* downward on both sides of the tongue

terior fasciculus is inserted into the posterior border of the thyroid cartilage and into the lateral and posterior wall of the pharynx The posterior fasciculus joins the opposite muscle in the midline An important muscular bundle connected with the latter fasciculus is the salpingopharyngeus muscle, which forms the salpingopharyngeal fold It arises from the inferior part of the auditory tube and blends with the posterior fasciculus of the pharyngopalatinus

Podvinec,[23] in a recent study of the physiology and pathology of the soft palate, maintained that as the individuality of the different muscles becomes lost in the velum, it is reasonable to conclude that they are functioning together He analyzes the functions of the soft palate as follows *a*, to facilitate the transport of the bolus from the oral cavity to the pharynx, *b* to close the nasopharyngeal port in swallowing and speech articulation, *c* to elevate the larynx in swallowing and speech, *d* to open the Eustachian tube during deglutition and yawning

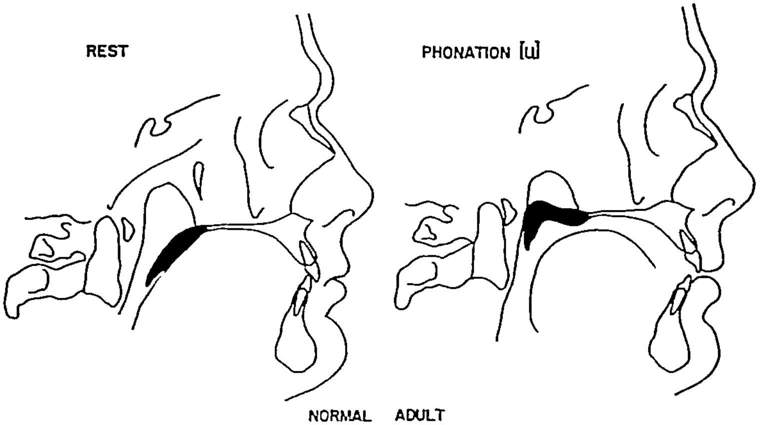

Fig 8 Palatopharyngeal valving in a normal adult Tracings of lateral cephalometric roentgenograms reveal the position of the soft palate within the nasopharynx At rest the soft palate outlined in black rests on the dorsum of the tongue During the sustained phonation of the vowel u the soft palate elevates to contact the posterior wall of the nasal pharynx.

The relationship between movements of the soft palate and opening of the Eustachian tube deserves more consideration Perlman[24] in an authoritative study, reviewed the literature and analyzed with personal observations the movements and the nature of the physiological opening of the Eustachian tube In phonation, the posterior lip of the torus tubarius is lifted passively during the elevation of the soft palate and floor of the tube by the levator palati, while the simultaneously rising salpingopharyngeus contributes actively to an addi-

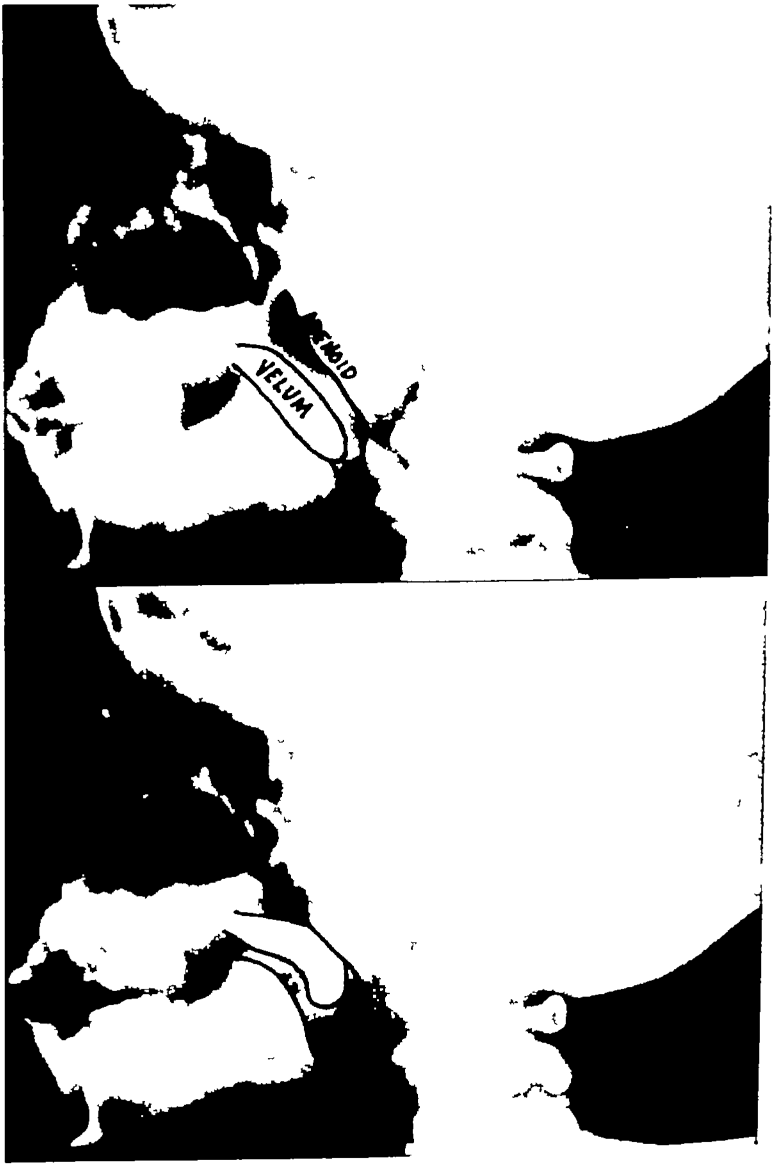

Fig 9 Palatopharyngeal valving in a child with an intact adenoid mass Note that during the sustained phonation of the vowel u as revealed in the lower illustration the soft palate makes contact against the adenoid projection into the nasopharynx rather than with the posterior wall of the pharynx.

tional displacement of the lower portion of the posterior lip In deglutition, there is an active movement of the anterior and posterior lips of the torus tubarius, associated with elevation and lateral retraction of the soft palate and floor of the tube Opening the tube during swallowing is not the result of simultaneous movements, but of a succession of movements of the tubal muscles There is an initial widening of the orifice of the tube, determined by the movement of the inferior edge of the posterior lip, due to active contraction of the rising salpingopharyngeus muscle While the soft palate and floor of the tube are elevated by the action of the levator palati, there is an outward movement of the lateral portion of the orifice of the tube due to the tensor muscle which afterward, when the palate drops, determines an anterior displacement of the tube, producing a deep and round opening

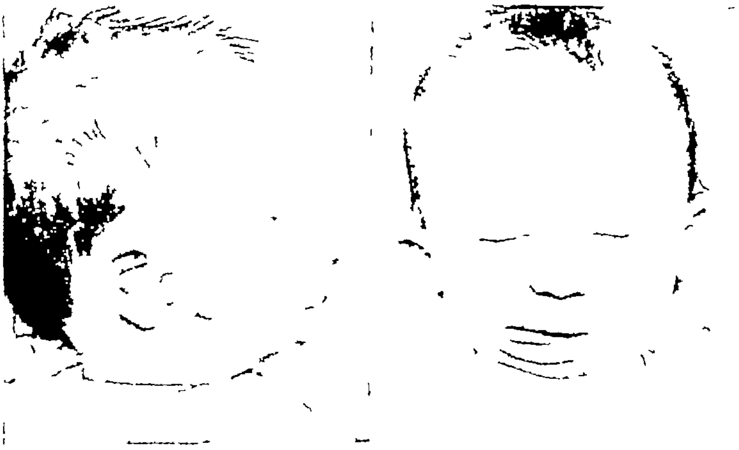

Fig 10

The Eustachian tube normally remains closed to shield the middle ear from pressure changes in the nasopharynx during quiet or forced respiration Palatal and tubal activity, as produced in phonation, does not cause opening of the tube, nor does sound pressure in the nasopharynx during phonation The tube as a rule opens during deglutition Swallowing liquid is most efficient in opening the tube In the reflex opening during swallowing the tube opens more widely than in voluntary opening

It is necessary to analyze the pathologic anatomy of cleft palate and the physiopathology of the Eustachian tube opening during deglutition According to Veau,[25] if a cleft is formed the aponeurosis does not develop, because it represents the consequence of the posterior pulling of the muscular sling The soft palate is, therefore, short, and the tendon of the tensor muscle, which has an abnormal oblique and upward direction, is inserted mainly on the posterior edge of the hard palate The action of the tensor palati on the velum is minimal in cleft palate, it may pull the velar tags forward and outward, causing the tips of the cleft uvula to point toward the midline On the other hand, arising partly from the posterior border of the hard palate it should be able to open the Eustachian tube orifice The activity of the levator palati becomes insignificant When present its action, associated with the one of the divided pterygopharyngeus segment of the superior constrictor, is to open the cleft more widely

Fig 11

The opening of the Eustachian tube orifice during deglutition appears definitely impaired in a cleft of the palate The levator palatini is unable to elevate the soft palate and floor of the tube The swallowing synergy is disturbed, and no reflex opening of the tube by means of the tensor muscle can be elicited The only active muscle in this mechanism is probably the salpingopharyngeus, which in some cases stands out like a band of muscular tissue on the lateral pharyngeal wall

Veau[25] maintains that palatal and pharyngeal muscles have a normal volume in a cleft palate fetus, however, with age, muscular atrophy develops secondary to the anatomical anomaly and inactivity, and the opening of the Eustachian tube will become more and more impaired It is particularly after a poor surgical result that atrophy reaches its maximum, the velum is whitish, tight and immobile

Fig 12

The idea that early closure would prevent muscular regression definitely fails to attain its goal when a poor result is obtained In these cases the dysfunction of the Eustachian tube is considerable, and a high percentage of ear pathology is recorded Even if a good surgical result is obtained, with restoration of the velopharyngeal sphincter, the dysfunction of the Eustachian tube is still great The division of the hamular process, advocated by so many surgeons, will release the tension of the tensor veli palatini and permit medial displacement of the velar tags restoring the velopharyngeal closure, however, the function of the tensor will be altered into an elevator, and no further lateral displacement of the lateral wall of the tube will be possible If a push-back or pharyngoplasty procedure is performed, the change of environment for palatal and pharyngeal muscles may result in a relative inactivity of the neuromuscular mechanism

Fig 13

On the other hand the action of the superior constrictor should be noted When compensatory hypertrophy of pharyngeal muscles develop and a considerable Passavant's ridge is seen, the medial displacement of the tubal cartilage and salpingeal folds unassociated with an anterior and outward shift of the tube impairs the opening of the Eustachian tube

If a patient is fitted with a speech aid, there is a possibility of ill-fitting and poor hygiene as a cause of impaired drainage of secretion, chronic pharyngitis and hyperplasia of lymphoid tissue

Nasal deformities were often found associated with alterations of nasal mucosa on a catarrhal or vasomotor basis In a certain number of patients, hyperplasia of tonsils and adenoids with accumulation of secretion in the nasal and nasopharyngeal cavities were observed In these cases the already impaired function of the Eustachian tube orifice becomes desperate and persistent, or recurrent middle ear disorders with hearing loss are the rule

Sataloff and Frazer[15] have advocated adenoidectomy in infancy at the time of the first palatal operation After the analysis of the multiplicity of factors involved in the middle ear disorders in cleft palate patients and the physiopathologic study of the Eustachian tube opening, it appears that adenoidectomy, in relation to speech rehabilitation, should be performed judiciously (see Fig 9) Special techniques directed toward the removal of the lymphoid tissue surrounding the Eustachian tube orifices, either surgically or with the use of a radium applicator, should be employed, when possible, in order to maintain the integrity of the velopharyngeal closure

Fig 14

Continuous otological study of cleft palate patients is of utmost importance When middle ear disorders develop, the several etiologic factors should be considered and removed, if possible Immediate treatment of the ear, nose and throat conditions is paramount in these children A hearing evaluation should be done as soon as possible To repeat—"Good hearing is essential to good speech"

CONCLUSIONS

1 Congenital anomalies of the ear are present in 2 per cent of all cleft palate patients and account for 13 per cent of associated anomalies to cleft palate They appear to be due to an arrest of development without a definite genetic basis

2 Forty-five per cent of cleft palate patients show definite evidence of ear pathology and 39 per cent have a definite hearing loss

3 There is no sex prevalence in the frequency of ear pathology in cleft palate patients

4 The middle ear disorders are predominantly bilateral with similar features in both ears There is no significant difference in frequency between purulent and catarrhal otitis media

5 The hearing loss is mild in more than one-half of the cases, moderate in about one-fourth of them Only about 4 per cent have severe hearing loss With the exception of five cases with a perceptive loss, all of the other cases have a typical conductive type of hearing loss with a similar pattern in both ears Close relationship is noted between the degree of ear pathology and hearing loss

6 The incidence of ear pathology is 6 per cent before one year of age, 27 per cent in pre-school children and 68 per cent in school children The incidence appeared to level off at this period

7 The frequency of ear pathology according to the type of cleft is strikingly uniform in school age children There is a smaller incidence of ear pathology in the clefts of the hard and soft palates in pre-school age children One-third of the cases with unilateral clefts of the lip and palate showed contralateral ear pathology

8 No definite relationship could be evinced between the width of the cleft and ear pathology

9 Surgical closure is related to a higher incidence of ear pathology in cleft palate children A correlation is noted between velar activity and frequency of middle ear disorders Early closure of the palate does not reduce the incidence of ear pathology

10 Ill-fitting or poor hygiene of speech aids interfere with nasopharyngeal physiology and may result in middle ear disorders

11 Nasal obstruction on an anatomical, catarrhal or vasomotor basis is a factor in the increased incidence of otitis media

12 Hyperplasia of the tonsils and adenoids is intimately related to middle ear disorders in a group of cleft palate patients

13 General factors such as prematurity, malnutrition and exanthemata surely predispose cleft palate children to a higher incidence of middle ear pathology

14 The pathogenesis of middle ear disorders in cleft palate patients is primarily related to a tubal dysfunction This dysfunction is definitely increased by all the above mentioned factors on a neuro-muscular or mechanical basis

15 The role of the otologist in a cleft palate care program is of extreme importance Continuous otologic vigilance of these children is a must Audiograms should be repeated at regular intervals Ear, nose and throat disease should be controlled immediately to prevent any further hearing impairment

SUMMARY

Otolaryngological implications in cleft palate patients have not been fully realized until recently A survey of the available literature fails to reveal an extensive study of ear pathology in cleft palate patients, 401 patients with various types of clefts are thoroughly investigated in the otolaryngological

field and receive accurate audiological study The anomalies of the ear associated with cleft palate are described, analyzed and discussed The higher incidence of middle ear pathology in cleft palate children than in normals receive a quantitative measure in this study The frequency of catarrhal and purulent middle ear infection is reported, as well as the frequency and nature of the hearing loss The several factors related to these findings are discussed in detail in the light of the statistical values age of the individual, type of cleft, width of cleft, surgical and non-surgical closure of cleft palate, nasal disturbances, hyperplasia of tonsils and adenoids, and general resistance The pathogenesis of middle ear disorders appears to be due to a Eustachian tube dysfunction, altered on a neuromuscular basis by the above factors

PRACTICABILITY OF IMMEDIATE FENESTRATION AFTER STAPES MOBILIZATION FAILURE*

W P ANTHONY,

Fort Worth, Texas

INTRODUCTION AND EVOLUTION OF THE PROBLEM

The return to popularity of direct surgical attack upon the stapes for improving hearing in otosclerotic deafness came slowly After reading Rosen's[1,2] first articles on stapes mobilization, I was skeptical, because I felt that most stapes fixed by an otosclerotic process would not mobilize, and if they were mobilized, fixation would quickly recur Followup reports[3,4,5] confirmed my first objection to the procedure (a low percentage of good results), but other reports[6,7,8] refuted my second objection that results would be short lived, therefore, I decided to learn the necessary technique and acquire the necessary skill to practice this procedure The idea of practicing a procedure which would result in disappointment to approximately two-thirds of the patients operated on was so unpalatable, however, that in November, 1955, I decided to work out a stapes mobilization technique which would lend itself to immediate Lempert fenestration in case of failure

That is the background of the present study, begun in December, 1955, and continued with its interesting ramifications to the present

The problem of surgical technique, the first to present itself, was not exceedingly difficult to solve, and is reported in the first part of this paper under technique and presentation of cases

Establishing methods to determine accurately which stapes mobilizations were failures, and in which to proceed with a

---

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication Feb 26 1958

fenestration, was the second and greater problem. This problem involves the patient whose stapes mobilization is apparently unsuccessful at the time of operation, but whose hearing is found to have improved considerably over the preoperative level weeks or months later. In such a case, an unnecessary fenestration would have been done. Because of this the combined procedure was abandoned.

The second part deals with the attempt to determine the incidence of this special problem, to solve it by establishing a criterion of failure or success of stapes mobilization on the table, and to evaluate this criterion by postoperative follow-up of a series of cases to which it had been applied.

REVIEW OF LITERATURE

Surgical attempts to improve conductive hearing loss by mobilization of the ankylosed stapes date from the work of Kessel[9] in 1876, when he tried to improve hearing loss resulting from infection by removing the drum, malleus, and incus. This method being unsuccessful, he later tried stapes mobilization and stapedectomy.[10] Boucheron[11] reported 60 cases in which he excised the posterior half of the drum, separated the incus from the stapes and mobilized the stapes. Miot[12] reported 200 cases of stapes mobilization in which he obtained only slight, temporary improvement in hearing. He believed that best results were obtained in early cases and that mobilization was not effective after complete ankylosis. Feraci[13] reported some success with mobilization. Blake,[14 15 16] Jack,[17 18] and Burnett,[19] in America, tried mobilization but eventually turned to stapedectomy performed through myringotomy incisions. The subject of oval window surgery disappeared from the literature after 1900. The following statement by Sourdille[20] is representative of the thinking that led to the abandonment of this type of surgical procedure:

> *The footplate of the stapes is so fixed by an osseous process and its crura so wedged in by the borders of the deformed oval window that extraction of the ossicle is practically impossible. If one exerts traction on the crura they are certain*

PRACTICABILITY OF IMMEDIATE FENESTRATION AFTER STAPES MOBILIZATION FAILURE *

W P ANTHONY,

Fort Worth, Texas

INTRODUCTION AND EVOLUTION OF THE PROBLEM

The return to popularity of direct surgical attack upon the stapes for improving hearing in otosclerotic deafness came slowly After reading Rosen's[1,2] first articles on stapes mobilization, I was skeptical, because I felt that most stapes fixed by an otosclerotic process would not mobilize, and if they were mobilized, fixation would quickly recur Followup reports[3,4,5] confirmed my first objection to the procedure (a low percentage of good results), but other reports[6,7,8] refuted my second objection that results would be short lived, therefore, I decided to learn the necessary technique and acquire the necessary skill to practice this procedure The idea of practicing a procedure which would result in disappointment to approximately two-thirds of the patients operated on was so unpalatable, however, that in November, 1955, I decided to work out a stapes mobilization technique which would lend itself to immediate Lempert fenestration in case of failure

That is the background of the present study, begun in December, 1955, and continued with its interesting ramifications to the present

The problem of surgical technique, the first to present itself, was not exceedingly difficult to solve, and is reported in the first part of this paper under technique and presentation of cases

Establishing methods to determine accurately which stapes mobilizations were failures, and in which to proceed with a

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication Feb 26 1958

Dr. Lempert,[35] who indicated, upon inquiry, that he did not do the stapes mobilization operation. More recently information has become available concerning this practice used by a few otologists in America and a number abroad, where it appears to be more popular.

Tato[36] (Argentina) states that he resorts to fenestration immediately if mobilization fails after every effort has been made, and that in cases of apparent mobilization with doubtful hearing gain he sometimes resorts to fenestration, according to personal impressions.

Wullstein[37] (Germany) frequently lists patients for stapes mobilization—possible fenestration, and in case of failure proceeds with fenestration. He makes the window in the knee of the external horizontal semicircular canal and covers it with a free graft.

Portmann[38] (France) reports that for stapes mobilizations he prefers a retro or suprameatal approach, with adequate removal of overhang for exposure of the round window. He dissects a long flap. He believes that this approach gives best conditions for working on the stapes and windows. He says, "In case of failure to mobilize the stapes and, if the round window is normal, it allows the opening of the oval window by resection of the affected footplate, or the possibility of immediately completing the operation by classical fenestration."

Cebrian[39] (Spain) says that, "When both crura are broken, the stapes or the incudostapedial articulation is luxated, or a noticeable hearing gain is not obtained, we immediately perform a fenestration so as to spare the patient a second operation." Cebrian[40] places great emphasis upon observation of the round window and its membrane as a criterion of success. He stresses that if the membrane or its light reflex can be seen to move when the stapes is palated, the stapes must surely have been mobilized.

In Canada, Smith[41] has combined the procedures. The only fault he and his associates have found with the combination procedure is the time consumed in shifting from one opera-

to be fractured and there is no other way of raising the foot-plate Besides, be assured that even if this could be done, the large communication established between the hole opened by the ablatum of the tympanus and the labyrinth will permit infection to enter and will thus lead to inevitable total deafness It was this simple conception which led in 1900 to an official condemnation of the operation which was so severe that we are still influenced by it 1937

The direct route to the inner ear having been abandoned, surgeons turned to fistulation of the horizontal semicircular canal Jenkins,[21] Barany,[22] and Holmgren[23 24,25] contributed to basic pioneering in this field Holmgren introduced microscope and magnifying glass to otosclerosis surgery Sourdille[26,20] developed a three-stage tympanolabyrinthopexy, which he reported at the New York Academy of Medicine, and Lempert,[27] in 1938, reported his practical one-stage procedure which with modifications, came to be the keystone of surgery for otosclerosis

In 1946, Lempert[28] reported a technique for detaching the tympanic membrane from its annular attachments as a surgical approach to the middle ear for tympanosympathectomy

In 1952, Rosen,[1] adapting Lempert's approach to the middle ear to verify the diagnosis of otosclerosis prior to fenestration, accidentally mobilized the stapes The patient's improvement in hearing was dramatic and long lasting

This inspired Rosen[2] to work out a stapes mobilization technique This technique has been modified and remodified by many authors,[29 30 31 32 33] and is now used by nearly all otologists before they consider the fenestration operation in cases of otosclerosis

At the outset of this investigation, the literature was completely silent about combining the stapes mobilization and fenestration procedures That Lempert[34] had spoken of such a procedure was known to me, however, a copy of his paper, "Evolutionary Progress in the Surgery of Middle Ear Deafness," presented in April, 1955, before the New York Academy of Medicine, was not available from the Academy or from either a stapes mobilization operation or fenestration operation were given a choice They could have the stapes mobilization operation by itself with the understanding that a fenestration would be done after the healing was complete, if the mobilization failed, or they could have the stapes mobilization procedure with preparation made so that, in event of failure, general anesthetic would be immediately administered and fenestration immediately performed

TECHNIQUE

Premedication Chlorpromazine hydrochloride (Thorazine) 25 mg is given intramuscularly 45 minutes preoperatively Another 25 mg ampule is sent to the operating room with the patient in anticipation of severe anxiety, or the occasional vertigo or nausea accompanying mobilization Chlorpromazine hydrochloride (Thorazine) tends to control anxiety without dulling the patient's senses to the point of uncooperativeness

With the patient under local two per cent lidocaine (xylocaine) hydrochloride and epinephrine anesthesia, a regular endaural incision is made A small amount of periostium is elevated posteriorly, and the outer thickened portion of the skin of the posterior external canal is trimmed A mastoid retractor is then placed and the wound opened widely A long flap is fashioned from the posterior skin of the canal from 12 to 6 (inferiorly) instead of from 9 (anteriorly) to 6 (inferiorly) as done regularly in the fenestration, to avoid an excess of redundant flap in the canal while doing the stapes mobilization The flap is lifted from the canal wall with the periosteal elevator and folded forward (see Fig 1) The posterior half of the drum is detached The detachment is not carried forward to nine o'clock anteriorly, as in the original Rosen technique, lest in rotating the flap into place following a fenestration one will put tension on the lower free portion of the drum, thus preventing its healing back to its inferior attachment, and thus producing perforation (combined technique Case 1), which is difficult to correct Bone is curetted posteriorly-superiorly, if necessary, for adequate visualization of the incudostapedial joint, stapedius tion to the other He believes that if the stapes appears to have been mobilized then one should not proceed with a fenestration regardless of audiologic findings

In the United States, Lindsay[42] has listed five cases to be done as combined procedures if the stapes fail to mobilize In two of them, the stapes mobilized and the procedures were discontinued In two cases mobilization apparently was not achieved, and fenestrations were immediately performed In the other case the stapes appeared to have mobilized satisfactorily, but the audiograms failed to indicate satisfactory improvement in hearing This confusion caused him to abandon the idea of the combined procedure

In the United States, also, Knight[43] has performed more than 39 immediate fenestrations after unsuccessful stapes mobilizations He says that by continuing the operation he has not had the problem of the disappointed patient after unsuccessful stapes mobilization Study of the footplate and oval window in these cases after removal of the bridge and a partial ossiculectomy has revealed that usually the crura were fractured and, even with excellent exposure, it was impossible to mobilize the footplate or to create a fracture across it

Fairior[44, 45] schedules cases having little chance for success with stapes mobilizations as exploratory tympanotomy and fenestration If he finds a small otosclerotic focus with easy mobilization, he stops If there is a large growth of bone which would necessitate a great deal of manipulation after which secondary closure would be likely, he proceeds with fenestration This he accomplishes by making the transmeatal portion of the regular fenestration incision, cutting a long flap, then doing the exploratory tympanotomy If the stapes mobilization fails, he makes the complete incisions and proceeds with the fenestration

PART I

MATERIAL AND METHODS

For nine months (December 15, 1955, to September 15, 1956) all patients who were considered good candidates for ical audiometry During this first period, various techniques of audiometry were tried in the struggle to find an infallible method When the mobilization result was questionable, fenestration was always deferred The problem of establishing a criterion will be taken up later under a separate heading.

RESULTS

Twenty-three patients were listed as stapes mobilization—possible fenestration during this nine-month period On the table, six cases appeared to be obvious failures, and immediate fenestrations were performed In 17 cases, the stapes mobilization appeared to be either successful or questionably successful, and immediate fenestration was not carried out. Four of this group were considered to be failures at the three-week postoperative audiometric check One appeared to be successful at three weeks, but had dropped back to the preoperative level in five months Three of these five failures submitted to later fenestrations carried out two to seven months postoperatively All were successful The previous long flap mobilization procedure did not interfere with subsequent fenestration in any way Cases done as a combined procedure are reported herewith

REPORTS OF CASES

Case 1 A white woman age 55 years was first seen in June 1953 for treatment of bilateral external otitis resulting from the use of a hearing aid Inquiry into her hearing problem revealed that she had had a bilateral progressive hearing loss accompanied by tinnitus for some 25 years

Physical examination of the ears nose and throat was negative except for mild external otitis which responded quickly to treatment Tuning fork tests and audiograms revealed a bilateral hearing loss averaging 62 decibels on the left and 60 decibels on the right in the speech frequencies Bone conduction audiograms indicated that the patient was a borderline Class A candidate for a fenestration on the left and Class C on the right Medical examination and laboratory tests as well as roentgenograms of the mastoids were negative A fenestration operation on the left was recommended but declined however two-and-one-half years later in January of 1956 the patient agreed to a stapes mobilization operation to be followed immediately by a fenestration in event of failure

Operation On January 17 1956 with the patient under local anesthesia an endaural incision was made and the usual fenestration flap was cut and elevated down to the annulus fibrosis posteriorly The posterior half of the tympanic membrane was then lifted out of its sulcus and folded forward to expose the middle ear The incudostapedial joint was found to be unusually far anteriorly so that it was impossible to place tendon, and stapes In all except two of these cases, the original Rosen[2] technique was employed for actual mobilization of the stapes

If the mobilization is successful, the long flap is replaced and packed in place lightly with cotton balls over surgical rayon

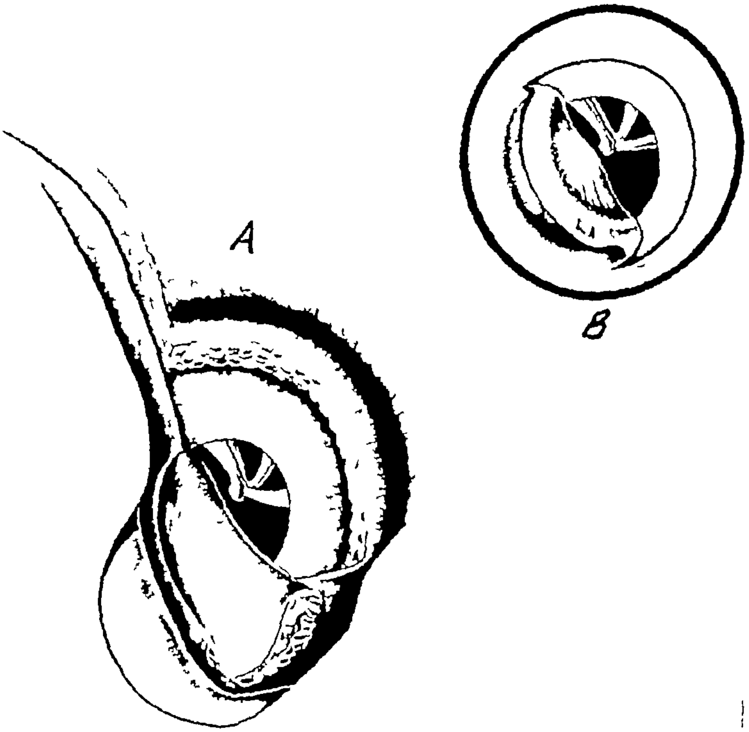

Fig 1—A. Incision used for stapes mobilization—possible fenestration procedure B Incision used for stapes mobilization only

If the mobilization is unsuccessful the incision in enlarged, the cortex is removed with the bur from the zygomatic route to the sinodural angle, and the usual fenestration is carried out, the flap having been previously dissected and fashioned

Criteria for success or failure of stapes consisted of visual and tactile observations of the stapes, spoken voice, and surg-

On February 1, 1956 with the patient under local anesthesia an endaural incision was made and a long flap elevated downward to the tympanic membrane The posterior half of the membrane was lifted away and folded forward, the incudostapedial joint was thus nicely exposed

The Rosen mobilizer was placed anteriorly on the neck of the stapes and posterior pressure was made This resulted in fracture of the crura without evidence of increased hearing The patient was then given thiopental sodium (Pentothal) by vein and intubated A fenestration procedure was done by the cupola technique of Lempert. When an attempt was made to fit the flap before completing the window it became evident that, in anticipation of a successful stapes mobilization and in an attempt to avoid the impediment of a redundant flap in the way for the mobilization the flap had been cut too short to cover the window properly, therefore a split thickness graft was taken from the inside of the thigh with an electric dermatone It was placed over the window and the area ordinarily covered by the tympanomeatal flap It was placed so as to cover the drum completely Two other portions were perforated and placed superiorly and posteriorly so that the complete cavity was covered by skin The graft was invaginated into the window and held by a small piece of cotton The cavity was packed with cellulose sponges and vaseline gauze over rayon strips

The outer dressing was removed on the fifth day as were the vaseline gauze and cellulose sponges The rayon strips and cotton were removed on the tenth day

Although the grafts seemed to take and the cavity became dry in time in nearly all the cavity the grafts have been replaced by mucus producing epithelium The central graft covering the window has remained A posterior inferior perforation of the drum has remained as in Case 1

Hearing improved to a 38 db average in the speech frequencies and the improvement has remained

Case 3 A white woman aged 32 years was first seen in December 1952 complaining of gradually progressive bilateral hearing loss associated with roaring tinnitus on the left. She said that this hearing deterioration had begun about 18 years previously She heard better in noisy rather than in quiet places

Physical examination was not remarkable Tuning fork tests and audiograms revealed a bilateral conductive deafness averaging 55 db on the right and 60 db on the left in the speech frequencies Bone conduction audiograms indicated that the right ear should be considered Class A for fenestration and the left a Class B for fenestration Medical examination routine laboratory tests and roentgenograms of the mastoids were normal

A fenestration on the right was recommended but never accepted The patient returned in December 1955 however requesting a stapes mobilization and consented to a combined procedure if the stapes mobilization failed

On February 3 1956 with the patient under local anesthesia an endaural incision was made and a self retaining mastoid retractor was placed The long fenestration flap was elevated down to the tympanic membrane which was in turn lifted from its sulcus from 12 to 6 o clock posteriorly The Rosen mobilizer was placed on the neck of the stapes anteriorly and pulsating pressure made posteriorly The crura fractured There was no subjective improvement in hearing A fenestration was then carried out without incident while the patient was under general anesthesia. Postoperative recovery was uneventful the Rosen mobilizer properly on the neck of the stapes to make posterior pressure The crura were fractured eventually without improvement in hearing after an attempt to mobilize the stapes by anterior pressure at the neck

Thiopental sodium (Pentothal) was administered intravenously, an intratracheal tube was inserted and from this point a fenestration operation was performed in the usual manner The window was made by the cupola technique of Lempert, and the flap was invaginated into the window In rotating the flap after this type of dissection (drum separated to or past six o'clock (anteriorly), the posterior inferior drum margin tends to stretch fairly tightly and to pull away from the tympanic sulcus so as to produce (as in this case) a perforation difficult to heal

Postoperative recovery was uneventful Secondary split thickness graft from the inside of the upper arm was laid into the cavity on healthy granulations on the twelfth postoperative day and healing was prompt As the cavity dried out and healed a wedge-shaped posterior inferior perforation was seen to exist This resulted in failure to obtain serviceable hearing

On April 13, 1956, three months after the fenestration on the left a stapes mobilization was attempted on the right. It also failed because of the anterior placement of the stapes as on the left, which made manipulation by the Rosen technique impossible *

Sporadic attempts to close the perforation in the left failed because the patient was unable to return regularly for treatment

In January, 1957 one year after her fenestration operation the perforation was grafted by the method of Wright [46] The cavity was exposed by incising through the old scar superiorly and spreading the meatus with a self retaining mastoid retractor With this exposure, the epithelium was removed about the perforation for a distance of 5 6 mm with the angled chalazion curettes A small split thickness graft was removed from the non hair bearing skin of the mastoid process laid over the perforation and made to overlap the perforation by 6 7 mm in all directions The graft was held in position by small cotton balls placed against it lightly without pressure

The patient left the hospital on the second postoperative day The cotton balls and sutures were removed on the fourth day The hearing level now averages 22 db in the speech frequencies two months post operatively The cavity is dry and the tympanic membrane is intact

Case 2 A white woman, aged 48 years first seen in January 1956 complained of bilateral deafness of about twenty years' duration She denied pain discharge or vertigo but said that she had a roaring tinnitus most of the time Her hearing defect had at first been rapidly progressive but had not seemed to change in recent years

Physical examination was not remarkable Tuning fork tests and audiograms revealed a bilateral conductive hearing loss averaging 55 db on the right side and 57 db on the left Bone conduction audiograms indicated that the right ear fell into Class B and the left Class A for fenestration Medical examination, laboratory tests and roentgenograms of the mastoids were normal

The right, or poorer ear was selected for operation An immediate fenestration was recommended if a stapes mobilization failed to improve hearing on the table not going ahead with the secondary fenestration procedure if the least possibility of a successful mobilization existed Technique had ceased to be a problem

---

*This stapes was successfully mobilized recently by transincudal pressure with the Derlacki mobilizer

Discussions at the meeting of the American Academy of Ophthalmology and Otolaryngology in October, 1956, (House[47] and Kos[48]) brought out a possible situation that I had not encountered in my practice What about the patient who apparently has no improvement at the time of mobilization but later, up to three months, demonstrates a strikingly successful result? These "sleepers" could be unnecessarily subjected to fenestration by combining the two procedures unless more accurate means of evaluating results on the table could be found

Baron[49] also had spoken out against the combined procedure He presented one case in which the crura were fractured, but the footplate was mobilized Surgical audiometry immediately after the procedure showed a very poor result, the hearing was worse Two weeks postoperatively an audiogram revealed that the air-bone gap had been closed On this basis, Baron concluded, "The evidence here is clear that one cannot tell at the time of surgery whether or not the mobilization is successful" He believed that fenestration should always be deferred until results of stapes mobilization can be properly evaluated

I abandoned the combined procedure pending further evaluation of this new problem, which I had not recognized

Whether I had done unnecessary fenestrations, or could possibly do them in my present mode of practice and, if so, what I might do to prevent such errors became a pressing issue, therefore, I decided on two studies

1 I would run a series of cases of stapes mobilization only At the time of operation, I would apply all criteria and judgment at my disposal On this basis, I would decide whether or not a fenestration should have been done in each case had it been scheduled as a combined procedure Then I would compare these on-the-table judgments with postoperative

Secondary skin grafts were laid into the cavity on clean granulations on the eighteenth day after operation Healing was satisfactory Hearing has improved and been maintained at the 25 decibel level in the speech frequencies

Case 4 A white woman, age 50 years, first seen on March 17, 1956 complained of hearing loss for 25 years She said that the loss had been progressive and accompanied by occasional roaring tinnitus, and that she had worn a hearing aid for two years

Physical examination of the ears, nose and throat was normal Tuning fork tests and audiograms revealed a conductive deafness of 55 db in the speech frequencies on the right and 48 db on the left Bone conduction audiograms indicated that she would be a Class A candidate for fenestration in either ear Discrimination scores were 84 per cent right and 88 per cent left

A stapes mobilization was recommended on the right (poorer ear) to be followed immediately by a fenestration in case of failure

On May 19, 1956, while the patient was under local anesthesia, an endaural incision was made and fenestration flap was elevated The posterior half of the membrane was freed and folded forward The incudostapedial joint was well visualized after curettage posterosuperiorly The mobilizer was placed anteriorly on the neck of the stapes Posterior pressure produced motion of the head posteriorly, but neither voice response or pure tone audiometry in the speech frequencies indicated any improvement in hearing A fenestration was, therefore, carried out with the patient under general anesthesia It was without unusual incident as in the previous cases, and postoperative recovery was uneventful The cavity was secondarily grafted with split thickness grafts from the inner surface of the arm on the sixteenth day The cavity healed quickly Hearing improved to a 20 decibel average loss in the speech frequencies, and the improvement has been maintained

Cases 5 and 6 are in no way essentially different from Case 4 In both cases, the Rosen maneuver resulted in fracture of both crura Voice tests, as well as pure tone audiometry, indicated that no improvement in hearing had been obtained Fenestrations were done, the cavities secondarily skin grafted, and anticipated improvements in hearing were obtained and have been held

No loss of cochlear function in any of these six cases was observed in postoperative bone conduction audiograms

PART II

THE SPECIAL PROBLEM OF ESTABLISHING AND EVALUATING CRITERIA OF SUCCESS OR FAILURE OF STAPES MOBILIZATION AT THE TIME OF SURGERY

Up to this point, a combined procedure apparently had no major disadvantages if one erred on the side of safety in

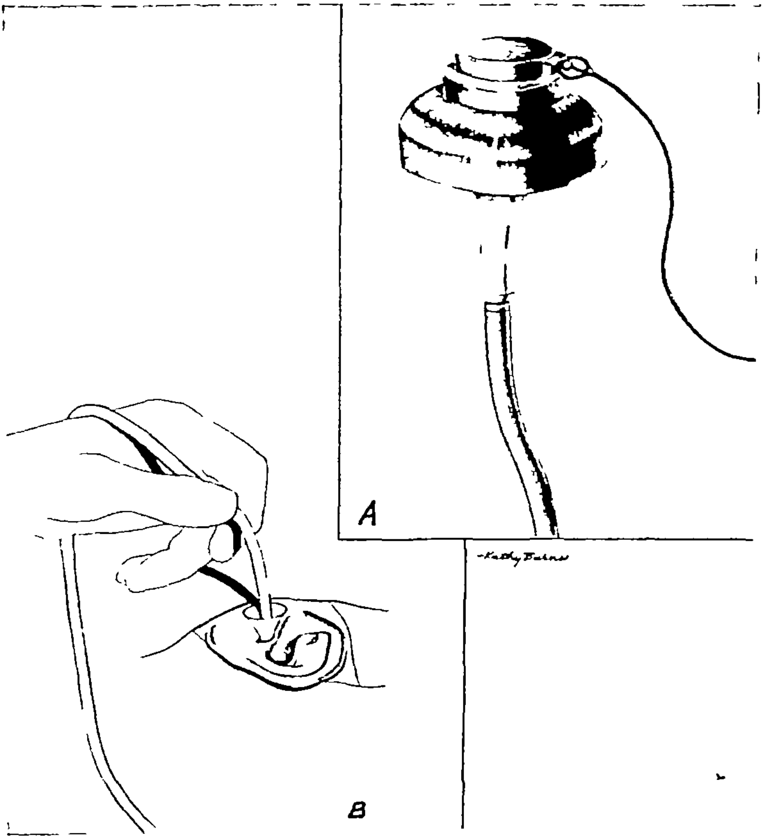

Fig 2—A Audiometer receiver with stethoscope bell and tube firmly fixed to face B End of rubber tube placed in ear speculum during testing

important in guidance as the average amplitude of response" They used the Fletcher[51] formula for converting pure tone threshold to an equivalent speech reception threshold This is done by averaging the two best responses of the three (500, 1000 and 2000) frequencies tested for an SRT, or single "figure of merit" for comparison of steps in the surgical audiometric procedure The analysis of Goodhill and Holcomb[30] of 20 typical successful stapes mobilizations showed a gain of 5 db at 500, 10 db at 1000 and 10 db at 2000 between stage 2 and 3 (the critical stage), therefore, I adopted the routine of "direct vision" audiometry, doing pure tone thresh-

audiograms I *would try to correlate* percentage of on-the-table errors in judgment with criteria applied

2 I would question other *otologists* about criteria of success and the incidence *of apparent* failures on the table resulting as successes postoperatively

THE DIRECT VISION TECHNIQUE IN SURGICAL AUDIOMETRY

Early in my experience with surgical audiometry, I had noticed that the windows would not infrequently fill with blood during the long *period of testing when the middle ear was hidden from vision by a sterile* towel and audiometer receiver Distrusting the audiograms obtained by this means, I devised a "direct vision" technique of "comparative surgical audiometry"

An A D C portable audiometer was used The circular rubber ear mold was removed from the receiver or earphone A stethoscope bell with a detachable 18-inch rubber tube was placed firmly *against the center of the face of the* receiver, and the rubber mold was then replaced tightly supporting the stethoscope in position firmly against the ear piece (see Fig 2) The rubber tube was kept sterile and attached to the bell by a Luer-Lok only when testing The stethoscope bell and rubber tube guided the sound directly to the ear *speculum, which remained in place*

The 10-15 db dampening effect of the rubber tube on the sound was such that audiometric *measurements* done in this *way could not be compared accurately* with preoperative audiograms, and it was used only to compare the second (*drum* off premobilization stage) with the third (drum off post-mobilization stage) and was, therefore, referred to as "comparative audiometry" only Between each change in intensity of each frequency, the tube could be removed from the speculum *and the windows examined, thus the term* "direct vision" audiometry This *method also had the advantage* of cutting out extraneous noises in the operating suite during testing

Goodhill and Holcomb[50] *pointed out that*, "Discrete frequency characteristics in surgical audiometry are not as was defined as an average 10 db or more gain in the speech frequencies over the preoperative average In these patients unnecessary fenestrations could have been performed if they had been scheduled for combined procedures and no other criteria had been relied upon In all four patients, visual and tactile impressions, as well as response to voice tests, indicated that mobilization of the stapes had been accomplished This criterion accurately indicated success in 35 patients or 53 8 per cent, and accurately indicated failure in 10 patients or 15 4 per cent It inaccurately predicted success in seven patients who showed no improvement at the three-month check

Audiometry could not be carried out in 9 of the 65 patients (13 8 per cent) for the following reasons

1 Oversedation in two patients

2 Excess bleeding in one hypertensive patient in whom adrenalin could not be used for hemostasis

3 Audiometer out of repair when two patients were operated on

4 In one patient, the stapes was inadvertently mobilized by transincudal pressure in obtaining proper exposure by curettage

5 Three patients were so deaf that the 10-15 decibel dampening effect of the tube on the sound transmitted through it made premobilization audiometry impossible by the "direct vision" technique

THE QUESTIONNAIRE

In May, 1957, while the foregoing data were being accumulated, an attempt was made to find out how other otologists were solving these problems of surgical audiometry, criteria of success, and the problem of the patient with apparent failure who later gained hearing I wanted to see also whether there existed any particular criterion or method of audiometry that uniformly and accurately predicted success or failure on the table in the hands of more than one otologist olds only twice, once just before mobilization and again immediately after mobilization The tests were repeated after successive mobilization attempts if necessary Only the frequencies 500, 1000 and 2000 were tested If responses for the second audiogram were 10 db better than the first in any two frequencies, the case was recorded as "successful" Any less improvement was recorded as "failure" Since the adoption of this technique and this criterion of success, 65 stapes mobilizations have been performed No combined procedures have been done, but at the time of the three-week postoperative audiogram and again at the three-month check I asked *On the basis of the criterion employed and its results at the time of operation, could an unnecessary fenestration have been performed?*

TABLE I

Results of Direct Vision Technique of Surgical Audiometry in 65 Consecutive Cases of Stapes Mobilization

Inapplicable for various reasons	9, or approximately	13 8%
Accurately predicted success in	35, or approximately	53 8%
Accurately predicted failure in	10, or approximately	15 4%
Inaccurately predicted success in	7, or approximately which were failures at three-month check	10 8%
Inaccurately predicted failure in	4, or approximately which were successful at three-month check	6 2%
	65	100 0%

RESULTS OBTAINED BY USING DIRECT VISION AUDIOMETRY AS A CRITERION

An attempt was made to use the direct vision technique of surgical audiometry in 65 consecutive patients (see Table I) in whom stapes mobilizations were done between July 1, 1956, and June 15, 1957 In four patients, or 6 2 per cent, this criterion inaccurately indicated failures at the time of surgery but later audiometric tests (*three months postoperative*) indicated that the operations had been successful Success

No generalizations were possible about criteria, but three points were of interest *1* The four otologists who stressed visualization of the footplate and round window reported considerably less than average errors in prognosis on the table, *2* It may be quite significant that the otologist who uses the pattern of sound coming from a vacuum pump reported no failures on the table who have later gained hearing, *3* Of the two otologists stressing reversal of the Rinné test, one reported 2 per cent failures on the table—later hearing—the other reported "very few "

Additional comment on the overall subject of the combined procedure was very interesting and raised many interesting thoughts

Enthusiastic about the combined procedure	3
Adamantly against	3
Generally favorable to the idea	6
Skeptical because of specific problems that came to mind	18
Interested but no special feeling pro or con	20

One otologist very significantly pointed out that since simple stapes mobilizations have been known to produce cochlear damage, it would be worse to attack the labyrinth twice at one sitting

Three otologists regularly schedule cases as stapes mobilization possible fenestration

One objected to the combined procedure because it defeats the simplicity which characterizes the stapes mobilization procedure

Two felt that a combined procedure would solve the problem of the stapes mobilization failures who will not return for fenestration

One said that the combined procedure "saves the patient a gamble "

Two expressed fear that the flap might not fit

Four objected on the basis of the difficult psychological and

Letters were sent to 88 otolaryngologists known to me personally to be doing otosclerosis surgery or assumed to be doing this surgery by virtue of membership in the Otosclerosis Study Group A brief explanation of the problem was given, and the following information was requested

1 In how many, or in approximately what percentage of your stapes mobilizations have you observed late hearing improvement in cases which were apparently failures at the time of operation?

2 What criteria were employed at the time of operation to decide whether the procedures were or were not successful?

3 Any additional comment you care to make concerning a combined stapes mobilization fenestration procedure would be greatly appreciated

More or less complete replies were received from 50 otologists The percentage of apparent failures improving later was given anywhere from 0 per cent to 42 per cent The median was 7 5 per cent of total cases Most percentages given were approximations rather than actual counts

As for criteria, 26 used some form of pure tone audiometry, and 10 of them specified four-stage audiometry Eleven indicated that voice or speech tests were employed with the audiometry Six used voice tests only

Four stressed the use of tuning forks, and two laid heavy emphasis upon reversal of the Rinné test as a criterion

One surgeon ingeniously and uniquely uses a Sorenson rotary electric vacuum pump which has a low hum Before the operation, this surgeon asks the patient if he can hear the hum of the machine and repeats the question after the stapes is mobilized All of this otologist's patients in whom mobilization was successful have been able to hear the pump He has had no late successes which were *thought to be failures* on the table

Four stressed visualization of the footplate and round window membrane tration so formidable or destructive that its performance in this small percentage should contra-indicate an otherwise reasonable and advantageous system of practice? At this point, no strong contra-indication to the combined procedure seems to exist The choice of procedure evolves as one of personal preference

In patients in whom fenestration of the oval window, chiseling, or other excess trauma to the footplate is anticipated, a fenestration should not be considered for fear that two inflammation-producing assaults upon the labyrinth might result in loss of cochlear function It is because of the increasing popularity of these footplate procedures that the combined procedure is not likely to come into general use

DISCUSSION

When one considers whether to practice separate stapes mobilization and fenestration procedures or the combined procedure, a host of major as well as minor advantages and disadvantages of the two concepts becloud one's judgment The individual otologist must place them in proper perspective in making his own decision Having temporarily discontinued practicing the combined procedure for approximately one year while collecting data for a part of this study, I find it difficult to decide whether or not to resume the procedure

The following factors must be evaluated in making a decision

1 Failure to hear after stapes mobilization has a bad psychological effect on the patient Failure occasionally may result in bitterness, but more often in loss of confidence in surgery as a means of rehabilitation The patient then is deprived of having serviceable hearing ultimately restored by returning for fenestration or stapes mobilization of the opposite ear Even in the patient who plans to go ahead with further surgery after a stapes mobilization failure, the anxiety and waiting between operations in undesirable and is avoided by the combined procedure

2 Cost to the patient in time and money is increased by economic problems involved in preparing a patient for a major or a minor procedure with subsequent long or short hospital stay

Three objected on the basis of the difference in premedication for two procedures, that is, a patient premedicated only for a stapes mobilization is not prepared for fenestration, also, some operators sedate stapes mobilization patients so heavily that they cannot reliably respond to hearing tests upon which the decision to fenestrate may be based

One objected that unnoticed blood in the middle ear might interfere with the accuracy of the audiograms

Three suggested parts of the following thought that footplate perforation, stapedectomy, and other such surgical attacks upon the oval window would not only render the hearing tests unreliable as far as predicting ultimate success of the operation, but also supplant the classical fenestration operation as a secondary procedure in case of failure of simple mobilization

One objected to excess bleeding and unwieldiness of the large flap

Under additional comments, the dangers of stapes mobilization were stressed Two otologists knew collectively of four dead labyrinths and one fatal meningitis resulting from stapes mobilization operations

CONCLUSIONS

The problem of technique, in combining the stapes mobilization and fenestration procedures if the former fails, lends itself to simple solution It may be considered practical

The special problem of establishing adequate criteria upon which to base the decision to proceed with the fenestration appears to be surmountable With adequate magnification, illumination, and exposure combined with painstaking direct vision audiometric control, very few patients submitting themselves to such a stapes mobilization-possible fenestration procedure would be unnecessarily fenestrated Is the fenesery has affected and will have further impact upon the concept of the combined stapes mobilization and fenestration procedure

a Perforation of the footplate[31 52] may result in improved hearing on the table with later loss, and may thus cloud the criteria of success at the time of operation This situation could not result in unnecessary fenestration, however, because the error would encourage failure to do a needed fenestration

b If simple stapes mobilization has been known to produce dead labyrinths and fenestrations only have been known to produce dead labyrinths, then combining these procedures might be expected to increase the number of these catastrophes The combined procedure, however, should be safe in cases in which the footplate is heavily overgrown and surgical attack is not attempted, or where it is attempted and found to be futile Good magnification and exposure are most important

c The practice of removing the stapes, as suggested by Portmann and Claverie,[53] Rambo,[54] Wullstein,[54] and Shea,[54] could conceivably result in all manipulations being confined to the oval window in the future If stapes mobilization fails, the stapes is removed *in toto* Then the stapes is replaced with "plastic substitution" (Wullstein, Shea), or the ear drum is placed directly over the opened oval window (Rambo), or a portion of a previously fashioned large tympanomeatal flap is invaginated down into the middle ear over the opened oval window (Portmann and Claverie) The general adoption of this concept would eliminate completely the use of a combined stapes mobilization, fenestra-nov-ovalis operation

6 Unfortunately all patients on whom combined procedures are anticipated must have regular endaural incisions which prove to be unnecessary in the majority of patients who ordinarily require only stapes mobilization Thus the patient whose mobilization is successful is penalized by the necessity of a mastoid dressing, extra trauma, bleeding and pain

7 The fashioning of a long tympanomeatal flap prior to two hospital admissions and two operating room charges The combined procedure is more economical for patients requiring two operations

3 The length of time consumed in performing a combined operation is very great, especially if a number of attempts are made to mobilize the stapes and each attempt is followed by an audiometric check A surgeon may very well be exhausted by the time he must perform the most critical part of the fenestration operation Great inconvenience to all persons concerned with the use of the operating room is caused by scheduling patients for combined procedures, because the time involved is unpredictable, it may range from a few minutes to all morning If there is any possibility that a patient scheduled as combined will require fenestration, the surgeon can scarcely list more than one patient in a morning Of course, the problem created is no greater than that frequently encountered in cancer surgery in scheduling a patient for biopsy and possible radical lymph node dissections

4 Sedation must, to a degree, be sacrificed if the patient is to be alert and cooperative enough to respond accurately to audiometric examination on the table I suspect that many prognoses of failure made on the table and later refuted were the result of heavy sedation The practice of giving only 25 mg of chlorpromazine hydrochloride intramuscularly before operation had seemed to allay the patient's tensions but leave the patient alert enough to be checked audiometrically If considerable nausea or vertigo occur or the patient becomes tense, another 25 mg of chlorpromazine hydrochloride may be given intramuscularly or intravenously

I have used 10 mg of prochlorperazine (Compazine) recently instead of 25 mg of chlorpromazine hydrochloride (Thorazine) The pharmacologic action is essentially the same, but the danger of the occasional jaundice following the use of even small doses of chlorpromazine hydrochloride is avoided

5 The increasing popularity of footplate perforation and stapedectomy in the rapidly changing scene of otologic surg-nificant minimum Though tests performed by this technique would seem to be rendered ineffective by the lack of sound protection for the round window during the test, nevertheless, its relative reliability is supported by clinical observation when it is performed as described

The recent tendency has been for stapes and oval window procedures to become bolder and consequently more traumatic. Though these new concepts are titilating to the curiosity and inventive genius of otologists few can be considered atraumatic, well controlled, or likely to produce high percentages of long lasting results The disappointing history of stapes mobilization and oval window surgery in general, prior to the turn of the Century, may well be upon the threshold of repeating itself Let us hope that some middle ground may be found before these procedures are once again "officially condemned" as in 1900 To the otologist the labyrinth should be held near sacred If we are to defile it, should it not be by way of the well controlled classical fenestration operation which time has established as a highly successful and relatively safe procedure? The concept of the combined stapes mobilization fenestration procedure offers a safe middle ground if the operator confines his efforts at mobilization to simple maneuvers which produce only minimal trauma. It would offer a safe middle ground for all operators, even those who prefer radical footplate procedures, if only adequate criteria could be developed by which an operator might know with reasonable certainty, in which cases the stapes might mobilize with minimum trauma and in which cases even radical procedures would be useless Time may give these answers

SUMMARY

Occasionally in this country, but more frequently abroad, the stapes mobilization is immediately followed by fenestration in case of failure This paper attempts to evaluate the practice and the rationale underlying it A technique developed for such combined procedure is described Twenty-three consecutive operations listed as stapes mobilization stapes mobilization has advantages and disadvantages In a narrow canal, the long flap may be redundant and awkward, and may to some degree obstruct vision On the other hand, with this type of preparation, bone may be removed without difficulty for better exposure I, personally, feel that visualization and maneuverability of instruments are easier than through the speculum as employed in the regular technique This freedom of motion is especially helpful in curetting the overhang postero-superiorly for better exposure of the incudostapedial joint and stapedius tendon

a In an attempt to avoid the long redundant flap, one is tempted to cut it too short to cover the fenestra adequately (Case 2), and one must then use a free graft This pitfall is solved by experience Knight[43] has not encountered this difficulty in more than 39 operations

b Another pitfall in technique is inadvertently creating a postoperative postero-inferior perforation of the drum If the drum is detached inferiorly anywhere nearly as far forward as Rosen[1,2] described in his original technique, the inferior part will pull away from the bone inferiorly when the flap is rotated This defect is not obvious at the time, but it is apparent postoperatively (see Case 1)

c An advantage of the longer flap is evident when an inadvertent tear in the posterior part of the drum occurs Sliding the long flap medially provides adequate extra skin so that the raw edges of the tear may be overlapped

8 Those who, after failure to mobilize the stapes, prefer to attempt the opposite ear and again re-enter the first ear for revision prior to fenestration, will find little use for a combined procedure Either the surgeon will eventually succeed in obtaining hearing by stapes mobilization only, or the patients will give up

I do not believe that the "direct vision" technique of surgical audiometry, or any form of audiometry, is a panacea for determining success or failure of a stapes mobilization at the time of operation It has, however, in combination with visual and tactile impressions, reduced any margin of error to an insig-

possible fenestration, of which six were actually performed as combined procedures, are reported

The special problem of developing criteria to determine at the time of stapes mobilization if fenestration is necessary is discussed A "direct vision" audiometry technique is described and suggested as one criterion This criterion was evaluated by applying it at time of operation to 56 stapes mobilizations cases and comparing its prognosis to the final outcome of the cases This audiometry technique appears to be a reasonably accurate indicator In this series of 56 cases only four, or 7 1 per cent, would have been unnecessarily fenestrated, even without the aid of visual and tactile impressions and voice tests which belied the audiometric findings in these four cases A fenestration would have been done on none of these patients

Analysis of questionnaire responses from 50 otologists failed to reveal an on-the-table criterion for predicting postoperative results of stapes mobilization which was uniformly accurate in the hands of different otologists Using various combinations of criteria, the median per cent of errors in judgment, which could have resulted in unnecessary fenestrations, had the combined procedure been used was 7 5 per cent

An attempt is made to review and discuss the many facets of the case for and against the concept of a combined stapes mobilization fenestration It is concluded that this choice will remain one of personal preference, for there is no strong, firm contra-indication to a combined procedure except when extensive traumatising footplate work has accompanied the stapes mobilization procedure No loss of cochlear function was observed in postoperative bone conduction audiograms in any of the six patients on whom the combined stapes mobilization fenestration procedure was performed

ALUMNI ASSOCIATION OF THE NEW YORK EYE AND EAR INFIRMARY

The Annual Spring Meeting of the Alumni Association of the New York Eye and Ear Infirmary last April was so well received that it has been decided to expand next year's meeting, which will take place from April 20-23, 1959

Symposia and lectures on Hearing Rehabilitation, Endoscopy, and Ear Surgery will be conducted It is also planned to offer refresher courses in Mastoid and Fenestration Surgery and Stapes Mobilization Techniques

More complete information regarding the meeting will appear in a later issue of THE LARYNGOSCOPE

be, 5 No confusion of the patient, and no need for his assistance, therefore, no difficulty in cases of paralysis, tremors, etc.

Disadvantages The salpingoscope is larger, heavier and more expensive than a simple ear tube

Inflation of difficult patients In this connection, I may repeat two modifications of simple tubal inflation which were published in the *Monatsschrift fur Ohrenheilkunde,* Vol 78, p 146, 1944 As is well-known, some apprehensive or nervous patients frustrate the attempt at tubal inflation by relaxation of the soft palate Instead of elevating the velum during the enunciation of certain palatal speech sounds, such as "kay-kay-kay," they maintain it in a flaccid state In this way, they suddenly present the abnormal articulatory condition of functional rhinolalia aperta This causes the inflation sounds "kay-kay-kay" to assume a nasal quality, and prevents the very purpose of tubal inflation Since the inflated air then escapes behind the descended velum into the pharynx, no pressure builds up in the nasopharynx to open and penetrate the Eustachian tubes Obviously, this irrational action represents the patient's unconscious defense against the remedial maneuver of which he is afraid Once he has established this conditioned reflex, it is not always easy to re-educate the patient to the correct inflation, and the more complex catheter inflation may be necessary Needless to state that an apprehensive patient is even more fearful of this instrumental tech-

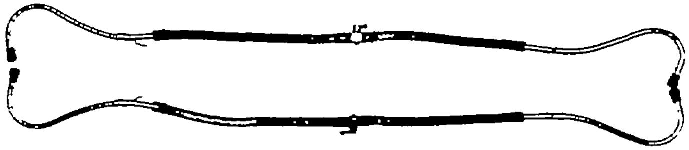

Fig 1 Differential salpingoscope Note the two one-way stop cocks which permit three choices of right monaural left monaural and binaural auscultation

DIFFERENTIAL SALPINGOSCOPE, A NEW DEVICE FOR TUBAL AUSCULTATION*

GODFREY E ARNOLD, M D ,

New York, N Y

After a century of Politzer inflation, word seems to have gotten around to some of the patients when to say "cuckoo" or "kay-kay-kay," but many still have trouble with holding the otoscope tube in their ears The tube also tends to fall out of the doctor's ear at the moment when he holds the catheter in place with one hand and reaches for the balloon with the other, not having a third hand to catch the dangling ear tube To obviate such needless aggravations of daily office work, I assembled a more practical device for tubal auscultation (see Fig 1) It consists of two pairs of binaural ear-pieces similar to a stethoscope Each ear olive of one set is connected to the homolateral olive of the other set by means of a rubber or plastic tube The two tubes between the two sets of ear olives are interrupted by one-way stop-cocks which allow the occlusion of one or both tubes One set with the black olives is introduced into the patient's ears, the other with the white olives is placed in the doctor's ears The device may be ordered from Storz Instrument Co , St Louis, Mo

Advantages *1* The physician's ears are partly masked for ambient noise, making it easier to concentrate on the tubal sounds, *2* Binaural auscultation of both tubes, simultaneously or alternatively, gives more audible information on the tubal function, *3* Simultaneous binaural auscultation provides immediate and impressive comparison of the two tubes particularly regarding temporal, qualitative or quantitative differences of their patency, *4* The self-retaining ear sets cannot fall out, no matter how narrow some ear canals may

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication April 22 1958

the soft palate by the left thumb and index finger This causes the palate to contract and to occlude the nasopharynx In case of organic paralysis, the same maneuver is used for the passive elevation of the flaccid velum At the same time, the third left finger occludes the patient's right nostril The left fourth and fifth fingers find support on the patient's right cheek Inflation is then effected by the right hand, using a standard Politzer balloon with a rigid tip and detachable nose olive

Advantages Prompt and rapid inflation of uncooperative or fearful patients, including children, or in cases of organic palatal paralysis The patient has nothing to do but to open his mouth

Disadvantages Not suitable in the presence of violent gag reflex

Inflation during continuous articulation Some patients behave awkwardly when told to say "kay-kay-kay" at the moment of inflation In such cases it is easier to utilize a fricative sound of longer duration for the elevation of the palate As is well-known to phonetic specialists, the strength of palatal occlusion is different for the various speech sounds While it is quite weak for the vowels, particularly for the "ah" sound, the occlusion power is highest for the sibilant sounds, hence, a prolonged unvoiced "sss" usually produces the strongest contraction of the palatal valve The palatal "k" sound is characterized by a lower pressure When a patient is instructed to pronounce a prolonged sharp "sss," it is very easy to inflate his tubes during this relatively long period of articulation His palate remains firmly contracted until he pauses to take a breath, and the physician does not have to concentrate on a precise synchronization of the "kay-kay-kay" with the moment of inflation, further, a sibilant sound tends to produce a very firm palatal occlusion which counteracts a timid patient's escape into the protective state of functional hypoinnervation of his palate

Advantages *1* Sibilants produce the strongest palatal contraction which is desirable for effective inflation, *2* They can be pronounced during a long period of time (10-20 sec) nique In such cases I use two physiologic principles to overcome the undesired relaxation of the soft palate

Inflation during reflex innervation It is a basic law of nerve physiology that reflex contractions are more resistant to psychogenic disorders than are the conscious and voluntary actions In hysterical aphonia, for example, the cough reflex remains normal, while voluntary phonation is lost Similarly, the functional form of open rhinolalia is differentiated from organic palatal paralysis by the preservation of the palatal gag reflex in the former This fact can be utilized for better tubal inflation

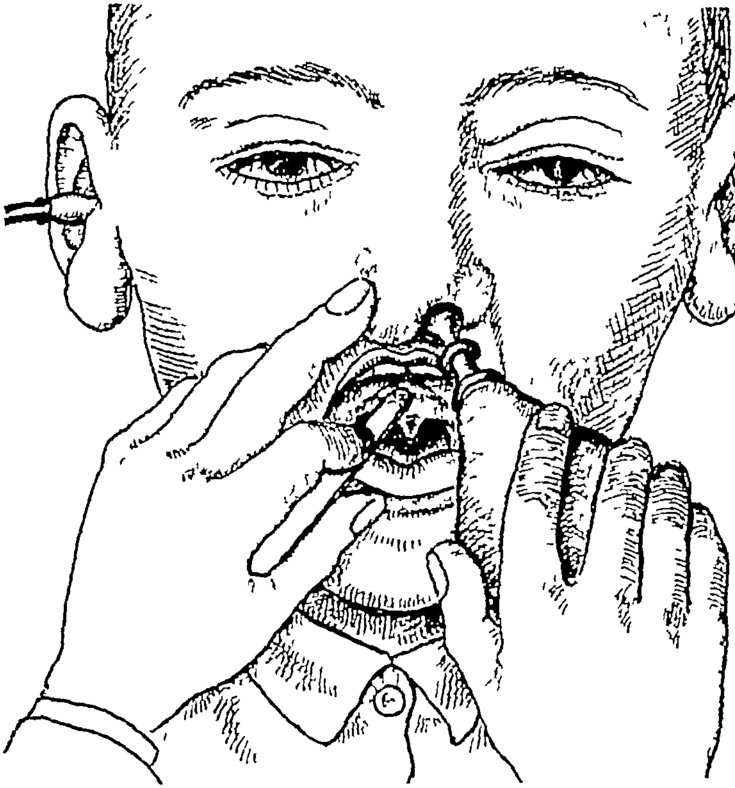

Fig 2 Inflation during reflex innervation of palate

As Fig 2 shows, a tongue depressor is held gently against

TRANSITIONAL CELL TYPE SQUAMOUS CELL CARCINOMA OF THE EXTERNAL EAR CANAL *

YOGINDER N MEHRA, M B B S ,

Montreal, Canada

The case of this 65-year-old female is being reported because of an uncommon type of lesion in the external ear canal

At the age of five years she had scarlet fever and both ears discharged Following this illness she had intermittent discharge from the right ear for a period of ten years She had no further evidence of ear infection until 1957 when following a cold the right ear began to discharge again Local treatment gave no relief The discharge persisted and occasionally was blood tinged

At the time of admission to this hospital in September 1957 she gave no history of headache dizziness or pain in the ear The nose accessory nasal sinuses pharynx and larynx were normal A general physical examination including X rays of the chest elicited no abnormalities

It was noted that her left ear drum was normal the right ear canal was filled with a large polyp and some discharge The fistula test was negative The regional lymph nodes were not palpable

X rays of the mastoids including tomograms showed suggestive evidence of some minimal enlargement of the mastoid antrum as if by a cholesteatoma There was no evidence of active bone destruction at the inner end of the external ear canal

Under local anesthesia with 2 per cent xylocaine infiltration the polyp in the right ear canal was removed The details of the drum and middle ear could not be made out The bleeding was not excessive Part of the tissue removed was sent to Pathology and part to Bacteriology departments for examination Bacteriology reported only micrococcal growth

Following the removal of the polyp from the right ear vestibular tests were normal in each ear The hearing tests showed the left ear to be normal On the right side there was an average loss of 25 db in the speech range in keeping with a mixed conductive and perceptive deafness

In view of the pathological diagnosis of transitional cell type carcinoma (see Fig 1) the case was discussed with the radiotherapist the radiologist and the pathologist and it was decided that radical excision should be attempted followed by radiation therapy

A radical mastoidectomy through combined endaural and postauricular approaches was carried out on Sept 28 1957 The mastoid cells and the middle ear were found to be free from obvious infection and definitely free from growth The ear drum though much thickened and scarred appeared to be intact when it was removed together with ossicles The growth and ulceration appeared to be limited to the skin of the inner

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication March 10 1958

so that inflation may be performed without haste, *3* It is easier for a patient to say a long "sss" than to pronounce "kay-kay-kay" at a precise instant

Disadvantages Cannot be used in the very rare case of nasal lisp, a speech disorder due to relaxation of the palate during the articulation of the S-sounds

---

THE COLLEGE OF MEDICAL EVANGELISTS

A course in "Reconstructive Surgery of the Septum and External Nasal Pyramid" will be sponsored by the Departments of Otolaryngology of the College of Medical Evangelists School of Medicine and the University of Southern California School of Medicine, and will be given at White Memorial Hospital, Los Angeles, Calif The course will begin at 7 00 P M, January 6, 1959, and end 12 00 noon Friday, January 16 Dr Maurice Cottle will be the director All applications should be forwarded to Leland R House, M D, 1720 Brooklyn Avenue, Los Angeles 33, Calif is undoubtedly rare, although a considerable number of cases have been recorded in the literature, and lately increasing numbers are being reported

Most of the published reports show squamous cell carcinoma to be the most common of all types Other types, like the basal cell carcinoma, adenocarcinoma, adnexal carcinoma from the sweat and apocrine glands, the lympho-epithelioma, and the transitional cell type carcinoma, have also been reported

Different proportions have been given in different reports Spencer[8] (1938) describes seven cases of carcinoma, out of which six were squamous cell, and one basal cell type

Figi and Hampstead[4] (1943), describing malignant tumors of the middle ear and mastoid, report 38 cases, of which 13 are squamous carcinoma, 11 basal cell carcinoma, five adenocarcinoma, three sarcoma and six hemangio-endothelioma

Lindahl[6] (1955), reported 16 cases of carcinoma of middle ear and meatus, of which 13 are squamous carcinoma (both poorly differentiated and well differentiated), one adenocarcinoma, one carcinoma-like lympho-epithelioma, one transitional cell carcinoma

Ellis and Pracy[3] (1954) have published six cases with only one well differentiated squamous carcinoma

Gisselsson[5] (1952) describes a case of squamous cell carcinoma of the tympanic membrane

Ash[1] (1956) stated that most cases of adnexal carcinoma are usually diagnosed as adenocarcinoma

Cancer may originate in the external auditory meatus or middle ear, and it is sometimes difficult to know the exact site of origin, although prognostically it is very significant According to Miller[7] (1952), cancer of the auricle located within 1 cm of external auditory meatus is a serious disease, regardless of the histological description He recommends wide excision for carcinoma of external auditory meatus

Wahl et al[9] (1953) classify new growths of the ear as third of the external canal especially of the floor and of the anterior wall The whole inner four-fifths of the skin of the ear canal was removed The underlying bone was scraped There was no sign of the growth invading or being connected with the middle ear The denuded cavities were covered with skin grafts from the thigh

Histopathological examination of over 20 pieces of tissue removed from the different parts of the mastoid, the middle ear and the external ear revealed that the growth was confined to the skin of the inner half of the anterior wall of the external auditory canal The drum itself was free from evidence of growth

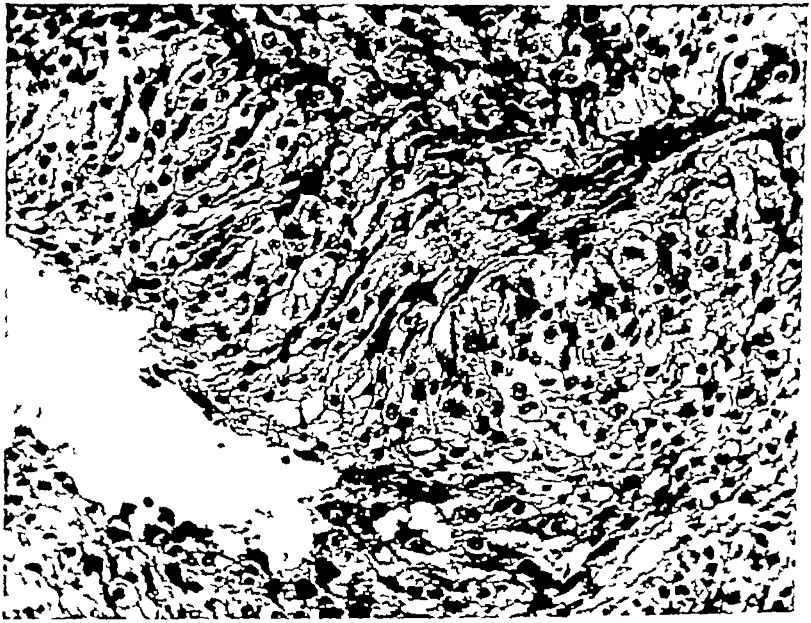

Fig 1 Transitional cell type carcinoma

The wound healed satisfactorily Radiation treatment was started on Oct 7, 1957 the ninth postoperative day and was terminated on Dec 13 1957 For the first six weeks, X ray therapy was given reaching a dose of 3120 *r* for the center of the petrous pyramid and the middle ear and skin dose of over 4600 *r* to anterior and posterior fields There was some skin reaction The graft had taken well Further treatment was given with Cobalt 60 using a direct lateral field An overall maximum tumor dose of 6045 *r* was reached

The patient was discharged on Dec 16, 1957 At the time of discharge the lining of the middle ear and mastoid cavities showed some erythema and moisture but no sign of growth or ulceration There was no cervical lymph node enlargement

Carcinoma of the middle ear and external auditory canal as transitional cell carcinoma, however, it also showed some areas in which the transitional character of the tumor became more differentiated and showed squamous features (see Fig 2)

The transitional cell type of squamous cell tumor is one of the undifferentiated types, morphologically Histologically, it resembles a carcinoma of the urinary tract. The cells have oval, elongated and fairly concentrated nuclei with a relatively small amount of cytoplasm, and have not differentiated into either frankly columnar cells or prickle cells

This tumor has a typical arrangement of cells in ribbon-like sheets that are looped and folded It commonly arises from mucous surfaces, but in the present case there was no evidence that it arose from the mucous surface of the middle ear It arose from the skin of the external canal, which is rather unusual Most pathologists would probably diagnose this as an undifferentiated type

The case reported by Lindahl[6] is the only similar one which could be found

SUMMARY

A case is reported of transitional cell type of squamous cell carcinoma of the external ear canal without involvement of the middle ear

A 65-year-old woman had had ear discharge during youth, which recurred during the past year and was occasionally blood-tinged Widespread excision of the growth and radical mastoidectomy was followed by radiation therapy

I express my thanks to Dr W J McNally, Dr E A Stuart and Dr G C McMillan for their help in the preparation of this report

2 Eggston A. and Wolff D Histopathology of Ear Nose and Throat Baltimore 1947

3 Ellis M and Pracy R. Carcinoma of Middle Ear *Brit Med Jour* 1 1413 1415 1954

1 Extrinsic, in which the auricle, concha, or the external ear canal is involved

2 Intrinsic, which involves the tympanic membrane, tympanic cavity or mastoid process

3 Undetermined, origin of which cannot be accurately ascertained

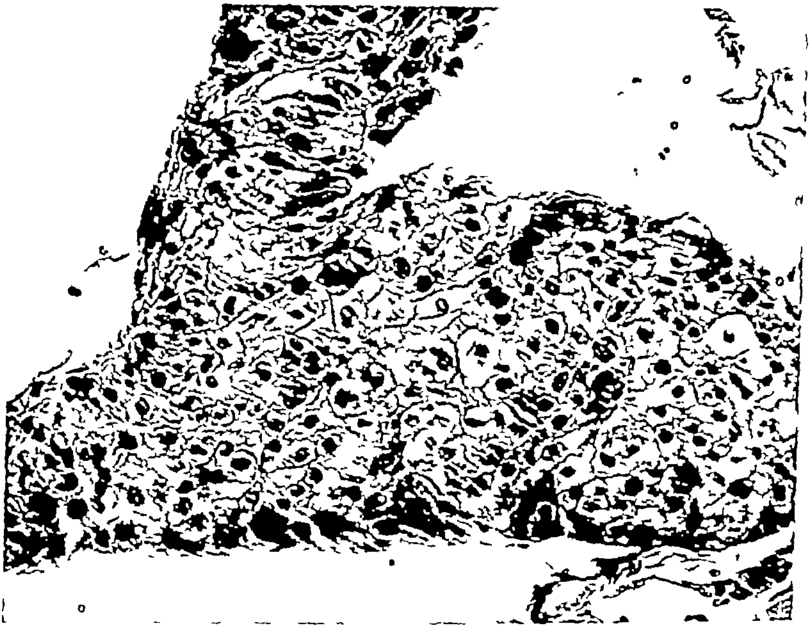

Fig 2 Squamous character of the tumor

The malignant neoplasm in the tympanic cavity probably results from a metaplasia of cylindrical cells of the lining membrane to the squamous cell type, or it may have its origin from the glandular elements within the cavity

The origin of carcinoma in this case was thought to be from the middle ear because of the long history of otitis media, however, at operation, and histopathologically this presumption was found to be incorrect The tumor involved the deeper part of the external canal without involving the drum or the middle ear cavity It was diagnosed initially

INTERNATIONAL SYMPOSIUM ON RADIOLOGY IN OTOLARYNGOLOGY

On December 7 and 8, 1958, the Gruppo Otorinolaryngologica of the Alta Italia will sponsor an International Symposium on Radiology in Otolaryngology under the direction of Prof Luigi Pietrantoni, Direttore della Clinica dell' Universita de Milan, Prof Arduimo Ratti, Direttore dell' latitudo di Radiologica dell' Universita de Milan, and Honorary President Prof Felice Perussia For further information write the Secretary of the Symposium, Clinica Otorinolaryngologica dell' Universite di Milan, via Commenda 16, Italy

DIRECTORY OF OTOLARYNGOLOGIC SOCIETIES

(Secretaries of the various societies are requested to keep this information up to date)

AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Erling W Hansen 90 So Ninth St. Minneapolis Minn
Executive Secretary Dr William L Benedict Mayo Clinic Rochester Minn
Meeting Palmer House Chicago Ill

AMERICAN BOARD OF OTOLARYNGOLOGY

AMERICAN BRONCHO ESOPHAGOLOGICAL ASSOCIATION

President Dr Francis W Davison Geisinger Memorial Hospital Danville Pa
Vice-President Dr George S McReynolds 615 N Boulevard Galveston Tex
Secretary Dr F Johnson Putney 1712 Locust St Philadelphia 3 Pa
Treasurer Dr Verling K Hart 106 W 7th St Charlotte N C
Meeting The Homestead Hot Springs Va March 10-11 1959

AMERICAN LARYNGOLOGICAL ASSOCIATION

President Dr Fred W Dixon Cleveland Ohio
Secretary Dr James H Maxwell Ann Arbor Mich
Treasurer Dr Francis E LeJeune New Orleans La
Editor Historian and Librarian Dr Edwin N Broyles Baltimore Md
Meeting The Homestead Hot Springs Va March 8 9 1959

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, INC

President Dr Gordon Hoople 1100 E Genesee St. Syracuse 10 N Y
President Elect Dr Theo E Walsh 640 So Kingshighway St Louis 10 Mo
Secretary Dr C Stewart Nash 700 Medical Arts Bldg Rochester 7 N Y
Annual Meeting The Homestead Hot Springs Va March 10 11 12 1959 (Mornings only)

Meetings of the Sections

Eastern Savoy Plaza New York N Y January 8-9 1959
Council Savoy Plaza New York N Y January 10 1959
Middle Park Plaza Hotel St. Louis Mo January 12 13 1959
Western The Ahwahnee Hotel Yosemite Valley Calif January 17 18 1959
Southern Academy of Medicine Hotel Atlanta Biltmore Atlanta Ga January 23 24 1959

AMERICAN MEDICAL ASSOCIATION, SECTION ON LARYNGOLOGY, OTOLOGY AND RHINOLOGY

Chairman Dr Victor R Alfaro Washington, D C
Vice-Chairman Dr Harold F Schuknecht, Detroit, Mich
Secretary Dr Walter E Heck, San Francisco Calif
Representative to Scientific Exhibit Dr Walter H Maloney, Cleveland, Ohio
Section Delegate Dr Gordon F Harkness, Davenport, Ia
Alternate Delegate Dr Dean M Lierle, Iowa City, Ia
Meeting Atlantic City, June 8 12, 1959

AMERICAN OTOLOGICAL SOCIETY, INC

President Dr Moses Lurie, Boston, Mass
President Elect Dr R C Martin
Secretary Dr Lawrence R Boies, University Hospitals, Minneapolis 14, Minn
Meeting The Homestead Hot Springs, Va, 1959

AMERICAN OTORHINOLOGIC SOCIETY FOR THE ADVANCEMENT OF PLASTIC AND RECONSTRUCTIVE SURGERY

President Dr *Joseph Gilbert, 111 E 61st St*, New York, N Y
Vice-President Dr Kenneth Hinderer, 402 Medical Arts Bldg Pittsburgh, Pa
Secretary Dr Louis Joel Feit 66 Park Ave New York 16 N Y
Treasurer Dr Arnold L Caron, 36 Pleasant St Worchester, Mass

AMERICAN RHINOLOGIC SOCIETY

President Dr Russell I Williams, 408 Hynds Bldg, Cheyenne Wyo
Secretary Dr Robert M Hansen 1735 No Wheeler Ave, Portland, Ore
Annual Clinical Session Illinois Masonic Hospital, Chicago, Ill, October, 1958
Annual Meeting

AMERICAN SOCIETY OF FACIAL PLASTIC SURGERY

President Dr Trent W Smith 327 East State St. Columbus 15, Ohio
Vice-President Dr Oscar J Becker Chicago Ill
Secretary Dr Samuel M Bloom, 123 East 83 St, New York 28 N Y
Meeting November 12 1958, in conjunction with the Section on Laryngology, Rhinology and Otology of the Medical Society of the County of Kings and Academy of Medicine of Brooklyn, 1313 Bedford Ave Brooklyn, N Y

AMERICAN SOCIETY OF OPHTHALMOLOGIC AND OTOLARYNGOLOGIC ALLERGY

President Dr Joseph W Hampsey Grant Bldg Pittsburgh 19 Pa
Secretary Treasurer Dr Daniel S DeStio, 121 S Highland Ave Pittsburgh 6 Pa
Annual Meeting

ASSOCIACAO MEDICA DO INSTITUTO PENIDO BURNIER—CAMPINAS

President Dr Antonio Augusto de Almeida
First Secretary Dr Alberto Galo
Second Secretary Dr Alfredo Porto
Librarian Treasurer Dr L de Souza Queiroz
Editors for the Archives of the Society Dr J Penido Burnier Dr Guedes de Melo Filho and Dr Roberto Franco do Amaral
Meetings Twice every month first and third Thursdays 8 30 P M

ASOCIACION DE OTORRINOLARINGOLOGIA Y BRONCOESOFAGOLOGIA DE GUATEMALA

Presidente Dr Julio Quevedo 15 Calle Oriente No 5
First Vice-Presidente Dr Héctor Cruz 3a Avenida Sur No 72
Second Vice-Presidente Dr José Luis Escamilla 5a Calle Poniente No 48
Secretario Tesorero Dr Horace Polanco 13 Calle Poniente No 9 D

ASOCIACION DE OTO RINO LARINGOLOGIA DE BARCELONA, SPAIN

Presidente Dr J Abello
Vice-Presidente Dr Luis Suñe Medan
Secretario Dr Jorge Perellò 319 Provenza Barcelona
Vice-Secretario Dr A. Pinart
Vocal Dr J M Ferrando

BALTIMORE NOSE AND THROAT SOCIETY

Chairman Dr Walter E Loch 1039 No Calvert St. Baltimore Md
Secretary Treasurer Dr Theodore A. Schwartz

BUENOS AIRES CLUB OTOLARINGOLOGICO

Presidente Dr K Segre
Vice-Presidente Dr A P Belou
Secretario Dr S A. Aranz
Pro-Secretario Dr J M Tato
Tesorero Dr F Games
Pro-Tesorero Dr J A Bello

CANADIAN OTOLARYNGOLOGICAL SOCIETY
SOCIETE CANADIENNE D'OTOLARYNGOLOGIE

President Dr Robert T Hayes 42 Cobourg St St John N B
Secretary Dr Donald M McRae 324 Spring Garden Rd Halifax N S

CENTRAL ILLINOIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr G C Otrich Belleville Ill
President Elect Dr Phil R McGrath Peoria Ill
Secretary Treasurer Dr Alfred G Schultz Jacksonville Ill

CHICAGO LARYNGOLOGICAL AND OTOLOGICAL SOCIETY

President Dr Stanton A Friedberg, 122 So Michigan Ave, Chicago 3, Ill
Vice President Dr Maurice Snitman, 408 So 5th Ave, Maywood, Ill
Secretary Treasurer Dr Fletcher Austin, 700 No Michigan Ave, Chicago 11, Ill
Meeting First Monday of each month, October through May

CHILEAN SOCIETY OF OTOLARYNGOLOGY

President Dr Enrique Grünwald S
Vice President Dr Agustin Estartus
Secretary Dr Marcos Chaimovich S
Treasurer Dr Benjamin Kapkan K
Director Dr Alberto Basterrica A

COLORADO OTOLARYNGOLOGY SOCIETY

President Dr James T Blair, Denver, Colo
Vice President Dr James Rigg, Grand Junction, Colo
Secretary Dr Will P Pirkey, Denver, Colo

DALLAS ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Ludwig A Michael, 3707 Gaston Ave, Dallas, Tex
Vice-President Dr Hal W Maxwell
Secretary Treasurer Dr Edward A Newell, 1511 No Beckley, Dallas 8, Tex

FEDERACION ARGENTINA, DE SOCIEDADES DE OTORRINOLARINGOLOGIA

Secretary of the Interior Prof Dr Atilio Viale del Carril
Secretary of the Exterior Dr Aldo G Remorino
Secretary Treasury Prof Dr Antonio Carrascosa
Pro Secretary of the Interior Prof Dr Carlos P Mercandino
Pro Secretary of the Exterior Prof Dr Jaime A del Sol
Pro Secretary of the Treasury Dr Jorge Zubizarreta

FIRST CENTRAL AMERICAN CONGRESS OF OTORHINOLARYNGOLOGY

President Dr Victor M Noubleau, San Salvador
Secretary Treasurer Dr Hector R Silva, Calle Arce No 84 San Salvador, El Salvador, Central America

FLORIDA SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Chas C Grace 145 King St, St Augustine Fla
President Elect Dr Jos W Taylor 706 Franklin St Tampa, Fla
Secretary Treasurer Dr Carl S McLemore, 1217 Kuhl Ave Orlando, Fla

FOURTH LATIN AMERICAN CONGRESS OF OTORINOLARINGOLOGIA

President Dr Dario
Secretary
Meeting

GREATER MIAMI EYE, EAR, NOSE AND THROAT SOCIETY

President Dr William B Steinman
President Elect Dr James H Mendel Jr
Secretary Treasurer Dr H Carlton Howard
Meeting quarterly (March May, October and December) on the second Thursday of the month 6 30 P M at Urmey Hotel Miami

INTERNATIONAL BRONCHOESOPHAGOLOGICAL SOCIETY

President Dr Jo Ono Tokyo Japan
Secretary Dr Chevalier L Jackson 3401 N Broad St Philadelphia 40 Pa U S A
Meeting

KANSAS CITY SOCIETY OF OTOLARYNGOLOGY AND OPHTHALMOLOGY

President Dr Clarence H Steele
President Elect Dr Dick H Underwood
Secretary Dr James T Robison 4620 J C Nichols Parkway Kansas City Mo
Meeting Third Thursday of November January February and April

LOS ANGELES SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Max E Pohlman
Secretary Treasurer Dr Wendell C Irvine
Chairman of Ophthalmology Section Dr Carroll A McCoy
Secretary of Ophthalmology Section Dr Philip D Shanedling
Chairman of Otolaryngology Section Dr Robert W Godwin
Secretary of Otolaryngology Section Dr Francis O N Morris
Place Los Angeles County Medical Association Bldg 1925 Wilshire Blvd Los Angeles Calif
Time 6 30 P M last Monday of each month from September to June inclusive—Otolaryngology Section 6 30 first Thursday of each month from September to June inclusive—Ophthalmology Section

LOUISIANA MISSISSIPPI OPHTHALMOLOGICAL AND OTOLARYNGOLOGICAL SOCIETY

President Dr Fred D Hollowell Lamar Life Bldg Jackson Miss
Secretary Dr Edley H Jones 1301 Washington St Vicksburg Miss
Meeting Edgewater Gulf Hotel Edgewater Park Miss May 15-16 1959

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

Chairman Members serve as chairmen in alphabetical order monthly
Secretary-Treasurer Dr Roland H Myers, 1720 Exchange Bldg, Memphis, Tenn
Assistant Secretary Treasurer Dr William F Murrah, Jr, Exchange Bldg, Memphis, Tenn
Meeting Second Tuesday in each month at 8 00 P M at Memphis Eye, Nose and Throat Hospital

MEXICAN ASSOCIATION OF PLASTIC SURGEONS

President Dr Cesar LaBoide, Mexico, D F
Vice-President Dr M Gonzales Ulloa, Mexico, D F
Secretary Dr Juan De Dios Peza, Mexico, D F

MISSISSIPPI VALLEY MEDICAL SOCIETY

President Dr Arthur S Bristow Princeton, Mo
Secretary Treasurer Dr Harold Swanberg, Quincy, Ill
Assistant Secretary Treasurer Dr Jacob E Reisch Springfield, Ill

NETHERLANDS SOCIETY OF OTO RHINO LARYNGOLOGY

(Nederlandsche Keel-Neus Oorheelkundige Vereeniging)

President Dr H Navis, Sonsbeekweg 6, Arnhem
Secretary Dr W H Struben, J J Viottastraat 1, Amsterdam
Treasurer Mrs F Velleman Pinto, Jac Ohrechtstr 66 Amsterdam

NORTH CAROLINA EYE, EAR, NOSE AND THROAT SOCIETY

President Dr J C Peele, Kinston Clinic, Kinston, N C
Vice-President Dr George E Bradord Winston Salem, N C
Secretary Treasurer Dr J D Stratton, 1012 Kings Drive Charlotte 7, N C
Meeting

NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY

President Mr G L Thompson 16 Ramshill Road, Scarborough, Yorkshire
Vice-President Mr J H Otty, Frizley Old Hall, Frizinghall Road, Bradford, Yorkshire
Secretary and Treasurer Mr R Thomas, 27 High Petergate, York Yorkshire

OREGON ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr David D DeWeese 1216 S W Yamhill St, Portland 5 Ore
Secretary Treasurer Dr Paul B Myers, 223 Medical Dental Bldg Portland 5, Ore
Meeting Fourth Tuesday *of each month from September through May* Henry Thiele Restaurant 23rd and W Burnside Portland Ore

OTOSCLEROSIS STUDY GROUP

President Dr L R Boies University Hospital Minneapolis Minn
Secretary Treasurer Dr Arthur L Juers 611 Brown Bldg Louisville Ky
Meeting Palmer House Chicago Ill

PACIFIC COAST OTO OPHTHALMOLOGICAL SOCIETY

President Dr H Leroy Goss 620 Cobb Bldg, Seattle 1 Washington
Secretary Treasurer Dr Homer E Smith, 508 East South Temple Salt Lake City, Utah
Meeting

PAN AMERICAN ASSOCIATION OF OTO RHINO LARYNGOLOGY AND BRONCHO ESOPHAGOLOGY

President Dr Paul Holinger 700 No Michigan Blvd Chicago Ill
Executive Secretary Dr Chevalier L Jackson 3401 N Broad St Philadelphia 40 Pa U S A.
Meeting Seventh Pan American Congress of Oto-Rhino-Laryngology and Broncho-Esophagology
Time and Place Miami Fla March 1960

PHILADELPHIA LARYNGOLOGICAL SOCIETY

President Dr John J O Keefe
Vice-President Dr Joseph P Atkins
Secretary Dr William A. Lell
Executive Committee Dr Harry P Schenck Dr Benjamin H Shuster Dr William A Lell Dr William J Hitschler and Dr Chevalier L Jackson

PITTSBURGH OTOLOGICAL SOCIETY

President Dr Bernard L Silverblatt 3500 Fifth Avenue Pittsburgh Pa
Vice-President Dr Emory A Rittenhouse 203 Masonic Bldg McKeesport, Pa
Secretary Treasurer Dr John T Dickinson Mercy Hospital Pittsburgh 19 Pa

PORTUGUESE OTORHINOLARYNGOLOGICAL SOCIETY

President Dr Albert Luis de Mendonca
Secretary Dr Antonio da Costa Quinta Avenida de Liberdale 65 1° Lisbon

PUGET SOUND ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Clifton E Benson Bremerton Wash
President Elect Dr Carl D F Jensen Seattle Wash
Secretary Dr Willard F Goff 1215 Fourth Ave Seattle Wash

RESEARCH STUDY CLUB OF LOS ANGELES, INC

Chairman Dr Orrie E Ghrist, 210 N Central Ave, Glendale, Calif
Treasurer Dr Norman Jesberg, 500 So Lucas Ave, Los Angeles 17, Calif

NOTICE TO CONTRIBUTORS

THE LARYNGOSCOPE reserves the right of exclusive publication of *all articles submitted This does not preclude their publication* in Transactions of various Societies

Manuscripts should be typewritten, double spaced, on one side of paper only and with sufficient margins to allow for corrections

Author's name and city should appear directly under title on first page, street address at end of article

All prints or photographs to be submitted in black and white, in good sharp contrast Good halftones depend upon clear photographs Line drawings for zincs to be in black and white Colored inks or red or blue quadrille rulings will not reproduce

References should be complete author's surname, initials, title of article, Journal, volume, page, month, year

Six illustrations will be furnished for each article without cost to author Authors will please limit illustrations to six or assume the expense of additional illustrations

Proofs will be submitted to authors for corrections If these are not returned, articles will be published as corrected in this office

Reprints will be furnished at the following prices

RHINOMANOMETRY IN SOME RHINOLOGIC DISEASES

JOSEPH H OGURA, M D ,*
and
POUL STOKSTEAD, M D †
St Louis, Mo

The function of the nasal passages during respiration can be determined by rhinomanometry, a method of measuring pressure variations within the nasal cavity Courtade[1] described pressure variations obtained from the right and left nostril by means of a simple U-shaped water manometer attached to a nasal plug His method gave a very rough idea about the passages of the nasal cavities since his liquid manometer was capable of indicating only the maximum and minimum pressure in the rhinopharynx The disadvantage of his method was that values obtained were dependent upon the respiration rate and provided no possibility of estimating the pressure during respiration through both nasal cavities

The great advantage of the Courtade method was the use of simple equipment and easy applicability to the patient One of us (P S [2]) has improved the method by replacing the liquid manometer with a recording diaphragm-type manometer that is capable of integrating as well as recording the pressure variations during each phase of respiration The manometer

†From the Department of Ear Nose and Throat Disease University of Copenhagen Denmark (Chief Prof H K Kristensen M D) Visiting Fellow in Otolaryngology Washington University School of Medicine St Louis Mo

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication Oct 27 1958

is connected with an amplifying unit provided with two ratemeters, which add up the inspiration and expiration pressures respectively The ratemeters are monitored by a timer which starts and stops the ratemeters at a previously stipulated time of one minute A recorder which registers the pressure curves and the respiratory rate per minute is attached to the rhinomanometer

From the recorded values it is possible to calculate the resistance during inspiration and expiration through the right and left nasal cavity and by means of a formula to calculate the total resistance of the nose during free respiration through both nasal cavities

Long practice has demonstrated that it is most convenient to measure the resistance in the right and left nasal cavities at intervals of half an hour, and to follow the deflections of the resistance for a period of 45 minutes To give a comprehensive view of the mutual proportions between the resistance of the right and left side together with the total resistance, the obtained values are plotted in a coordinate system in which the time is plotted along the abscissa and the resistance along the ordinate

In the last two years we have been able to make about 350 tests from normal persons and from patients suffering from various nasal diseases Fairly good impressions of the normal rhinometrical curves and curves typical for the nasal diseases in question have been obtained Unfortunately, most people will have more or less deviated septa or asymmetrical development of the turbinates This will result in obtaining curves of a mixed type

THE NORMAL NOSE

The ideal nose has a relatively uniform calibrated slit-shaped nasal cavity, ½-mm wide at its narrowest point with the septum The regular alternating movements of the turbinates adjust in such a way that the total lumen or resistance during the inspiration and expiration is kept at a constant level Few normal noses will comply with the mentioned demands due to deviations of the septum, spurs and cristae

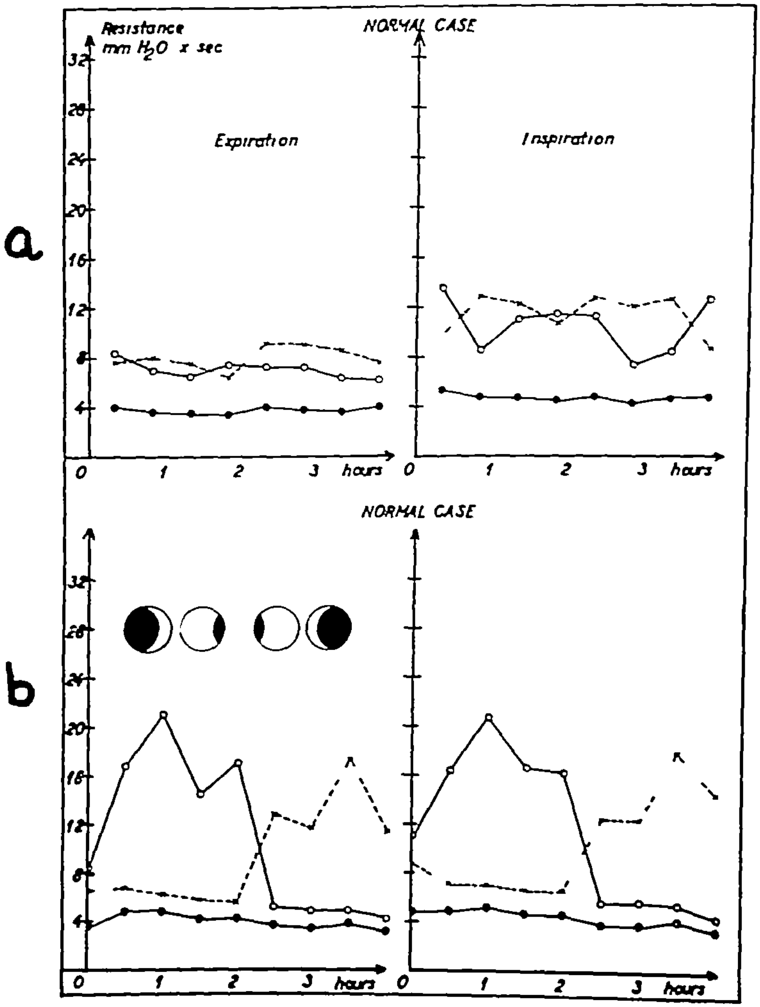

Fig 1 Inspiration and expiration curves from two normal persons with normal deflections of the turbinates and normal resistance in the nasal cavities o - o - o - o Resistance in the right nasal cavity x - x - x - x Resistance in the left nasal cavity ● - ● - ● - ● Calculated resistance of the entire nose (Total resistance)

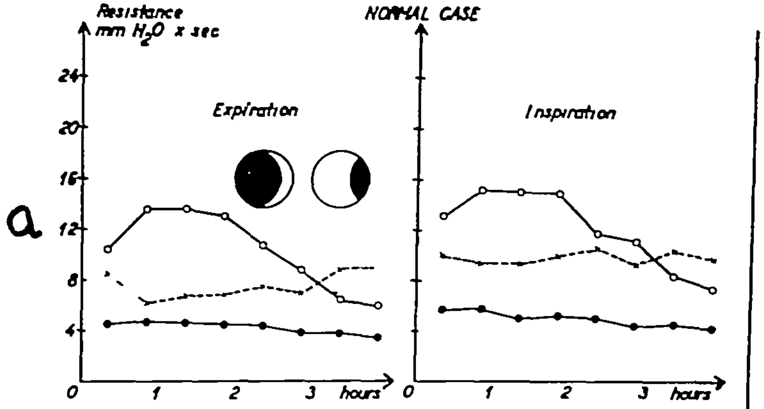
The curves in Fig 1-a are from a person with very high and narrow nasal cavities while Fig 1-b shows curves from a person with ample space in the cavities and large prominent turbinates The black moons indicate the engorgement of the turbinates with corresponding narrowing of the airway and the associated open airway on the opposite side of the nose with constricted turbinates when one considers these anatomical deformities with irregular development of the turbinates The curves shown in Fig 1-a are, however, approaching the "normal" circumstances The curves are obtained from a normal person with high and narrow nasal cavities The deflections of the turbinates are fairly small and the curves from the right and left nasal cavity intersect irregularly due to a slight contraction of the left side

Fig 1-b shows curves from a person with a broad, low nose with large prominent turbinates in the nasal cavities The movements of the turbinates are very pronounced and alternate in such a way that the total resistance in the nose is kept on an almost constant level At the beginning of the curves the turbinates on the right side are constricted but increase rapidly to the peak of dilation and reach the next phase of contraction in two and one-half hours, while the left turbinates undertake the opposite movements According to Heetderks[3] these movements are called the physiologic cycle of the nose, and the purpose of this cycle is to moisten and heat the respiratory air and prevent drying and cooling of the mucous membranes in the lower respiratory passages Warming of the respiratory air occurs mainly in the contracted nasal cavity, where the turbinates are dilated owing to the copious blood supply On the opposite side the turbinates are contracting and throwing off thin secretion from the serous glands and in this way create a situation for adequate evaporation

The length of the nasal cycle is measured between two similar phases of the movements of the turbinates and has an average duration of two and one-half hours, but in normal cases usually show variations between one and five hours

COMPENSATORY HYPERTROPHY OF THE TURBINATES

In instances where significant differences between the lumina on the right and left side exist, the turbinates in the wider side will hypertrophy for the purpose of filling this cavity This hypertrophy is usually explained as the effort of the body to compensate for this deformity Fig 2 illustrates such a case, where the left nasal cavity is considerably



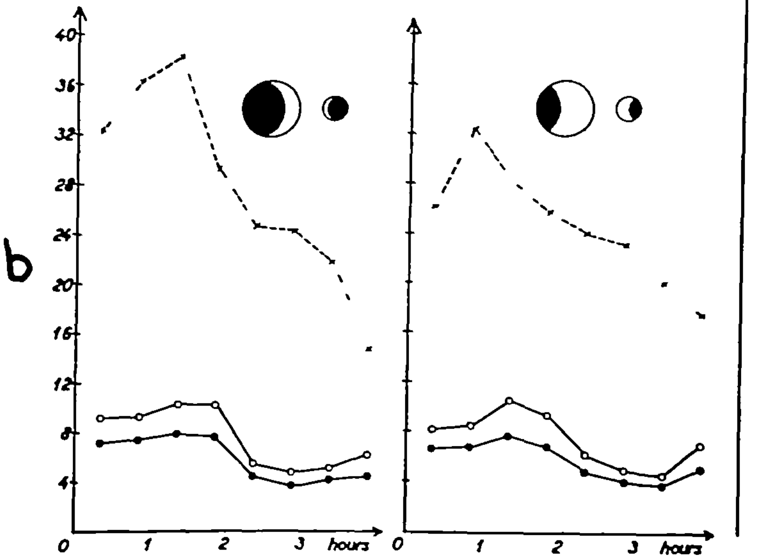


Fig 2-a Rhinometric curves from a person with normal alternating movements of the turbinates

Fig 2-b Inspiration and expiration curves from a patient showing pronounced contraction of the left nasal cavity and with ample space and hypertrophy of the turbinates on the right side The movements of the turbinates are synchronous

contracted, while the right side has ample space and large prominent turbinates The left side is narrowed to such a degree that it contributes only slightly to the air passage, and the right nasal cavity is the main conductor of the air current during respiration For this reason the resistance curve from the right side and from the entire nose will show parallel courses rising and falling according to the movements of the right turbinates In several instances the turbinates showed synchronous instead of alternating movements, which accelerate the fluctuations of the resistance curves

Patients of this category will usually complain of stuffiness in the wider side of the nose Diagnostic errors can be easily made, for inspection of the wider nasal cavity usually reveals that the turbinates are small and appear shrunken

DEVIATION OF THE NASAL SEPTUM

The most frequent cause of alteration in the rhinometric curves are deviations of the nasal septum Generally, one side will show an almost normal space and normal cyclic curve, but the contracted nasal cavity will show pronounced irregularities caused by contact of the turbinates against the septum during a part of the dilating phase Fig 3-a shows a case of a marked septum deviation with the spine and septum projecting into the left nostril During the dilatation of the turbinates the left side is almost shut off, but during the contraction phase the nasal cavity will open suddenly resulting in a short period of decreasing resistance In the case shown, the total resistance is so high that the patient has to undergo reconstruction of the septum for the purpose of re-establishing a normal airway

VASOMOTOR RHINITIS

By rhinometric examination of a normal nose with the surrounding atmosphere kept at a constant temperature and humidity, we have observed alternating movements of the turbinates On one side of the nose the turbinates contract and throw off thin secretion from the serous glands, while the turbinates on the other side dilate with engorgement of the vascular system for the purpose of heating the inspiratory

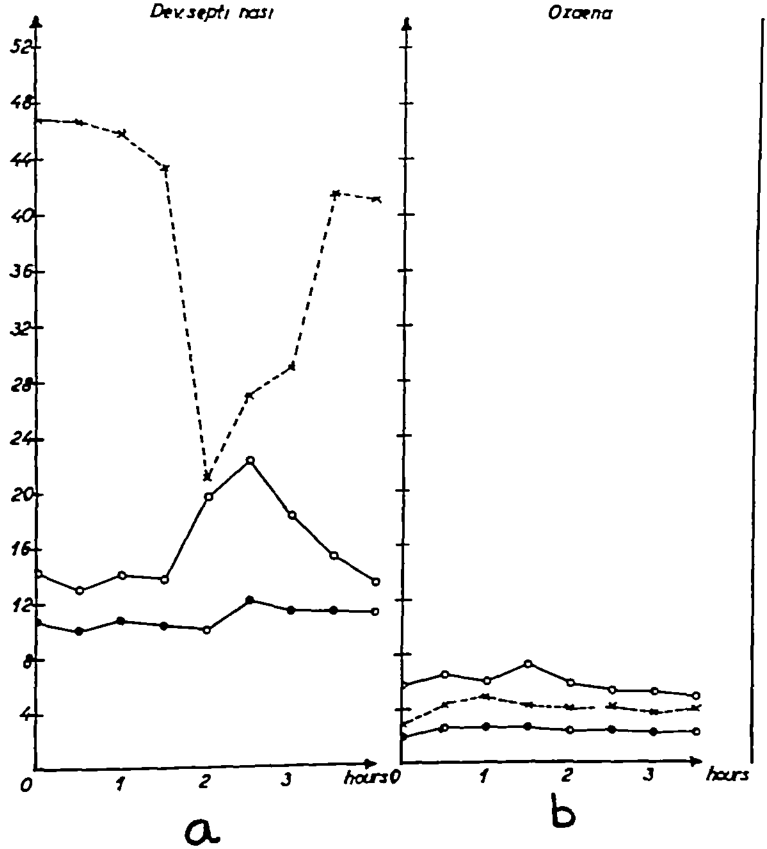

Fig 3 Resistance curves during expiration from a patient with septum deviation to the left (3-a) and from a patient suffering from ozena (3-b)

air current The movements are connected with alternating changes in the lumina of the nasal cavities in such a way that the computed lumen of the nose is kept at the same level

Physical factors such as variations of temperature and humidity cause the turbinates to respond with synchronous movements and contract or dilate at the same time in both nasal cavities in order to prepare the air for the lung[3] The deflections caused by the synchronous movements are generally so pronounced that they almost cover the alternating movements, which will first appear again when the nasal cavities have accomplished their adaptation to the new atmosphere

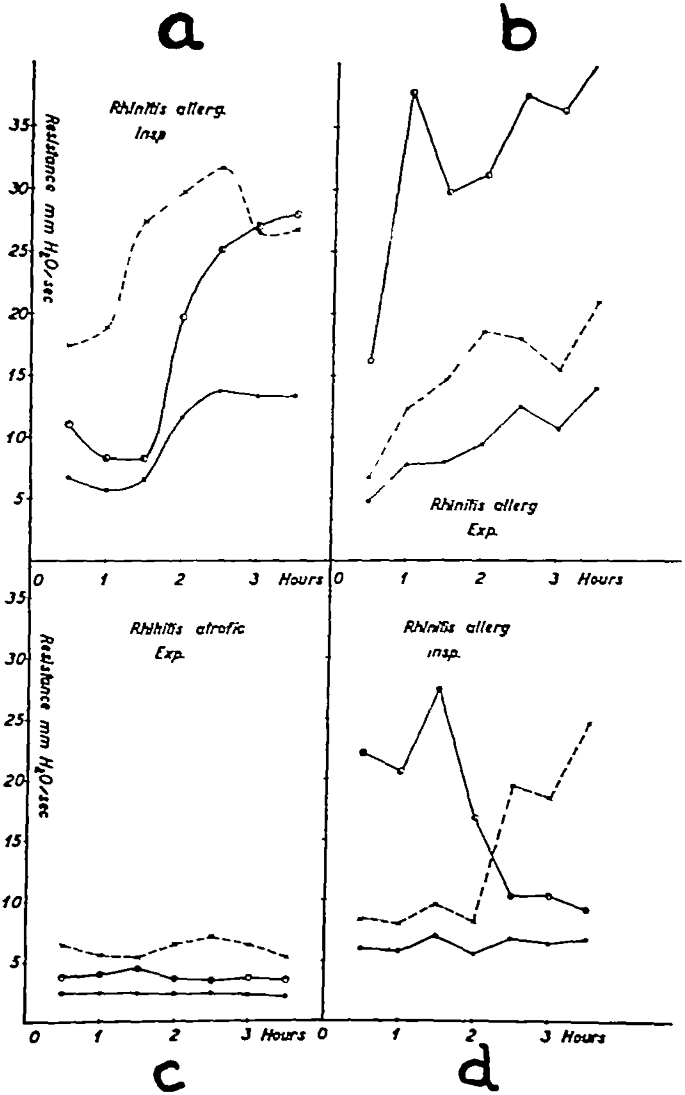
In a normal nose the changes elicited in the vascular system by changes of the temperature and humidity will be kept within such limits that there remains sufficient space for adequate respiration, but in vasomotor rhinitis the reactions are exaggerated, and the responses arise even with abnormally small variations in the atmospheric condition Furthermore, the engorged phase of the turbinates is maintained over abnormally long periods, causing stuffiness of the nose and an accumulation of secretion in the glands of the turbinates, resulting in a profuse thin secretion from the nostrils when the turbinates reach the stage of relaxation

Typical curves are shown in Figs 4-a and 4-b in patients with vasomotor and allergic rhinitis The resistance curves from right and left nasal cavity start at normal level, but after a short period of time the turbinates respond to the temperature and humidity of the laboratory, which results in a steady increase in resistance on both sides, and breathing difficulty for the patient

In a few cases we have seen another curve as shown in Fig 4-d with exaggeration of the alternating deflections of the turbinates, and sometimes with acceleration of the nasal cycle We are inclined to believe that this is a variant of vasomotor rhinitis, but the investigations so far are not conclusive

OZENA AND ATROPHIC RHINITIS

Before testing the patients suffering from ozena it has been necessary to remove crusts from the nasal cavities with irrigations of saline solutions Crusts obtained from ozena patients are identical with the diagram shown in Fig 4-c, with extreme low values indicating complete lack of movement of the turbinates Extensive chronic inflammation and atrophy of the turbinates have affected their ability to influence the air currents during inspiration and expiration In a few instances normal or slightly increased resistances are observed in one or both cavities due to a narrowing of the internal *os*,



Figs 4-a and 4 b Rhinometric curves of patients with vasomotor rhinitis The abrupt rise in the resistance are caused by synchronous movements of the turbinates

Fig 4-c Atrophic rhinitis with very small deflections of the turbinates and a diminutive cycle of the nose

Fig 4-d Vasomotor rhinitis with exaggeration of the alternating movements of the turbinates

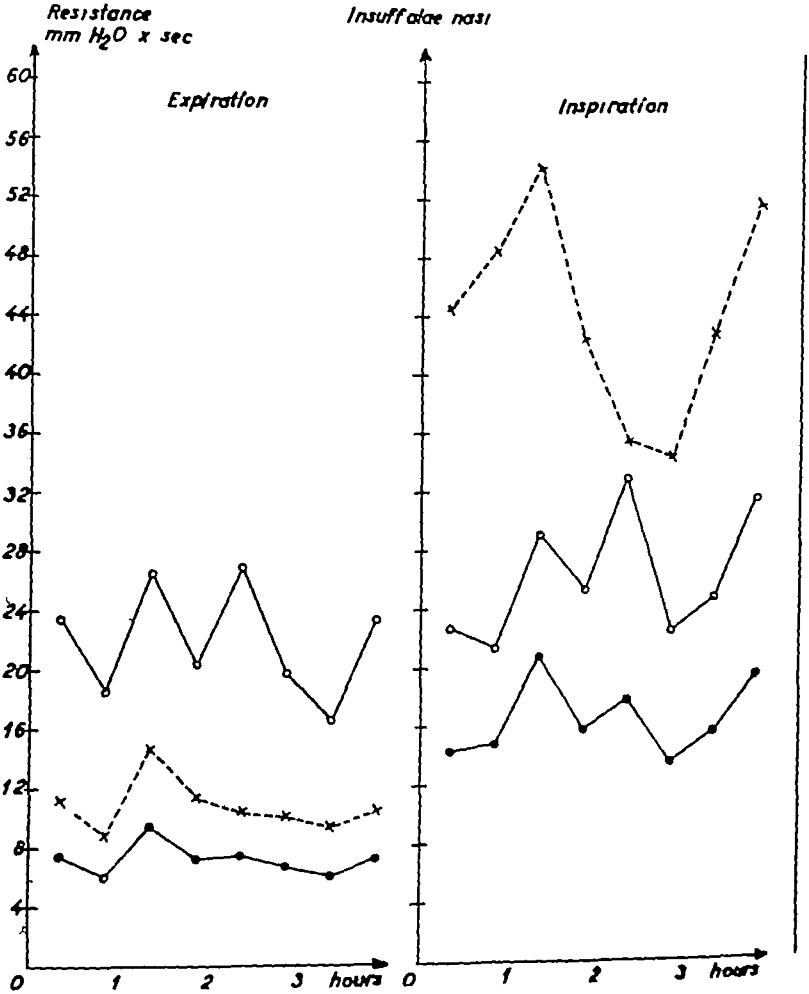


Fig 5 Rhinometric curves during inspiration and expiration in a case of collapsing alae nasi The obstruction is most pronounced on the left side which has normal resistance during expiration but a pronounced increase of resistance during inspiration

that portion between the vestibule and the nasal cavity proper, despite the atrophy and reduced excursion of the turbinates With such small and low pressure deflections in atrophic rhinitis it is almost possible to identify the movements of the turbinates and a diminished cycle of the nose

In a normal patient the turbinates will show a very pronounced engorgement, resulting in complete obstruction of the nasal cavity in question if the stellate ganglion is blocked, however, in atrophic rhinitis since the vascularity is reduced there is a very incomplete response to the stellate ganglion block, and the dilation will disappear much faster than in normal cases

COLLAPSING NASAL ALAE

During each moderate respiration the nasal alae move outwards like a pair of floodgates,[4] thereby dilating the internal *os* and reducing the resistance during the inspiration phase to such an extent that both respiration phases are kept at almost the same resistance level, despite the fact that the inspiration phase lasts a somewhat shorter time than the expiration The movements of the alae are controlled by the levator alae muscles and increase in magnitude by forced respiration The contractions of the muscles occur just before the inspiration begins and continue during the whole inspiratory phase, while the muscles relax during the expiration The activity of the muscles was demonstrated by Van Dishoeck,[5] who was able to detect action potentials from the muscles The movements depend upon a reflex arc, which has its efferent pathway via the facial nerve

Collapsing nasal alae are observed in patients with high, long and narrow noses, and is due to the disturbed anatomical relationship of the upper lateral and alar cartilages to the septum, and in some instances with paralysis of the facial nerve The high and elongated septum is associated with the narrowing of the caudal end of the upper lateral cartilage relationship to the septum This effectively reduces the size of the internal *os* and collapses the nasal alae upon moderate forced inspiration

Usually there are differences in the degree of insufficiency of the nasal alae on the two sides, and this must be considered in naasl reconstruction for the purpose of obtaining satisfactory ventilation of both nasal cavities

RELATIONS BETWEEN THE NOSE AND LUNGS

Recently we have tried to establish a relationship between the nose and the lung Few studies have been made on efforts to measure pulmonary function together with the nose In this respiratory test, one measures the ability of the lung to expire through the nose against a calibrated resistance An inflatable rubber mask is fixed tightly to the head by means of rubber ribbons and is provided with a calibrated valve[2] In beginning the test, the diaphragm of the valve is adjusted to an opening that does not interfere with the respiration of the patient The valve is later closed in steps, at five minute intervals up to the valve opening, which allows the patient just a sufficient supply of air The respiratory resistances arising in the mask during the test are measured by the rhinomanometer unit and the respiration rates are registered at every step by which the valve is closed

Most normal people are able to breathe against a resistance ranging from 80 to 100 mm H_2O x sec, which is about 20 to 25 times as much as the normal resistance of the nose In some apparently normal cases we have seen much lower values, which is in conformance with the investigation of McKillick,[5] who found 20 to 30 per cent of lowered pulmonary function among normal persons

In a few mouth-breathing patients with this respiratory test, we have been able to detect very low resistance values, due to a decreased ability of the lungs to respirate against the normal resistance of the nose Many of these cases have shown, at the same time, decreased nasal resistance with an almost normal proportion between this respiratory test and nasal airways For this reason these patients have maintained their normal respiration through the nose

DISCUSSION

Much information has been obtained about the configuration of curves typical in normal patients and in certain nasal diseases We have obtained typical curves in cases of vasomotor rhinitis, septum deflections and collapse of the nasal alae, and we have been able to determine the degree of each factor involved Obviously this is of importance from the therapeutic point of view A correction of the septum, the abolition of the collapsing nasal alae would be of value to the patient when the vasomotor component is not too pronounced The exaggeration of the alternating movements of the turbinates and the acceleration of the nasal cycle will be evident in vasomotor rhinitis

In other cases we have found a normal nasal airway despite the severe complaints of nasal discomfort Most of those instances are cases of nasal neurosis, or possibly an undetected pulmonary or cardiac disease of short duration In both instances surgical intervention is not advised Surgery would not be advised, even though obvious anatomical deformity was present In the former instance the complaints of the patient will usually increase if surgery is performed Often nasal complaints will disappear after appropriate treatment for pulmonary or cardiac disease

The measurement of the ability of the patient to breathe against resistance, as measured through the nose is a respiratory test, but may not represent a true pulmonary function test Many variables enter into this picture The muscular strength of the chest wall, general condition of the patient, bronchial resistance, volume exchange, elasticity—the problem of lung compliance—which is not measured in this instance The real importance of measuring the pulmonary function in connection with the rhinometric test of the nasal cavities was emphasized by Sercer[6] several years ago, but it has to some extent been neglected by later investigators It is significant that to date no definite relationship of the nose and the lung has been established by an objective test Nasal function test, as measured by the rhinomanometer, and the establishment of pulmonary function tests are well documented by simultaneous observations of both present major technical problems

Clinically it is important to know whether this relationship exists Why is it that some people with obstructive nasal airways, due to a badly traumatized nose, complain of dyspnea? The "chronic lunger" who bitterly complains about nasal obstruction, the chronic mouth breathing child often has a deformity of the chest with a pronounced flattening of the ribs One wonders about this relationship! The adult patient with oral respiration may have decreased ability to breathe against resistance In such instances, it seems that attention should be directed toward improving the nasal airway surgically, and perhaps even toward proper pulmonary exercises

Since the nose serves as a protective organ and prepares the air for the lung, it seems logical that we should look for better objective methods for testing nasal and pulmonary functions

SUMMARY

On the basis of about 350 rhinometric examinations of the nasal passage with resistance measuring from the right and left nasal cavity, typical resistance curves are shown from normal persons and from patients with deviations of the septum, vasomotor rhinitis, and atrophic rhinitis with ozena and collapse of the nasal alae

The relationship between the nose and lung is discussed briefly A method is outlined for measuring the ability of the lung to breathe against increasing resistance

pressure of 30 lbs/in.² How closely these figures approximate those found from this study will be apparent soon.

In 1937 Armstrong and Heim[3] reported the effects of positive and negative pressure on the eardrum membrane of five apparently healthy men. They found that as atmospheric pressure decreased (as in an ascending airplane) the Eustachian tube opened automatically, first, when the pressure differential reached 15 mm. of mercury, next, when it reached 11.4 mm., until at 40,000 feet it opened at a differential of only 3.5 mm. This they attributed to a rarefaction of the air, which then passed through the Eustachian tube more easily; however, when the atmospheric pressure increased (as on the descent of an airplane) the Eustachian tube failed to open spontaneously and remained closed at all pressures unless voluntarily opened. At a differential of 60 mm. of mercury of negative pressure, pain became severe, at 60-80 mm. very severe, and at more than 80 mm. agonizing. They stated that the eardrum membrane ruptures between 100 and 500 mm. of mercury, and reported one case that ruptured at 470 mm. of mercury accompanied by a loud report, shock and severe dizziness. (It was not revealed how the figures of 100 to 500 mm. of mercury were derived, nor how many eardrum membranes were ruptured.) It was noted that when a negative pressure differential of 80 to 90 mm. of mercury developed, the muscles of the Eustachian tube could no longer voluntarily open the tube.

In 1941 Van Dishoeck[17] studied tension on the human tympanic membrane in relation to hearing and decided that any deviation from the normal tension led to hearing impairment. He used pressures up to 100 cm. of water without any reported rupture. Canfield[6] in 1944 reported results of pressure chamber experiments on the tympanic membrane, *e.g.*, decompression from 7,000 feet (equivalents), and found severe retraction and aerotitis, which readily responded to myringopuncture, but he did not mention any spontaneous ruptures.

In 1942, and again in 1945, there appeared articles by H. B. Perlman[40,41] of Chicago concerning the effect of explosion and blast on the human acoustic conduction apparatus. By attaching tiny mirrors to various parts of the conduction apparatus in fresh, human, temporal bones he was able to measure the displacement of the part under study (*e g* , malleus or stapes) and record its excursions under the influence of the shock pulse produced by explosions or loud sounds He discovered that at a magnification of 200 times the malleus moves when stimulated by a sound at 50 db above the threshold of hearing It was mentioned in these papers that static pressure of 200 to 400 mm of mercury would rupture the tympanic membrane, but how these figures were determined was not elucidated Several other figures regarding the pressure developed by the shock pulse were mentioned Since the threshold of sound perception at 1000 cycles is 10^{-16} watts/cm ^{2} it can be seen that the intensity of the shock pulse is usually many times greater than the "loudest sustained sounds" and may equal many atmospheres For example, Perlman points out that Thompson measured the intensity of the shock pulse 26 feet from the explosion of 10 lbs of TNT and arrived at a figure of 10^4 watts/cm ^{2} which is equal to 200 db above the threshold of sound perception He quotes Miller as stating that the pressure developed 12 feet in front of a 12-inch gun is 542 lbs /in ^{2} Sustained sound becomes unbearably loud at about 10^{-4} watts/cm ^{2} (or 120 db), so it is easy to see how greatly shock pulses exceed the usual decibel intensity of sustained periodic sound Craig[11] stated that probably the first case of traumatic perforation of a tympanic membrane by explosion to be examined and visualized by otoscopy was that seen by Gruber in 1866, three weeks after the battle of Sadowa

In 1943 Dean[16] discussed blast injuries, and pointed out that a 70-pound charge created a pressure of 110 lbs /in ^{2} at 14 feet distance, 60 lbs /in ^{2} at 18 feet, 15 lbs /in ^{2} at 30 feet and 6 lbs /in ^{2} at 50 feet and that 100 lbs /in ^{2} is dangerous to life

The effect of aircraft noise upon hearing was reported in 1944 by Senturia,[46] who noted that noise levels of 128 db were reached in trainer planes and stated that this decibel intensity approaches pain level as well as causing auditory fatigue Also in 1944 Silov[47] reported on 82 cases of blast injury and noted that the loss of hearing was more severe when the tympanic membrane remained intact than when it ruptured Cantor[7] in 1945 sought to explain this observation on the basis that the pulse wave enters by way of the Eustachian tube, and if the tympanic membrane remains intact the middle ear acts as a pressure chamber transmitting force to the windows of the inner ear In 1945 Henry,[20] in discussing 292 blast injuries of the ear, failed to find any drum membranes perforated in Shrapnell's area

Fitz-Hugh[20] in 1946 discussed traumatic perforation in 58 servicemen due to high explosives, but did not suggest what pressure was exerted on the eardrum membrane Ireland[28] tabulated 317 cases of traumatic perforation from blast injury and concluded that high explosive and mortar fire was most often implicated, but the pressure necessary to rupture the eardrum membrane was not discussed In 1949 McReynolds[42] was able to report on 286 ears subjected to blast injury in the Texas City disaster but no mention of rupture pressure was made Whittingham[52] in 1954 discussed an unusual case of perforation of both eardrum membranes during anesthesia, when the patient was "hand breathed" with the bag, but the pressure exerted was not suggested and would be hard to predict Schnurbusch[45] in 1954 described a case of unilateral perforation of the tympanic membrane in a 30-year-old construction worker who was hammering on a tin cylinder and attributed the rupture to sound trauma There was a perforation anterior and posterior to the malleus handle associated with tinnitus and hearing loss Within three weeks the membrane healed, and the hearing returned to practically normal In the discussion of this case the author points out that the type of resistance offered to sound pressure by the tympanic membrane is varied At lower frequencies the drum membrane acts like an elastic membrane, whereas at higher frequencies, say about 800 cycles, it shows a resistance more like a mass reaction to the sound pressure Consequently, the elasticity of the drum membrane at low frequencies offers effective resistance, and considerable sound pressure is necessary to cause rupture At higher frequencies, due to the resistance of the drum membrane in mass, much less protection is offered, and higher frequency sounds can cause rupture with less pressure; however, higher frequency sounds are very directional, so the axis of the sound must be at right angles to the drum membrane to exert maximum effect. It can thus be seen that the main protective feature of the eardrum to low frequency sounds is its elasticity, while at higher frequencies the highly directional quality of the sound waves helps prevent sound trauma unless the axis is oriented at right angles to the drum membrane.

The lower frequency sounds would be expected to produce more bilateral perforations while the higher frequency, more directional sounds, would produce more unilateral perforations of the tympanic membrane.

A large number of discussions of blast injuries of the eardrum membranes appear in the literature, *e.g.*, Craig[11] in 1941, Alexander[1] in 1941, Dean,[16] Alexander,[2] Palmer[38] in 1943, Craig,[13] Silox,[47] Senturia[46] in 1944, Cantor,[7] Bennington,[5] Henry[26] in 1945, Korkis,[31] Ireland,[28] Fitz-Hugh[20] in 1946, Falbre[21] in 1947, Friedman,[23] Collins[10] in 1948, McReynolds,[42] Rice[43] in 1949, Garcia-Vaquero[24] in 1953; yet, insofar as it was possible to glean this material, no reference was found as to the pressure necessary to rupture the human eardrum membrane. Parenthetically, frequent reports have been made of perforations of the eardrum membrane associated with lightning injuries, and of sudden death due to drowning related to a perforation of the eardrum membrane. Obviously, these could not be concerned with pressure analyses.

Of the many available methods of rupturing the human eardrum membrane experimentally, the use of air pressure most nearly resembles the common manner in which many accidental ruptures occur, and so a method was devised whereby air under a measurable amount of pressure could be directed against the membrane in a closed system. Originally two 260 mm. sphygmomanometer tubes were sealed together, giving an effective pressure of 520 mm. of mercury, but this pressure failed to rupture either of the first two drum membranes tested. This method was discarded. Then, a hand-pumped air pressure tank was attached to a metal handpiece, with one pressure gauge at the tank and another

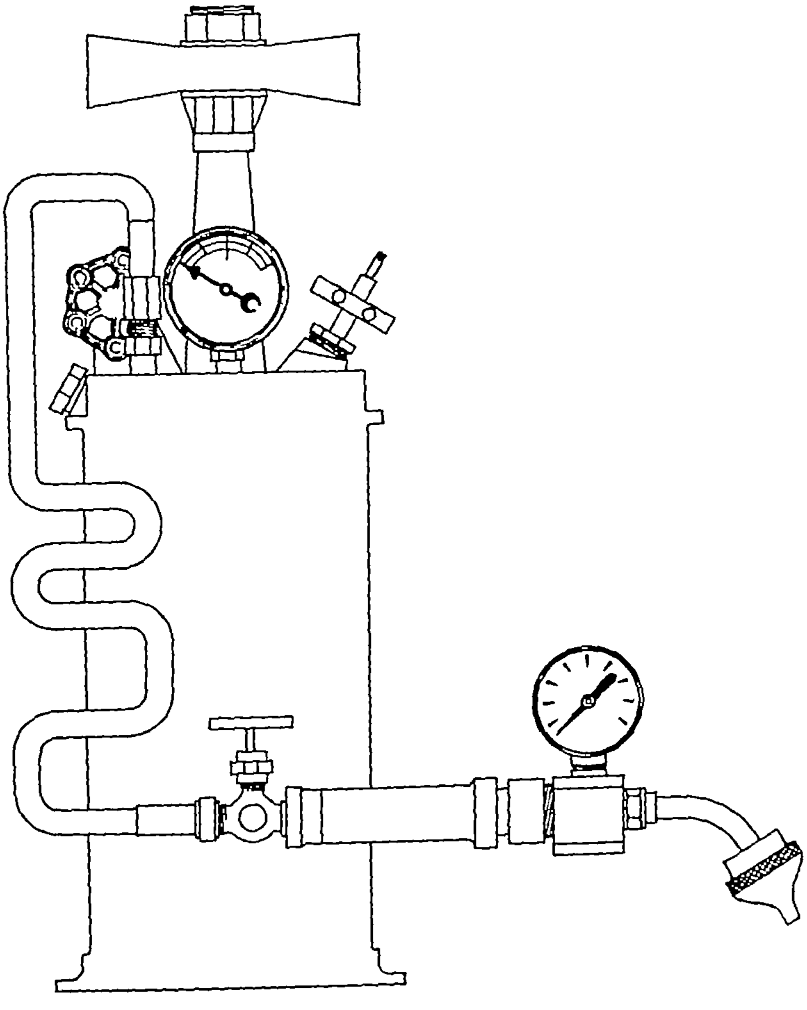

Fig 1 Drawing of Apparatus Utilized

at the hand piece, which was inserted into the external auditory canal A tightly fitting earpiece connected the pressure apparatus to the external auditory canal and transmitted the air pressure to the outer surface of the tympanic membrane (see Drawing) This was used for most of the work, but the hand-pump was later supplanted by a tank of compressed air, which was easier to transport and utilize

With such an apparatus air was directed against the outer

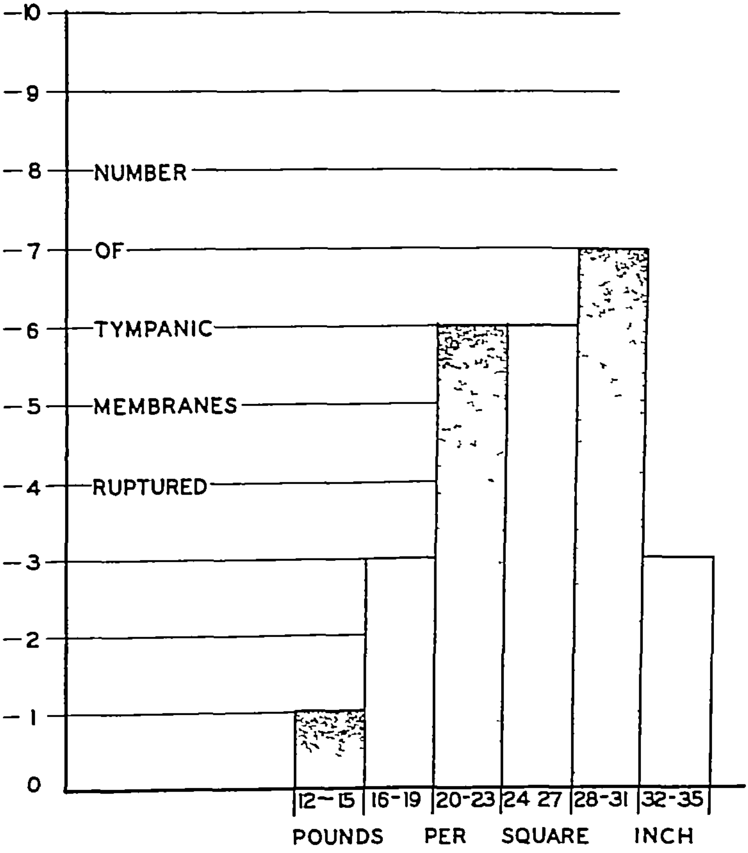

Chart 1

surface of the tympanic membrane of recently deceased human beings under a variety of conditions First, gradually increasing pressure was utilized until rupture occurred, then suddenly applied pressure was utilized, increasing the pressure with each application until rupture occurred, finally, in order to be sure that the pressure being measured was actually that required to rupture the eardrum membrane, and not also that necessary to open the Eustachian tube, the tegmen tympani was exposed and an opening made through this structure into the middle ear so that only the eardrum membrane opposed the air pressure

*Sudden †Gradual

The number of subjects tested was 15 The ages of the subjects at the time of death varied from two weeks to 83 years Four subjects were Negro, the remainder white Thirty eardrum membranes were examined by one of the above methods four did not rupture, either because of insufficient pressure (original attempts) or because of mechanical difficulties Of the eardrum membranes which did rupture the following observations were possible (see Chart 1) The lowest pressure at which any ruptured was 14 lbs /in ^{2} The highest pressure required to rupture any in the series was 33 lbs /in ^{2} The mean breaking pressure was 25 lbs /in ^{2} The right eardrum membranes ruptured at an average pressure of 24 lbs /in ^{2}, and the left eardrum membranes at an average pressure of 26 lbs /in ^{2} There was no significant difference between rupture pressures when gradual or sudden application was made Individual cases are presented with comments concerning each (see Table)

It is realized that the first question to be raised may be whether or not the eardrum membrane of a dead human being has the tensile strength of that of a live person In the living human being the stapedial and tensor tympani reflexes could act to protect the tympanic membrane, but it has been shown that the latent period of this reflex is such that it would not have time to act in blast injuries, as the pulse wave reaches its maximum in much too rapid a time interval Some of the ears tested were only slightly over two hours postmortem, and the longest time after death was 14½ hours There was no distinct relationship evident between length of time postmortem and the pressure necessary to rupture the eardrum membrane All subjects had been kept refrigerated until examined

All except two of the eardrum membranes which were ruptured showed tears in the pars tensa, the two exceptions occurring in the pars flaccida, 15 perforated in the anterior half of the pars tensa and eight in the posterior pars tensa In the two cases where the perforation could not be found, the pressure registered just prior to a sudden drop in pressure (accompanied by an audible escape of air through the Eustachian tube and nose) was recorded as the breaking pressure That there is a measurable loss of pressure between the gauge and the eardrum membrane is admitted, but is not considered significant in the gross measurements taken here, nor of clinical value because of the range of pressures in the series

After arriving at an average figure for the pressure at which a human eardrum might be expected to rupture, what then becomes of more import is the question of practical application of these figures Vail[49] has already reported that two different patients had ruptured eardrum membranes from positive pressures of 27 and 30 pounds per square inch respectively, and so the necessity of a caisson worker having functional Eustachian tubes (and voluntarily opening them)

FORMULATION

To Change lbs/in² to Decibels

Threshold of hearing = 10^{10} Microwatts/cm

Sound level in decibels 0

$$\text{Intensity} = \frac{\text{Power}}{\text{area}}$$

$$= \frac{\text{Force} \times \text{distance}}{\text{time}} \Big/ \text{Area}$$

10^7 dyne-cm or ergs = 1 joule

1 joule/sec = watt

$$\therefore \text{Watts/cm}^2 = \frac{\text{dyne}}{10^7} \quad \frac{(\text{cm})}{(\text{sec})} \Big/ \text{cm}^2$$

10^6 microwatts = 1 watt.

$$\therefore \text{Microwatts/cm}^2 = \frac{\text{dyne} \quad (\text{cm}) \times 10^6}{10^7 \quad (\text{sec}) \quad \text{cm}^2}$$

$$(\text{cm/sec} = \text{velocity}) \quad \frac{\text{dynes}}{10^7} \times \frac{\text{velocity} \times 10^6}{\text{cm}^2}$$

Velocity of sound = 33100 cm/sec at 0° C and increases 61 cm/sec for each 1° C rise above 0° C

$$\therefore \frac{\text{dynes}}{10} \times \left(\frac{33100 + (61 \times t^\circ\,\text{C})}{\text{cm}^2}\right)$$

$$\text{or } \frac{\text{dynes}}{\text{cm}^2} \times \left(\frac{33100 + (61 \times t^\circ\,\text{C})}{10}\right)$$

Acceleration of gravity = 980 cm/sec²

$$\text{dynes/cm}^2 = \text{lbs/in}^2 \times \frac{454 \times 980}{2\ 54 \times 2\ 54}$$

$$\text{lbs/in} \times \frac{454 \times 980}{2\ 54 \times 2\ 54} \times \frac{33100 + (61 \times t^\circ\,\text{C})}{10}$$

$$= \text{microwatts/cm}$$

$$\text{Decibels} = 10 \log \frac{E}{E^\circ}$$

$E^\circ = 10^{10}$ microwatts/cm² = Threshold of hearing

$$\text{Decibels} = 10 \log \left(\frac{\text{microwatts/cm}^2}{10^{10}}\right) = \text{Intensity}$$

$$10 \log \left(\frac{\dfrac{\text{lbs}}{\text{in}^2} \times \dfrac{454 \times 980}{2\ 54 \times 2\ 54} \times \dfrac{33100 + 61\ t^\circ\,\text{C}}{10}}{10^{10}}\right) = \text{Intensity in decibels}$$

Now in this formula $\frac{454 \times 980}{2\ 54 \times 2\ 54}$ = 68,980 or a constant of 69,000 and if the average temperature is assumed to be 30° C then $\frac{33{,}100 + 61 \times 30}{10}$ = 3,493 or as a constant 3 500 and the formula is reduced to

$$10 \log \left(\frac{\text{lbs/in} \times 241\ 000\ 000}{10^{10}}\right) \text{ or}$$

$$10 \log \quad \text{lbs/in} \times 241 \times 10^{14} = \text{Intensity in decibels}$$

is immediately apparent Similarly, Armstrong and Heim have indicated the practical value of this knowledge in aviation Numerous articles have indicated the relation of these figures to underwater diving, as in a recent review by Martins[36] Another phase is the relation of these pressure-rupture figures to sound Perlman[40] states (probably indirectly quoting Collier[9]) that if a 200-pound bomb exploded in State Street, Chicago, everyone on the street within a radius of 50 feet from the bomb would likely have ruptured eardrums

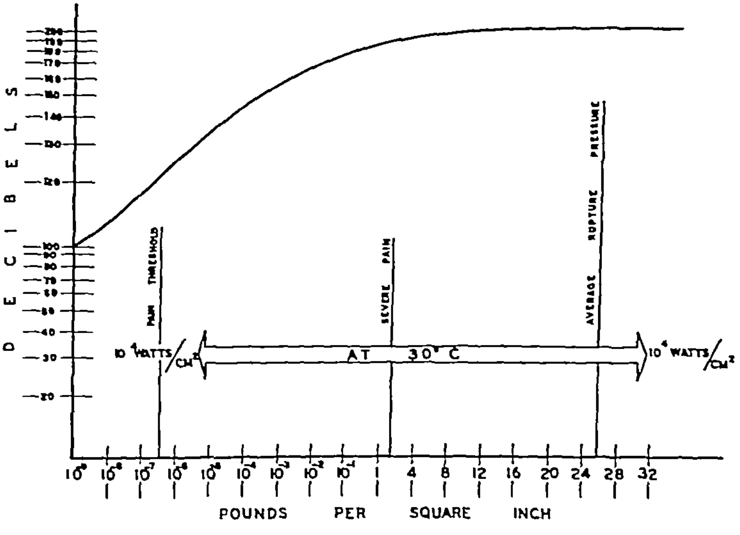

Chart 2

As the atom and hydrogen bombs and jet engines have opened new vistas in sound study, and a recent judicial verdict has made hearing loss due to acoustic trauma in industry compensable, it would seem well to know at what decibel intensity a human eardrum membrane might be expected to rupture It then becomes necessary to convert decibel intensity to pounds per square inch The earliest successful attempts to measure sound velocity in air were those of Marin Mersenne, a French physicist in 1640, and two Italian physicists, Borelli and Vivani, in 1656 One of the most recent, detailed and apparently accurate measurements of sound velocity was done by Miller[37] in 1934 The conversion of decibels (microwatts/cm^2) to lbs /in^2 is dependent upon two values being constant, namely velocity and temperature This is because the velocity of sound varies directly with the temperature and the variant between watts/cm^2 and lbs /in^2 is (flow) cm /sec (velocity) , therefore, in any description of lbs /in^2 in terms of decibels (watts/cm^2), it is necessary to state at what temperature the conversion is made, as this in turn would alter the velocity (see Formulation)

By substituting in the above formula it would seem that a human eardrum membrane may be expected to rupture at between 195 and 199 dbs at 30° C The threshold of pain, 120 dbs , is equal to 0000005 pounds per square inch, and if the figures of Armstrong and Heim are accepted, then very severe pain occurs at 186 dbs if the temperature be taken at 30° C (see Chart 2) It is felt that the system utilized in this study approximates that present in conditions resulting in *low frequency*, sonic, traumatic perforations and consequently may be expected to give higher decibel figures than would be encountered if high frequency sound waves were utilized For example, Davis et al[16] in 1949 described a perforation of the tympanic membrane after exposure to a 6500 frequency sound at 156-164 dbs for five minutes The low decibel figure attained by these workers may be due to the high frequency of the sound wave (and duration) and lower temperatures (not recorded)

SUMMARY AND CONCLUSIONS

1 The literature concerning tympanic membrane rupture due to air pressure has been reviewed

2 Tympanic membranes of recently deceased human beings have been ruptured by the application of air pressure by way of the external auditory canal, and the myringorupture pressures recorded

3 The tympanic membrane reacts differently to sound pressures from high and low frequency waves, and this study probably more closely resembles results to be found in low frequency sound trauma

4 Some clinical correlations are suggested as related to decibel intensity, air pressure and myringorupture

POSTGRADUATE MEDICAL INSTRUCTION DEPARTMENT—THE MOUNT SINAI HOSPITAL

An intensive Course in Rhinoplasty, Reconstructive Surgery of the Nasal Septum and Otoplasty will be given July 11, to July 24, 1959, by Dr Irving B Goldman and staff at the Mount Sinai Hospital in affiliation with Columbia University

Candidates for the Course should apply to Registrar for Postgraduate Medical Instruction, The Mount Sinai Hospital, Fifth Avenue and 100th Street, New York 29, New York

LARYNGOLOGIC EXPERIENCE IN BULBAR POLIOMYELITIS [*]

CHARLES P LEBO, M D ,[†]

San Francisco, Calif

> "When you know a thing, to hold that you know it, and when you do not know a thing, to allow that you do not know it this is knowledge" CONFUCIUS, Analects, Book II, Chap XVII

A critical evaluation of the experiences of a consulting laryngologist on the poliomyelitis service of an active, private communicable disease hospital is presented This report may appear to be redundant and ill-timed, since it is written in the wake of a large number of excellent articles on the recognition and management of the respiratory complications of poliomyelitis, published by competent observers, and is offered at a time when the incidence of this dreaded neurotropic virus disease is declining

Why then, does the author have the temerity to undertake the writing of still another paper on this subject? The answer lies in the writer's strong conviction that there remains much to be learned about the prevention, diagnosis, and treatment of the respiratory complications of poliomyelitis At the beginning of his clinical contact with the disease, the essayist prepared himself by means of an extensive review of the pertinent literature and discussion of the subject with physicians qualified by actual clinical experience with poliomyelitis Initially, all phases of the laryngologic management of bulbar poliomyelitis seemed to be very clear to the author, however, as his experience with the disease became greater, he began to perceive that the indications for laryngologic intervention in bulbar poliomyelitis in a disturbingly large number of cases, were not clearly delineated After several

Editor's Note This manuscript received in The Laryngoscope Office and accepted for publication Jan. 27 1958

years of clinical experience with the disease, the author found himself distressed by his progressive inability to give categorical answers to questions posed by members of the house staff, questions which he had previously thought to be easily answerable The writer was thus stimulated to take inventory of his knowledge and ignorance with the aid of a review of the case records of patients in this category admitted to Children's Hospital during the years 1948 through 1956

OBJECTIVES

The objectives of this study are

1 To review the literature concerning the role of the otolaryngologist in the management of bulbar poliomyelitis

2 To study the cases encountered by the author and his colleagues at Children's Hospital and to compare their experiences with those of other groups reporting from similar institutions

3 To describe the *modus operandi* of the poliomyelitis team at Children's Hospital

4 To formulate certain general principles which might serve to guide other otolaryngologists in the therapy of the respiratory complications of bulbar poliomyelitis, and those of other diseases in which analogous problems occur

BACKGROUND

Much has been written during recent years of the respiratory complications of poliomyelitis, and particularly those of the bulbar form of the disease In 1929, Durand[1] published what appears to be the first report concerning the dangers of the hypopharyngeal secretions to the patient with bulbar poliomyelitis He described two cases in which postural drainage appeared to be beneficial Shaw,* in his discussion of this paper, made the following remarks, which may serve well as the theme of this discourse " the tendency of these cases is to progress rapidly to death or to complete recovery " and " successful employment of Dr Durand's method simply removes a great obstacle in the way of complete recovery"

---

*Shaw E B Chief of the Communicable Diseases Service Children s Hospital San Francisco Calif

Wilson,[2] in 1931 observed that poliomyelitis may interfere with respiration in three ways *1* directly, by actual paralysis of the intercostals and diaphragm, *2* directly, by involvement of the respiratory centers in the medulla, *3* indirectly, in patients with pharyngeal paralysis, by secretional obstruction with or without associated glottic spasm He stressed the importance of differential diagnosis of the nature of the respiratory difficulty as a basis for rational management He did not mention tracheotomy

In a review article published in 1936 Davison,[3] in reference to the care of patients afflicted with bulbar poliomyelitis, recommended that the foot of the bed be elevated for postural drainage, and that the hypopharyngeal secretions be aspirated frequently Gastric tube feedings, intravenous infusions, and proctoclysis were advocated as methods of choice in providing nourishment for these patients Finally this author stated that in such cases the use of the respirator is contraindicated, but that tracheotomy may be indicated

Wilson,[4] commenting in 1941 upon the use of the respirator emphasized that patients having respiratory difficulty, due to bulbar paralysis, are not helped by this device, but are actually made worse by its use He reaffirmed the importance of careful examination and evaluation of poliomyelitis patients with emphasis upon the differential diagnosis of respiratory difficulty Recommended therapy included postural drainage, aspirations of the pharynx, and even tracheotomy, although no actual experience with the latter procedure is mentioned

The first report of actual tracheotomies in bulbar poliomyelitis (encountered by the essayist in his review of the literature) was that of Galloway,[5] who is 1943 described the use of tracheotomy in two cases, with subsequent recovery in both patients This report also describes a third case in which the patient died during preparation for tracheotomy Two years later, Nelson-Jones and Hunt Williams[6] reported one case of bulbar poliomyelitis, occurring in a British dental officer, with survival after a tracheotomy. In 1947, Hamilton[7] asserted that the indications for tracheotomy are not clear cut, and possibly they may never be.

In their account of 400 cases of bulbar poliomyelitis treated in the Minneapolis epidemic of 1946, Priest, Boies, and Goltz[8] reported 75 tracheotomies. Of the operated patients, 29 recovered. The mortality in the non-tracheotomized group of patients is not included in their report. Galloway and Seifert[9] reported in 1949 concerning 14 patients afflicted with bulbar poliomyelitis, all of whom recovered following tracheotomy. In this classic paper the problem of respiratory complications in poliomyelitis is presented in a concise, yet comprehensive manner. Using drawings of a model, the authors demonstrate the physical basis for the effectiveness of tracheotomy as a by-pass for preventing aspiration of pharyngeal secretions in patients with bulbar paralysis. They stress the need for this tracheotomic by-pass when patients, having pooling of secretions due to pharyngeal paralysis, are placed in respirators. According to these authors, the respirator is not only not contraindicated for patients with bulbar involvement, but that this device is actually helpful to such patients providing they are afforded the protection of tracheotomy. Galloway and Seifert offer the following indications for tracheotomy in bulbar poliomyelitis:

1. Progressive anoxia with secretions in the upper airway.

2. Unconsciousness or pronounced restlessness in a patient who does not respond to other treatment in a few minutes.

3. Pronounced restlessness or stupor in a patient in a respirator, even if the paralysis is apparently of a spinal type.

4. Food accumulation, not otherwise certainly taken care of, in a patient who requires a respirator.

5. Bilateral paralysis or spasm of the vocal cords.

6. Rapidly progressive bulbar symptoms.

7. Grave signs of vasomotor failure.

8. Untrained or inefficient attendants, inadequate equipment, or poor cooperation of the patient, with doubt that the airway will be kept constantly free of secretions

West and Bauer,[11] also reporting in 1949, gave a different set of indications for tracheotomy

1 Definite bulbar signs such as nasal voice, signs of interference with swallowing, and pooling which endangers the airway

2 Bulbar or spinal cases, at first doing well, but later showing gradually increasing anoxia, whether in or out of the respirator

3 Atelectasis

4 Vocal cord paralysis

Lenarsky,[12] reporting in 1950 from the Willard Parker Hospital in New York, questioned the value of tracheotomy in bulbar poliomyelitis, and presented a mortality of 72 7 per cent in tracheotomized cases as opposed to a mortality of 24 4 per cent in non-tracheotomized cases This author advocated that bulbar poliomyelitis patients be treated, not by a single physician, but by a team of specialists, including the internist or pediatrician, the otolaryngologist, the orthopedist, the physiatrist, and the psychiatrist Lenarsky emphasized that the otolaryngologist should not be sought for the tracheotomy alone, but should function as a part of the team in the early treatment of the patient

Stimson,[14] in 1950, presented still another set of indications for tracheotomy These were

1 Bilateral abductor paralysis of the vocal cords This causes a mechanical obstruction which must be by-passed

2 Inability to keep the airway reasonably clear Some clinics with good teamwork can be notably more successful in this than others that are overcrowded or have inadequate or untrained personnel

3 Progressive hypoxia, not otherwise correctible

The same author enumerates the following as disadvantages of tracheotomy

1 The operation is at best an ordeal to the patient, who needs rest and a minimum of handling

2 There are possible complications

3 The mortality following tracheotomy in polio is high

4 The tracheotomy tube narrows the airway and, as a foreign body, it increases endotracheal secretions

5 Tracheotomy makes oxygen administration difficult unless a proper oxygen attachment is available

Since these earlier reports, a multitude of other papers have been published on the subject of tracheotomy in bulbar poliomyelitis Almost without exception, these accounts have echoed the reasoning of Galloway, and have confirmed his results

REPORT OF CASES

During the years 1948 to 1956 inclusive, the total number of poliomyelitis cases admitted to Children's Hospital was 2,158 Of these cases, 345 were of the bulbar and bulbospinal types, the overall mortality in this group was 19 4 per cent, or 67 deaths Tracheotomies were performed in 40 cases having bulbar involvement There were 15 deaths (37 5 per cent) in the tracheotomized group Endotracheal intubation, planned as a temporary measure, was performed in six moribund, comatose, respirator cases, all of which expired

Fig 1 shows, year by year, the total number of patients with bulbar involvement, their mortality, and the number of tracheotomies performed This table demonstrates graphically that, in our series of cases, no apparent relationship exists between the total number of cases, the number of tracheotomies performed, and the mortality statistics As an example of this lack of correlation, let us compare the years 1951 and 1952 In the year 1951, 67 cases of bulbar and bulbospinal poliomyelitis were admitted to Children's Hospital, in this series of cases two tracheotomies were performed and the overall mortality was 12 cases or 17 8 per cent In the year 1952, of a total of 59 cases with bulbar involvement, there were ten tracheotomies, nine deaths, and an overall mortality of 15 2 per cent Certainly the case data from 1951 and 1952, as well as those of the other years included in this study, do not enable one to conclude that the mortality experience in bulbar and bulbospinal poliomyelitis cases at Children's Hospital was significantly influenced by the number of treacheotomies performed

Fig 2 indicates that in our series of patients, the mortality in the bulbar cases was approximately twice that occurring in the bulbospinal cases Shaw[10] explains this finding on the basis that patients with bulbospinal poliomyelitis tend to have mild, widely-disseminated central nervous system involvement, while patients with pure bulbar poliomyelitis are more likely to have more severe local involvement occurring in vital centers

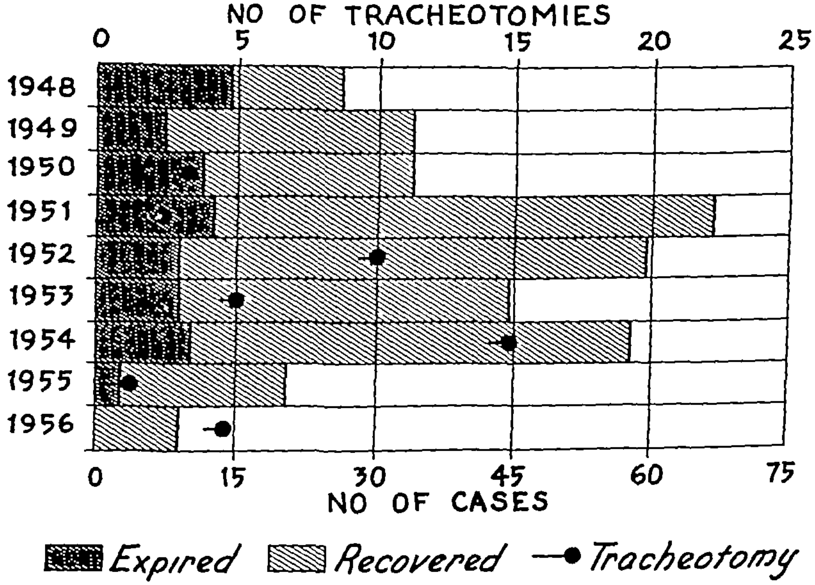

Fig 1 A graph showing the total number of bulbar and bulbospinal poliomyelitis cases year by year together with data concerning the mortality experience and the number of tracheotomies performed

A comparison of our experience with that of four other groups is illustrated in Fig 3 In the percentage of bulbar

Type	Total Cases	Mortality
Bulbar	115	33 or 28 7%
Bulbospinal	230	34 or 14 8%

Fig 2 The comparative mortality experience at Children s Hospital in bulbar polio myelitis and in bulbospinal poliomyelitis during the years 1948 to 1956 inclusive

Reporting Group or Institution	Total No Bulbar Cases	Tracheotomy Cases	Deaths in Tracheotomy Cases	Deaths in Non-Tracheotomy Cases
Minneapolis Gr , 1946	400	75 (18 7%)	46 (61 3%)	not specified

Combined Experience (based upon specified data in each category)	1708	395 (23 1%)	76 (54 3%)	122 (18 9%)

Fig 3 This chart is a comparative compilation of the experience of the designated groups or institutions with tracheotomy in bulbar poliomyelitis. The percentages expressed are based only on those reports which included a complete breakdown of data within the terms of reference of this chart.

cases tracheotomized, Children's Hospital occupies a median position Our *death rate in both the tracheotomized patients* and in the non-tracheotomized patients is the lowest of all groups in whose reports these statistics are specified Like the investigators at Los Angeles County Hospital and at Willard Parker Hospital, we found the mortality to be higher in the tracheotomized bulbar cases than in the non-tracheotomized bulbar cases

LARYNGOLOGIC MANAGEMENT OF POLIOMYELITIS CASES AT CHILDREN'S HOSPITAL

The facilities at this institution are particularly favorable for the care of poliomyelitis patients The communicable disease building is well equipped, and is generously staffed with resident physicians, interns and experienced nursing personnel During the period covered by this report a group of consulting laryngologists participated on a "poliomyelitis team" which, in addition to the attending physicians and the house staff, included anesthesiologists The laryngologists were consulted as early as possible, thereby giving them the opportunity of following each case with manifest or developing bulbar involvement, and thus enabling them to gain a dynamic perspective of each individual problem Because of the care it was possible to render under these circumstances, the indications for tracheotomy at Children's Hospital differed from those reported by physicians working in similar institutions

TRACHEOTOMY

The indications for tracheotomy at Children's Hospital are best presented in reference to those of Galloway, which are widely accepted as the standard indications for this surgical procedure in poliomyelitis Galloway's first indication (progressive anoxia with secretions in the upper airway), his fifth indication (bilateral paralysis or spasm of the vocal cords), and his sixth indication (rapidly progressive bulbar symptoms) are considered to be quite important by the author and his colleagues

We differ from Dr Galloway in reference to his second (unconsciousness or pronounced restlessness in a patient who does not respond to other treatment in a few minutes), and third (pronounced restlessness or stupor in a patient in a respirator, even if the paralysis is apparently of a spinal type) indications It is our opinion that it is imperative in such situations to determine the etiology of the restlessness or of the comatose state before instituting therapeutic measures, tracheotomy, under the conditions specified in these two indications, may often be inappropriate therapy

Indication four (food accumulation not otherwise certainly taken care of in the patient who requires a respirator) is not generally applied, since the use of intravenous and tube feedings eliminates this problem, however, such patients require extremely close observation and may have need for tracheotomy for other reasons.

While indication seven (grave signs of vasomotor failure) may be the result of prolonged hypoxia, such findings may also be due to medullary involvement by the disease process *per se*, hence we do not, as a rule, perform tracheotomies merely on the basis of vasomotor failure.

As some of the foregoing remarks have implied, indication eight, which concerns problems relative to personnel and equipment, is one that we have not had to apply at Children's Hospital. On the contrary, it is believed that many of the bulbar poliomyelitis cases which were treated successfully at this institution without tracheotomy would have been tracheotomized at most other hospitals.

In reference to the indication concerning bilateral vocal cord paralysis, the poliomyelitis team at Children's Hospital considers the presence of unilateral vocal cord paralysis, or paresis, to be a valid indication for tracheotomy, all other factors being considered. Another indication referred to by Galloway, but not included in his list, concerns the patient with mild bulbar involvement, in whom progressive respiratory paralysis necessitates his transfer to a respirator. It has been our policy to protect such patients with preliminary tracheotomies.

Although the indications of Galloway, with the aforementioned modifications, are generally employed at Children's Hospital, the author and his colleagues prefer not to adhere to any specific set of indications. In all patients, the indications for tracheotomy are considered in the light of many important factors, such as the general condition of the patient, the stage and severity of the disease, the presence of pulmonary complications, and the level of consciousness. We consider the situation to be far too complicated to permit the use of any categorical list of indications; nonetheless, we recognize the value of such a list of indications in hospitals in which bulbar poliomyelitis is not frequently encountered.

The main considerations in regard to the indications for tracheotomy in this disease revolve around a careful initial examination of the patient, which must include either indirect or direct laryngoscopy When the findings of the initial examination do not indicate tracheotomy, the laryngologist is then obligated to follow the patient with as many subsequent examinations as may be needed for careful evaluation of the patient's progress We have employed the policy of utilizing postural drainage, pharyngeal aspiration, and other conservative measures in order to evaluate and manage all bulbar patients who were not obvious candidates for immediate tracheotomy

The following case reports are presented as illustrations of typical situations in which we have not performed this surgical procedure

Case 1 H N, a 37 year old male physician, was admitted on Sept 17, 1952, with a history of sore throat and fever for five days, gagging and vomiting for two days, and inability to swallow for six hours Initial examination disclosed a well developed and nourished, apprehensive person with rhinolalia, hoarseness and gurgling speech The patient was neither able to cough nor to swallow his secretion The positive physical findings included marked weakness of the soft palate with deviation of the uvula to the left, pronounced weakness of the pharyngeal constrictors, greater on the right, and a mild but definite adductor paresis of the right vocal cord The intercostal muscles and the diaphragm were judged to function normally No weakness nor spasm was demonstrable in the extremities The lungs were clear

The patient was given a diagnosis of acute bulbar poliomyelitis and was treated by means of postural drainage, intermittent suctioning of the pharyngeal secretions, and feeding via nasal tube It was the decision of the staff that this patient, having weathered the storm, would probably continue to improve under conservative management Tracheotomy was deferred

The fever, which was 39° C rectally on admission, lysed rapidly The patient was afebrile by Sept 19, 1952 On Oct 8, 1952, the feeding tube was removed and the patient was discharged four days later

COMMENT

This case report has been included in order to illustrate a statement made earlier in this paper to the effect that the indications for tracheotomy in bulbar poliomyelitis should be tempered with consideration of the stage of the disease process Certainly this patient would have done very well with a tracheotomy, yet the staff reasoned that since H N appeared to be near the end of the acute phase of his disease and had reached this point without the development of pulmonary complications, tracheotomy might be avoided so long as the clinical picture continued to improve

Case 2 V M a five-year-old boy, was admitted on Aug 29 1954 with a history of vomiting and fever of two days' duration and of headache and backache for one day prior to admission The initial physical examination revealed slight neck stiffness partial left sided facial paralysis weakness of the pharyngeal constrictors associated with a moderate degree of pooling and a rectal temperature of 40° C The sensorium was clear No cyanosis was observed The function of the respiratory muscles was unimpaired

At a conference held on the date of admission it was predicted that since this child was in an early phase of his disease progression was likely to occur Accordingly the boy was given postural drainage intermittent pharyngeal aspirations tube feeding, and close observation On Aug 30 1954 progression was evidenced by beginning intercostal paralysis increased rightsided facial weakness and slight lethargy without cyanosis It was then decided that immediate tracheotomy should be performed

The operation was completed without incident under general anesthesia a No 2 snorkel tracheotomy tube being inserted[21] Postoperatively the child was placed in an open topped tent which was ventilated with oxygen containing a nebulized detergent.* Forty-eight hours post operatively because of increasing respiratory paralysis with attendant diminution of his tidal volume the patient was placed in a tank type respirator His initial adjustment to the machine was good, and progressive improvement began The patient was removed from the respirator after five days and was extubated two days later He was discharged from Children s Hospital on Sept 20, 1954

COMMENT

The case of V M is presented for contrast with Case No 1 The boy was very ill, and still in an early stage of his disease, when admitted It was anticipated that progression would occur, and unfortunately this prognosis was valid It became necessary to perform a tracheotomy and eventually, to place the child in a respirator In retrospect, it would not have been improper to perform the tracheotomy on the day of admission This case serves to reinforce the thesis that the indications for tracheotomy in bulbar poliomyelitis should be tempered by the chronology of the disease process

Case 3 Mrs S M a 41year-old housewife was admitted to Children s Hospital on Aug 4 1951 twenty four hours after the sudden onset of headache fever and inability to swallow On admission, the patient was quite restless and presented a complete paralysis of the left facial nerve deviation of the tongue to the right, pooling of secretions in the hypopharynx fixation of both vocal cords in abduction and the characteristic signs of meningeal irritation Although she was dusky in color initially her color improved promptly with elevation of the foot of her bed, nasal oxygen and intermittent pharyngeal suctioning

---

*Alevaire Winthrop Laboratories New York

One hour after admission the patient suddenly became cyanotic and appeared to have no respiratory exchange She was immediately placed in a tank respirator and was provided with an endotracheal airway Again her color improved, particularly after aspiration of the contents of the tracheobronchial tree through the endotracheal tube The patient maintained this improvement for 90 minutes, and then expired

COMMENT

This woman suffered an overwhelming invasion of her central nervous system by the poliomyelitis virus In her management, the insertion of an endotracheal tube offered all that might be expected from a tracheotomy, but did not expose her to a surgical procedure at a time when her life was in jeopardy Had she responded to therapy, a tracheotomy would have been performed before removal of the endotracheal tube

Endotracheal intubation has a very definite place in the management of bulbar poliomyelitis Certainly, it is a desirable substitute for an emergency tracheotomy Another advantage of the procedure is that it may be done at any hospital by the anesthesiologist on duty, should the arrival of the otolaryngologist be delayed

TECHNICAL CONSIDERATIONS

It so happened that local and general anesthesia were used with equal frequency in the entire series of cases Local anesthesia predominated in the earlier years, while general anesthesia predominated in the more recent years Both types of anesthesia were found to be satisfactory and well tolerated, even in very sick patients[31] General anesthesia was initially employed to facilitate the care of respirator patients, but as our experience with this technique grew, we elected to use it also in patients whose disease did not necessitate the use of the respirator Currently at Children's Hospital, general anesthesia is considered the method of choice for respirator cases and is utilized interchangeably with local anesthesia in non-respirator cases

Whenever possible, patients requiring tracheotomy were removed to the operating room of the communicable disease building Respirator patients were usually transferred to an operating table as a preliminary to tracheotomy Removal of the patients from the respirators was accomplished after induction of general anesthesia, with endotracheal intubation enabling the anesthesiologists to render artificial respiration throughout the procedures It was thus possible to avoid the pitfalls of performing this operation in the respirator Artificial respiration after insertion of the tracheotomy tube, and before replacement of the patient in the respirator, was simplified with the use of the snorkel tracheotomy tube[21] It is pointed out that this special tracheotomy tube has also been helpful in facilitating the respirator care of tracheotomized patients (The snorkel tracheotomy tube is illustrated in Figs 4, 5)

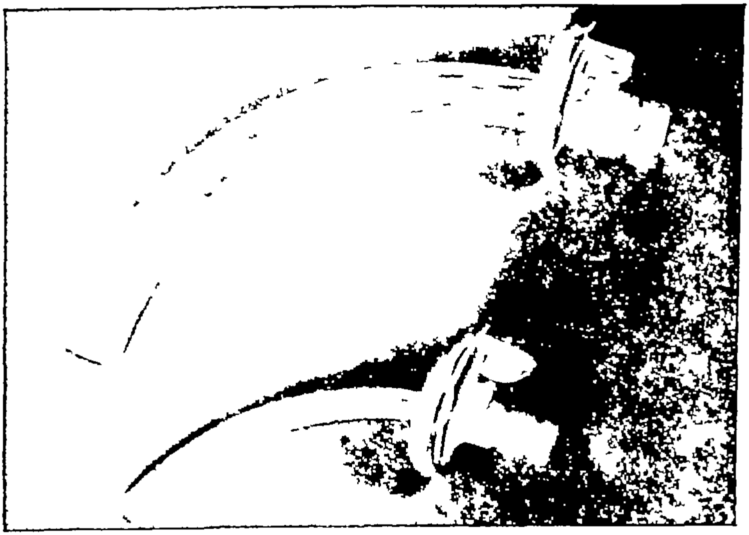

Fig 4-A. Lateral view of snorkel tracheotomy tubes in sizes No 5 and No 0

BRONCHOSCOPY

While bronchoscopy as a single or repetitive procedure is

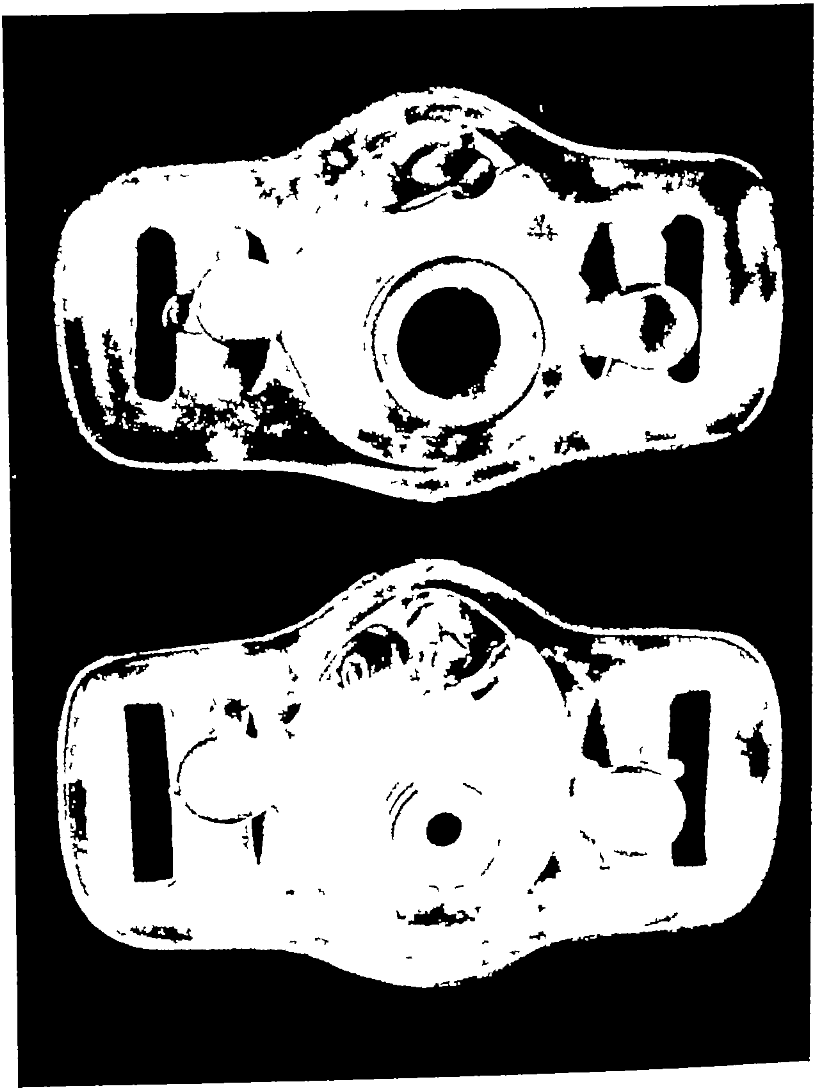

Fig 4-B Anterior view of snorkel tracheotomy tubes in sizes No 5 and No 0

often performed independently of tracheotomy in bulbar poliomyelitis, it was frequently undertaken as a preliminary to this surgical procedure When a bronchoscopy preceded a tracheotomy, the bronchoscope was usually left in the trachea during the surgery By means of a heavy flow of the anesthetic mixture, artificial respiration was administered very satisfactorily through bronchoscopes of the type which is fitted with an oxygen adapter near the proximal end[32]

We have favored general anesthesia for peroral bronchoscopy in nontracheotomized respirator patients because we have seldom obtained satisfactory topical anesthesia in this group of patients The difficulty in inducing adequate topical anesthesia in this group is attributed to both the pooled secretions in the pharynx and to the recumbent position Under these circumstances thiopental sodium and a curarizing agent are administered intravenously The respirator provides artificial respiration during anesthesia as well as in the preanesthetic and postanesthetic periods General anesthesia is not required in bronchoscopic procedures performed through tracheotomies In this instance topical anesthesia is employed, except for comatose patients in whom no anesthesia is required A major advantage of tracheotomy is that it facilitates bedside bronchoscopy

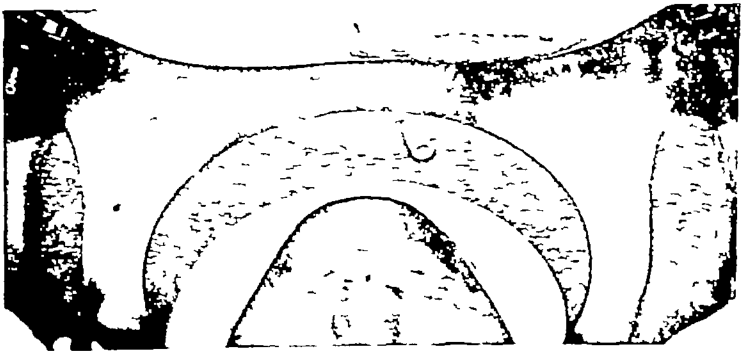

Fig 5 Illustration of snorkel tracheotomy tube in use as viewed from outside of respirator Note the end of the tube emerging from the sponge rubber collar of the respirator this is an endotracheal tube the opposite end of which is attached to a snorkel tracheotomy tube inside the respirator

POST-TRACHEOTOMY CARE

As pointed out by Negus,[33] the previously anoxic patient may be in danger after a successful tracheotomy because of apnea induced by a rapid loss of excess carbon dioxide resulting from restoration of an adequate airway at a time when the chemoreceptors are no longer responsive to the normal range of plasma carbon dioxide concentrations Although no complications of this sort were encountered in our series of cases, we have been aware of this possible danger and have taken the recommended precautions against it

It is considered advisable to change tracheotomy tubes every 48 hours for the first seven to ten days, and twice weekly thereafter Although extra large tracheotomy tubes have been advocated by other workers,[34] we have not encountered a need for their use

The procedure of aspiration of the tracheobronchial tree through the tracheotomy tube is to be undertaken with caution, since pulmonary complications may follow traumatic suctioning Plumb and Dunning,[35] and Conley,[36] have emphasized these dangers, and both have suggested methods of avoiding such trauma

EXTUBATION

It is believed that allowing the tracheotomy tube to remain in place should be considered to be just as active a process as electing to perform the tracheotomy The tracheotomy tube, which is no longer needed, is both a physical and psychological detriment to the welfare of the patient who wears it The duties of the laryngologist do not end with the termination of the acute phase of the tracheotomized poliomyelitis patient's illness, he is obligated to follow the progress of the patient and to extubate at the proper time Successful extubation demands the judicious use of the art of medicine and requires a positive, confident attitude on the part of the laryngologist

The tracheotomy tube constitutes a foreign body, and as such evokes the formation of excessive secretions The presence of such secretions does not necessarily indicate that the tube is still needed

DISCUSSION

Many reports of tracheotomy in bulbar poliomyelitis list groups of cases in which tracheotomy is regarded as a life-saving procedure This author is unable to conclude that tracheotomy was life-saving nor that this procedure was not life-saving in any of the surviving cases included in this report The clinical picture is far too complicated Many of our patients exhibited dramatic initial improvement after tracheotomy, but subsequently died, some patients showed no change after tracheotomy, but recovered, other patients maintained whatever improvement followed tracheotomy

Most authors stress the importance of clinical hypoxia in their lists of tracheotomy indications and include restlessness, anxiety, hyperpnea, flushed fascies, tachycardia, lethargy, coma, and cyanosis as manifestations of hypoxia In this they are indeed correct, however, most of the features of this clinical picture also occur in viral invasion of the higher centers, in hypokaliemia, and in disturbed acid-base balance, hence the presence of the aforementioned symptoms and physical findings is not specific Even when hypoxia is demonstrated by oximetry, these other conditions may also be present It may, therefore, be concluded that tracheotomy is most useful in those cases in which these "hypoxic symptoms" are due primarily to hypoxia resulting from respiratory obstruction in the hypopharynx and in the cephalic portions of the tracheobronchial tree Tracheotomy may be futile when these "hypoxic symptoms" are principally the result of conditions other than hypoxia

The differential diagnosis of the etiology of "hypoxic symptoms" is most difficult, even with the assistance of laboratory tests, which time may not always permit This differential diagnostic problem, however, should not deter one from performing a tracheotomy if the procedure appears to be indicated The coexistence of extensive spread of the virus in the medulla, altered electrolyte metabolism, and impaired acid-base equilibrium with primary and secondary hypoxia accounts for a large proportion of the deaths occurring in tracheotomized (as well as non-tracheotomized) bulbar and bulbospinal poliomyelitis patients

It is considered significant that no complications attributable to tracheotomy were encountered in any of the patients in this series; furthermore, evaluation of the records (including autopsy reports) of patients expiring after tracheotomy in no case indicated that tracheotomy was a factor contributing to the patient's demise Stimson[14] states that the mortality following tracheotomy in poliomyelitis is high; it is conceded that Stimson is correct in this contention *The reason for the high death rate in tracheotomized poliomyelitis patients is that this operation is usually performed on patients afflicted with the severest forms of this disease, and in whom the anticipated mortality is very high* It is believed that the mortality scores for tracheotomized poliomyelitis patients would, in all series, be significantly higher if these patients had not been afforded the benefits of tracheotomy

The task of evaluating therapeutic procedures in poliomyelitis is most difficult Since this disease exhibits marked annual and geographic variations in incidence and severity, controlled studies are not feasible As is illustrated in Fig 1, there is no constant relationship in our series of cases between the incidence of bulbar poliomyelitis cases, their mortality, and the number of tracheotomies performed This observation serves to point out the fallacy of attaching too much significance to reports of the results of tracheotomy in poliomyelitis which include but one year, or even a few years, of experience

SUMMARY

A comparison of nine years of experience at Children's Hospital with 345 cases of bulbar poliomyelitis, with similar experience reported by four other groups demonstrated that

1 Children's Hospital occupied a median position in regard to the percentage of such cases in which tracheotomy was performed

2 The mortality experience at Children's Hospital in both tracheotomized and in non-tracheotomized bulbar poliomyelitis cases is the lowest of that of all groups specifying these statistics

No definite conclusions are drawn from the case data included in this report All that may be said is that the experience of the staff of Children's Hospital did not differ significantly from the experience reported by others working with this disease

CONCLUSIONS

1 The indications for tracheotomy in bulbar and in bulbospinal poliomyelitis are ill-defined Therapy based upon the standard indications may often be inappropriate Each case must receive consideration as an individual problem

2 Tracheotomy is most beneficial when done early, *i e* before the occurrence of pulmonary complications and hypoxic central nervous system damage, both of which the operation is intended to prevent

3 General anesthesia, in our experience, is a safe and satisfactory technique for use in bulbar poliomyelitis It permits removal of the respirator patient from the respirator, and thus avoids surgical complications due to inadequate exposure

4 Bronchoscopy is a valuable adjunct in the management of bulbar and bulbospinal poliomyelitis, and may be employed for the prevention as well as the treatment of, pulmonary complications

5 The necessity for meticulous evaluation of the bulbar poliomyelitis patient by the team of consultants, both initially, and at each stage of the disease, cannot be overemphasized

6 The use of endotracheal intubation, both in lieu of emergency tracheotomy and as a means of providing a temporary airway for very ill patients, is recommended

7 Whenever in the management of bulbar poliomyelitis patients the need for tracheotomy cannot be ruled out, the operation should be performed

ments have given support to the hypothesis that elevated temperatures and humidities, and contamination with gram-negative bacilli, play an important role in production of some diseases of the external auditory canal. Much has been written regarding the role of infection in the pathogenesis of diseases of the external ear, and recently this subject was thoroughly reviewed.[1]

During the Second World War numerous cases of external otitis occurred among troops stationed in tropical and subtropical latitudes, and it was thought that elevated temperatures and humidities were factors in the development of the dermatoses.[2-8]

Horne[9,10] showed a relationship between the incidence of such diseases as miliaria and the minimum dry bulb temperature and humidity in India. Senturia[11] and Bianca[12] correlated high temperatures and humidities with the incidence of external otitis in certain regions of the United States. On the basis of clinical laboratory observations, the former postulated that prolonged exposure to these environments permitted the absorption of moisture by the stratum corneum, interruption of normal keratinization, plugging of the apopilosebaceous units and, therefore, interference with the delivery of the antimicrobial substances to the surface of the skin of the ear canal.[13]

There are also other indications that the absorption of moisture by the stratum corneum in a hot, humid environment may be related in some manner to the high incidence of external otitis. Mali[14] noted that the permeability of the skin rose with an elevation of environmental relative humidity. Buettner[15] was of the opinion that water and water vapor pass into nonsweating skin in proportion to the surrounding air vapor pressure. Mole[16] and Blank[17,18] demonstrated that the stratum corneum will take up moisture from a high humidity environment. Blank[17] clearly showed that cornified epithelium absorbs increasing amounts of moisture as the relative humidity rises.

Gaul and Underwood[19] suggested that a reduced amount of moisture in the air will influence the pliability, softness and

STUDIES OF FACTORS CONSIDERED RESPONSIBLE FOR DISEASES OF THE EXTERNAL EAR [*][†]

I Survival of Exogenous Bacteria in the External Auditory Canal Under Varied Conditions

BEN H SENTURIA, M D ,
and
CHARLES D CARR, M T ,
St Louis, Mo

INTRODUCTION

The factors suspected of contributing to diseases of the external auditory canal are numerous Some investigators believe that prolonged exposure to high temperatures and high relative humidities is of prime importance in the production of external otitis On the other hand, it has been proposed that low relative humidities and low temperatures, leading to desiccation of the skin, constitute a means by which the natural defense mechanism of the skin is overcome Others are of the opinion that removal of surface lipids and/or trauma break the natural barrier against infection and may, at the same time, provide the means by which exogenous microorganisms are implanted on the surface of the skin

In this study, attention has been directed towards some of these factors, *viz* , temperature, humidity, trauma and the removal of the surface lipids, as they influence the survival of exogenous organisms in the external auditory canal of the cat

LITERATURE REVIEW

Reports of external otitis occurring in hot, humid environ-

organisms or fungi onto the untraumatized skin but demonstrated extensive morphologic changes following contamination and the application of various irritating acids. Salvin[30] introduced a suspension of *Pseudomonas aeruginosa* after excoriating the ears of rabbits, and produced vesicles and papules. Fluid from the vesicles was removed, and "in all cases, pure cultures of the isolate originally inoculated into the ears were obtained." Haley[31] showed that trauma to the skin of the ear canal was a necessary factor in the experimental production of mycotic infections in the rabbit. More recently, Senturia and Liebmann,[32] using cats, demonstrated that contamination or trauma alone did not produce external otitis, but after trauma and contamination with pseudomonas organisms, morphologic and pathologic changes were consistently produced.

Perry and Nichols[33] "liberally seeded" *Pseudomonas aeruginosa* into the untraumatized external auditory canals of human volunteers. One week later the organism could not be recovered, and no clinical evidence of external otitis could be found. Senturia[1] described eight healthy ears with normal bacterial flora in which acute diffuse external otitis developed seven to 17 days after irrigation for removal of ear wax. Positive cultures for *Pseudomonas aeruginosa* were obtained in all cases.

The absence of lipids on the surface of the skin is believed to be a factor in the occurrence of diseases of the external ear.[1] The bactericidal and fungistatic action of the skin lipids may be an important factor in the inhibition of microbic growth as suggested by Ricketts et al,[34] Burtenshaw[35] and Peck et al.[36]

It has been postulated that high environmental temperature and relative humidity decrease the viscosity of the sebum layer, causing the lipids to spread thinly over a much greater surface area and preventing the formation of an adequate protective coating.[37-39] Gessert et al[40] were unable to demonstrate any decrease in the lipid covering of the cat and rabbit ear canals after the animals had been exposed to high temperatures and humidities (see Part II).

smoothness of the skin Blank[20] proposed that a loss in the flexibility and fissuring of the stratum corneum occur when there is a reduction in the moisture content of the skin under conditions of low relative humidity

Swimming under water and diving can bring about the production of skin maceration and secondary infection of the external ear canal Failure to remove all the water present in the meatus after swimming was considered the cause of external otitis by Gordon[21] Punt[22] noted that most of the cases of ear diseases occurred not only during hot, humid weather but also after patients had been swimming

On the other hand, numerous patients deny any history of swimming prior to symptoms of external ear inflammations[1] In a series of experiments, Collins[23] produced maceration and desquamation but no secondary infection after filling the osseous portion of the ear canal with chlorinated swimming pool water or sea water Collins concluded that this factor alone was not enough to cause external otitis Senturia, however, reported the development of acute external otitis following irrigation of the ear canal with hypertonic saline for the routine removal of ear wax in 13 normal ears[1]

A factor often implicated in the production of external otitis is trauma produced by the insertion of foreign objects into the ear canal[4,24,25] In a study by Syverton et al,[26] it was recorded that 50 per cent of the patients habitually picked at the ear canal Infection associated with the traumatic removal of foreign objects from the meatus has been described frequently[1,27]

In observing the effects of trauma and increased humidity on the skin of the meatus, Shelley and Perry[28] obstructed the external ears of adult males by inserting ear plugs and/or applying small strips of adhesive tape to the canal wall One-half of the subjects showed no changes, while the other half showed a "soggy maceration" of the skin of the canal, which the investigators believed resembled "hot weather ear"

Senturia, experimenting with mice and rabbits at the School of Aviation Medicine,[29] was unable to produce gross lesions of the ear canal by the introduction of pseudomonas genous and exogenous skin bacteria, Pillsbury and Rebell[49] found that various bacteria applied to normal and pathologic skin were markedly decreased after desiccation Cornbleet and Montgomery,[50] using *Staphylococcus aureus* on various parts of the body, found that moist areas were poor in self-sterilization, and that this power was restored when the skin area was exposed to the air and allowed to dry

Colebrook[51] showed that approximately 29 per cent of *hemolytic Streptococci* placed on the skin remained viable for one hour and 4 per cent for two hours after drying *E coli*, Proteus and Klebsiella appeared to be sensitive to skin-sterilization Burtenshaw[52] performed similar observations to Colebrook's[51] using streptococci on various skin areas, and suggested that slow self-disinfection occurred after the desiccation phenomenon was over Colebrook and Maxted[53] pointed out that *Streptococcus pyogenes*, not normally present on the skin of the hands, would spontaneously disappear when artificially implanted on it They stated that the Coli, Proteus and Friedlander bacilli would also disappear in the same manner

Price[54] noted that implanted *B subtilis* could not be found on the hands and arms after three hours, while exogenous staphylococcus, *B coli* and *Pseudomonas aeruginosa* persisted on the hands for many weeks despite scrubbing and application of germicides He was of the opinion that certain exogenous microorganisms seemed to be able to adapt to the new environment Prolonged exposure of the skin to these contaminants could result in their becoming endogenous organisms, and once this transition had occurred the skin could not easily be disinfected

Rebell et al[55] reported a series of experiments in which *E coli* staphylococcus and streptococcus (Group G) were the test organisms in determining the self-sterilizing ability of the skin Staphylococci were found to be more resistant to autogenous sterilization than *E coli* When the skin lipids were removed prior to contamination, it was noted that there was a marked decrease in the ability of the skin to sterilize itself It was further shown that in test subjects exposed to high temperatures and humidities for a period of eight hours after inoculation of the skin with *E coli* the contaminant was

It is generally accepted that contamination with Gram-negative bacilli plays an important role in the production of diseases of the external ear Schiemann and Landau[41] showed that a bacterial suspension, especially Gram-negative bacilli, placed on the normal skin of the hand were rapidly destroyed, and they believed that this destruction was due to some mechanical or chemical action Arnold et al [42] stated that *E coli* and *S typhosa* would remain viable on dirty or fatty skin for short periods Singer and Arnold[43] showed that the skin, after being washed with soap and warm water, was able to destroy from 90 to 95 per cent of the *B prodigiosus*,* *B pyocyaneus*, *S typhosus*, *S paratyphi*, *S enteritidis*, *E coli*, *S aureus* and *S albus* within 10 minutes after being applied to the skin When these same microorganisms were applied to dirty or fatty skin they disappeared more slowly

Montgomery[44] studied the destruction of *B prodigiosus* on fingers which were submerged in various dilutions of bacteria and air-dried for 15 minutes It was noted that the higher the dilution, the greater the percentage of bacteria destroyed In the undiluted suspension only 25 per cent of the bacteria were destroyed, while 90 per cent were eliminated in the 1 200 dilution In similar experiments performed by Karns and Arnold,[45] using a 1 50 saline dilution of *B prodigiosus*, 91 per cent of the bacteria were found to be killed in 60 minutes These authors believe that despite considerable variations in results, the skin showed a 100 per cent disinfecting power for these bacteria

Norton and Novy[46] and Bryan and Mallmann[47] disagreed with the findings of Arnold and his associates,[41] and attributed the reduction of bacterial counts to desiccation rather than any specific antibacterial action Arnold and Bart[48] presented data to show that there was no decrease in the rate of disappearance of organisms kept on moist skin, and no increased sterilizing ability of the skin after scrubbing with soap and water and cleansing with alcohol and ether They reiterated their belief that factors other than desiccation played an important role in the disappearance of the organisms

In a study of the factors influencing the growth of endobacteria *Pseudomonas aeruginosa,* hemolytic *Micrococcus aureus* and *Beta-type Streptococcus*

---

*Serratia marcesens

Biochemical reactions for conclusive identification of the Gram-negative bacilli were performed according to the procedures suggested by Edwards and Ewing[56] Coagulase and mannite fermentation tests were made on all strains of micrococci used as contaminants Only those micrococci which gave a strongly positive reaction with these tests were utilized

In those experiments in which dilutions were prepared, the organism was grown in broth, then serial dilutions were made to the required suspensions After incubations for one hour at 37° C, 0 5 ml of broth suspension was instilled into the ear canals A light cotton packing was inserted into the orifice of the canal to prevent periauricular contamination Plate counts, performed simultaneously on the diluted suspensions, gave an indication of the number of organisms present *

Removal of the surface lipid film from the skin of the cartilaginous ear canal was accomplished by using two ether-saturated cotton swabs Trauma was produced by gently stroking the skin of the ear canal with a ringed metal ear curette until erythema developed Trauma sufficient to cause bleeding was avoided

Morphological changes in the skin lining the external ear canals consisted of various degrees of erythema (R), exudate (X), crusting (C), edema (E) and dryness (D) The degree of change was noted as from 4-plus (indicating severe involvement) to plus-minus when only slight changes were found

When anesthesia was considered desirable, pentobarbitol sodium (approx 12 mg per pound of body weight) was injected intrathoracically in cats The majority of animals were completely recovered within four to five hours

The temperature in the hot room was controlled automatically† and the humidity sustained within the planned range

---

*10^{6} = 1040 colonies ml

†Two Chromolon electric heaters thermostatically controlled by Mercold Switch

recovered from a majority of subjects one to two weeks later These observations concurred with an earlier experiment of this same study, in which it was demonstrated that *E coli,* and staphylococcus, kept moist by spraying, showed a prolongation in survival time In a later report, Pillsbury and Rebell[49] found *A aerogenes, Ps aeruginosa, Pr vulgaris,* and *E coli* to be somewhat more resistant to fatty acids of sebum than *M epidermidis, albus, candidus, flavus* and coagulase-positive micrococci The *Corynebacteria (xerose* and *tenuis)* were also slightly sensitive to some fatty acids

METHODS AND TECHNIQUES

The skin lining the external auditory canal of the cat has been shown to have skin appendages similar to those of the human (*viz ,* apocrine and sebaceous glands) and, therefore, this animal was chosen for use in this study Only animals which had been through a quarantine period and showed no signs of either systemic or local disease were selected The animals were housed in separate cages and fed a balanced diet

Cultures for bacteria and fungi of the external auditory canal were routinely taken on all animals before and after procedures were performed The swabs were inoculated onto MacConkey, Sabouraud's and blood agar plates * In the later series of experiments, swabs of the external ear canals were placed immediately into Tryptose broth, incubated for one hour at 37° C , and then 0 1 ml of the broth was inoculated to solid culture media The material was spread over the surface, with an "L" shaped wire needle in order to obtain isolated colony growth The number of bacterial colonies was recorded as follows 0 = #, 1-25 = ±, 26-50 = +, 51-75 = 2+, 76-100 = 3+, >100 = 4+

The microorganisms used to contaminate the external auditory canals of the experimental animals were obtained from patients suffering from acute diffuse external otitis, chronic otitis media or mastoiditis These included the following in very small numbers The Pseudomonas group was not found in the normal human or cat meatus

---

*Citrated whole human blood and defibrinated rabbit blood were used in the preparation of blood agar plates

Experiment B

This experiment was designed to determine the effect of high temperatures and high relative humidities on the bacterial flora and morphology of the skin of the normal external auditory canal of the cat

Two groups of cats were selected one group of eight cats (16 ears) were placed for a period of four days in a room in which the average temperature was 86° F and the average relative humidity 95 per cent Another group, consisting of 20 animals (28 ears)* were exposed to the approximate temperatures and humidities of the first group for a period ranging from four to 17 days

TABLE II —EXPERIMENT B

Effect of High Temperatures and Humidities upon the Bacterial Flora and Morphology of the Cat External Auditory Canal

Av T * = 86° F Av R H † = 95%

8	16	4 Days	Unchanged	Unchanged‡
20	28	4 17 Days	Unchanged	Unchanged

*T = Temperature
†R H. = Relative Humidity
‡Some ears may show an increase in the amount of cerumen

In neither group was there any noteworthy change in the bacterial flora, or in the morphologic characteristics of the skin lining of the ear canal (see Table II)

Experiment C

Because of the conflicting information in the literature, this study was performed to determine how long a suspension of *Pseudomonas aeruginosa* introduced into the external ear canal of the cat, would persist and what morphologic skin changes would occur under conditions of high temperatures with humidifiers * The cool room temperature was maintained by use of a window air-conditioner† and the humidity lowered with a standard commercial type dehumidifier ‡

---

*In this group are included the untreated control ears of other experiments performed at these same temperatures and humidities

EXPERIMENTAL PROCEDURES AND FINDINGS

Experiment A

Since no data could be found in the literature concerning the microbiologic flora of the normal external auditory canal of the cat, a limited study of the bacterial and mycologic flora was performed This provided some basis for comparison with the bacterial flora of the human ear and a control on the changes occurring after contamination with exogenous bacteria Cultures of the external auditory canals of 48 cats (96 ears) were taken after the animals had been maintained at ambient temperatures and humidities in the animal quarters

TABLE I—EXPERIMENT A

Bacteriologic Flora of the Normal Cat and Human External Auditory Canals

Microorganism	Cat (96 ears)	Human[11] (66 ears)
Pseudomonas group	0 0%*	0 0%*
Proteus group	1 0%	0 0%
Coli Aerogenes group	5 0%	6 1%
Micrococcus albus	79 2%	10 6%
Micrococcus albus hemolytic	65 6%	80 3%
Micrococcus aureus	5 2%	10 6%

R = Erythema, C = Crusting X = Exudate E = Edema. N = Normal D = Dry * = No growth of Pseudomonas and high relative humidities (Av T 81° F , Av R H 92 per cent)

Five-tenths ml of an undiluted 24-hour broth suspension of Pseudomonas was instilled into the external ear canal The animals were examined and cultures of the ear canals taken at two or four-day intervals thereafter (with one exception) for 16 days

It may be seen in Table III that in all ears the Pseudomonas was still cultured on the tenth or twelfth day after contamination In four of the 11 ears the bacteria could be recovered on the fifteenth or sixteenth day

While not consistent in degree, there were some morphologic changes recorded at varying intervals in all ears Marked changes occurred in the skin lining the ear canals in four of the 11 ears Six of the ears had a dry appearance, erythema was noted in six, crusting was present intermittently in eight, exudate in three and severe edema in one At the conclusion of the experiment, six of the 11 ears were normal in appearance

Experiment D

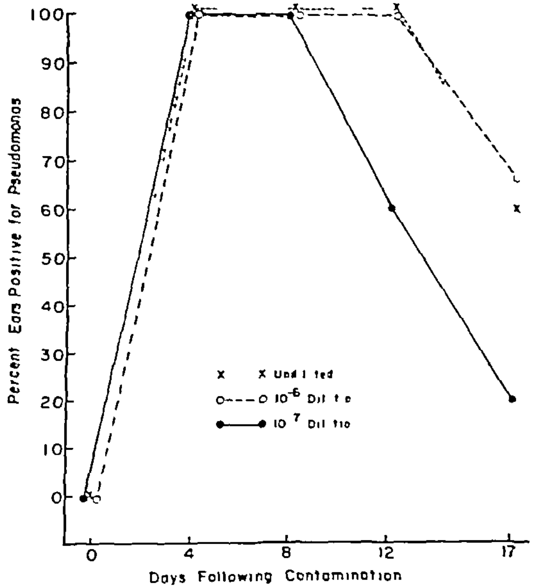
It has been demonstrated that an undiluted inoculum of Pseudomonas would survive for a period of weeks in the normal, untreated ear of the cat kept in a hot, moist environment It was considered desirable to determine whether diluted suspension of the organism would persist under similar conditions

Five-tenths ml of a 10^{-6} broth dilution of a 24-hour suspension of *Ps aeruginosa* was instilled into one ear of each of three cats, and 0 5 ml of a 10^{-7} dilution of the same organism was used to contaminate one ear of another group of five cats The contra-lateral ears served as controls The animals were housed in quarters in which the average temperature was 86° F , and the average relative humidity was close to 100 per cent Cultures were obtained at intervals for 17 days

It was noted in the first group (10^{-6} dilution) that there was a gradual diminution in the number of colonies grown, although the organisms persisted in all ears through the

One ear of each of three cats was contaminated with 0.5 ml of a 24-hour broth suspension of hemolytic *M aureus* and two animals with *Beta-type Streptococci* The contra-lateral ears of three of the animals were contaminated with 0.5 ml of a 10^{-6} dilution of *Pseudomonas aeruginosa,* and the remaining ears served as untreated controls for the experiment The animals were placed in an environment of high temperatures and high relative humidities (Av T 88° F , Av R H 96 per cent), and cultures were taken at intervals

Graph I
Experiment D
Comparison of Percent of Cat Ears Remaining Positive
After Contamination with Ps aeruginosa under Conditions
of High Temperatures and Humidities



In all three animals contaminated with *M aureus* there was a heavy growth on the first and second day There followed a rapid decrease in the number of organisms by the fourth day with all ears being free of the Micrococcus on the sixth

12th day and were present in two of the three contaminated ears on the 17th day.*

In all the contaminated ears of the second group (10^{-7} dilution), cultures remained positive on the 8th day while the organism was recovered on the 12th day in only three of the five ears. The Pseudomonas persisted in only one of the five ears on the 17th day. All control ears remained free of contamination (see Table IV).

TABLE IV.—EXPERIMENT D

*No growth of Ps. aeruginosa.

When these two sets of data are compared and contrasted with the findings after the use of undiluted cultures, it is seen that the percentage of contaminated ears remain the same through the 8th day. The ears which received the more dilute suspension of bacteria appear to return to normal a little more rapidly than do those in which undiluted Pseudomonas was instilled (see Graph 1).

Experiment E

The purpose of this experiment was to determine the length of survival of undiluted cultures of *Micrococcus aureus* and *Beta-type Streptococci* in the healthy meatuses of the cat under conditions of high temperatures and humidities and contrast this with the known survival time of the Pseudomonas organism.

---

*In one animal cross-contamination occurred in the control ear.

growth of the Pseudomonas was obtained on the first and second day in the ears in which it had been instilled (see Table VII)

Experiment H

In this experiment it was considered desirable to determine the effects of low temperatures (Av 61° F) and low relative humidities (Av 51 per cent) on the morphology and bacterial flora of the cat meatus Two cats (three ears) were observed for a period of seven to 15 days, while six cats (six ears) in a second group[*] were observed for 15 days

Experiment J

Undiluted suspensions of *Pseudomonas aeruginosa* have been shown to persist and morphologic changes have occurred in the external auditory canal of the cat for long periods under conditions of high temperatures and humidities This experiment was designed to determine whether *Ps aeruginosa* would similarly persist and morphologic changes occur in the cat meatus in a cooler and drier environment

The external auditory canals of five cats (five ears) were contaminated with 0 5 ml of an undiluted 24-hour broth suspension of *Ps aeruginosa* The animals were then placed in an environment of lowered temperatures and humidities (Av T 56° F , Av R H 50 per cent) Cultures of all ears were taken at various intervals for 17 days

In all of the contaminated ears, the organisms were recovered in large numbers through the eighth day, but a rapid reduction occurred thereafter, so that only two ears showed any growth on the seventeenth day Minimal skin changes were observed on the eighth day with one exception, and most of the changes had subsided by the fourteenth day (see Table IX)

Experiment K

It has been shown that morphologic changes are less after Pseudomonas contamination in a lowered environmental temperature and humidity, but that there is little effect upon the persisting exogenous bacterial flora To observe the changes which occur to the skin of the cat meatus after lipid removal, trauma and the instillation of *Pseudomonas aeruginosa* under cool, dry conditions the following experiment was conducted

Three cats (six ears) were contaminated with 0 5 ml of an undiluted 24-hour broth suspension of *Ps aeruginosa* after trauma and removal of the surface lipids The animals were placed in a cool, dry environment (Av T 58° F , Av R H 51 per cent) for a period of 15 days Cultures of the secretions of the ear canal and examinations of the skin lining the canals were made at two, three or four-day intervals

In all of the ears, the skin of the ear canal showed varying degrees of dryness, crusting, erythema and exudate on the

DISCUSSION

The inadequacy of the techniques for obtaining precise serial estimates of the number and variety of the bacteria implanted into the animal external auditory canal is recognized Preliminary studies were performed in an effort to find more satisfactory methods, but the peculiar and highly variable anatomical configuration of the meatus made these more accurate procedures clinically and experimentally impractical In an effort to reduce possible errors in interpretation, experiments were set up in duplicate and, although not always included in the data, controls were introduced in all the studies

It was found necessary to perform a survey of the bacterial flora in the normal external auditory canal of the cat in order to determine whether the organisms which are cultured from acutely infected human ear canals were present in the endogenous flora of these animals Upon comparison of the flora of the human and animal ear canals, there is noted a striking similarity Conspicuously absent is the pseudomonas group of bacteria in the flora of both humans and animals This observation is of particular interest since *Pseudomonas aeruginosa* has been shown to be the exogenous organism most frequently cultured from acute diffuse external otitis

Because numerous investigators have demonstrated that normal intact human skin in other parts of the body rapidly eliminates implanted exogenous bacteria in a matter of minutes or hours, it was surmised that this same phenomenon would occur in the meatus of the experimental animal On the contrary, *Ps aeruginosa* introduced into the external auditory canal of the cat exposed to a hot, humid environment persisted for as long as 18 days This finding substantiates our previous observations.[32] The results of these experiments duplicate the experience of the otologists in tropical and subtropical regions, who report the persistence for indefinite periods of pseudomonas organisms in the meatus of patients with "cured" diffuse external otitis. They are not in agreement with the observations of Shelley and Perry,[28] who were unable to recover *Ps. aeruginosa* which had been introduced one week previously into the ear canals of human subjects.

It was anticipated that *Ps. aeruginosa* in dilute suspensions would survive for shorter periods when introduced into the healthy cat meatus. The diluted suspensions of *Ps. aeruginosa* appeared to increase to a maximum just as rapidly as the undiluted cultures for the first six to eight days, while the undiluted cultures seem to reduce in numbers more rapidly thereafter. Diluting the cultures did not appear to exert an appreciable influence upon the rapidity with which the bacteria were completely eliminated. The results appear to confirm the theory that bacterial infection of the ear canal is not necessarily caused by overwhelming contamination, but rather that only a few virulent organisms implanted on a fertile skin substrate will rapidly multiply in the ear canal and institute infection in a susceptible individual.

In addition to the persistence of the contaminating bacteria, gross morphologic changes (crusting, erythema, edema and exudate) occurred after the introduction of *Ps. aeruginosa*. The changes were not present in all the infected animals and they varied in severity, thus simulating the clinical findings in human external otitis. These observations conflict with previous studies[30, 31, 32] in which we, as well as other investigators, were unable to produce disease of the external ear or only minimal microscopic changes in the skin by the mere instillation of fungi or bacteria. This difference may be a consequence of uncontrolled factors, such as the virulence of the contaminating organism and individual susceptibility of the experimental animal.

Although no experiments were designed to test the virulence of pseudomonas cultures, it was noted that frequent subculturing of the stock strains resulted in attenuated organisms which failed to survive or produce morphologic changes in the cat ear, consequently, it was found necessary to discard some strains of *Ps aeruginosa* after a period of growth on artificial media

Individual differences in susceptibility of the experimental animals were also demonstrated throughout the experiments Some animals appeared to be highly sensitive to the infecting bacteria, with consequent prolonged survival of the organisms and severe morphologic changes Other animals used in these studies were apparently resistant regardless of environmental conditions or combinations of factors Further studies are desirable concerning virulence and susceptibility of both animals and humans to *Ps aeruginosa*

Our observations failed to substantiate the hypothesis that exposure of our experimental animals to hot, moist atmospheric conditions would make the skin of the ear more susceptible to infection with exogenous organisms [11] Gross morphologic changes or alterations in the endogenous bacterial flora of the uncontaminated external auditory canal did not occur during exposure of cats to markedly elevated or moderately lowered temperatures and humidities, however, when cats with infected ears were transferred from a hot, humid environment to a cool, low-humidity room, no startling reduction in the number of bacteria was noted, although some improvement of the skin morphology occurred [29]

High temperatures and high relative humidities were not found to be the sole factors responsible for the prolonged survival of implanted exogenous bacteria or the concomitant skin changes, since the organisms were shown to persist in some animals for long periods at low temperatures and humidities Some of the data, however, would indicate that at high temperatures and humidities the growth of the *Ps aeruginosa* was more luxuriant than when the animals were kept in a cool, dry environment

Various reports have shown that there is a distinct difference in the ability of healthy, intact skin to eliminate bacteria belonging to the Gram-positive and Gram-negative categories In our series of experiments, as in other skin areas, it was noted that streptococci failed to persist even for very short periods The suspension of coagulase-positive *M aureus* was not eliminated as rapidly as the streptococci, but much more rapidly and completely than any of the Gram-negative bacilli tested A warm, moist atmosphere did not appear to be conducive to the survival of the Gram-positive bacteria, nor did removal of the fatty covering or trauma contribute to persistence of the organism

In this study it was not possible to test a sufficiently large number of animals, or to control the many variables in such a manner that statistical evaluation of the data could be performed Should further investigations of the influence of temperature, humidity, trauma and lipid removal on the survival of exogenous organisms be undertaken, then the number of animals used should be increased or the number of variables reduced to make statistical studies possible

CONCLUSIONS

The endogenous bacterial flora of the healthy cat meatus is very similar to that of the normal human external auditory canal

Elevated or lowered temperatures and humidities do not alter the endogenous flora or produce any change in the morphology of the skin of the cat ear canal

Exogenous Gram-negative bacteria, particularly the *Ps aeruginosa,* will survive for prolonged periods in the external auditory canal of the cat at low or high temperatures and humidities The Gram-positive organisms, *i e , Beta-hemolytic Streptococcus* and *M aureus,* are eliminated after a relatively short period

Suspensions of *Ps aeruginosa* introduced into susceptible cat ear canals will produce morphologic skin changes at high temperatures and humidities

Some of the data suggest that, in a cool, low-humidity environment, there may be less luxuriant bacterial growth, a shorter survival time and fewer morphologic changes after instillation of Gram-negative bacilli

Trauma to the skin of the cat external auditory canal and removal of the surface lipids did not appear to alter the survival time of the exogenous organisms

The concentration of organisms instilled into the cat ear (within the range tested) is not an important factor in the length of survival of this organism or the severity of the morphologic changes produced

STUDIES OF FACTORS CONSIDERED RESPONSIBLE FOR DISEASES OF THE EXTERNAL AUDITORY CANAL[*]

II Evaluation of Temperature and Humidity as They Influence the Amount of Ether-Soluble Substances in the External Auditory Canal

ELIZABETH S BAUMANN, B A ,

St Louis, Mo

INTRODUCTION

It is generally accepted that the highest incidence of diffuse external otitis occurs in hot, humid climates, while there are comparatively few cases observed in cool, dry environments It has been suggested that an alteration of the lipid skin cover, caused by conditions of high temperature and high humidity, may play a role in the production of this disease[1]

Studies have been made of the effects of temperature and moisture on the lipid covering of the skin of various other parts of the body,[2-9] but there is a paucity of data pertaining to these effects on the lipids of the skin of the ear canal[10] Although determinations were previously made in this laboratory on the amounts of ether-soluble substances (ESS)[†] which are found in the external auditory canals of various groups of humans,[11] none of the data were obtained under controlled environmental conditions The present experiments, therefore, were designed to measure ESS in the external auditory

canals of animals, which could be maintained in environments of controlled temperature and humidity In this way, an evaluation could be made of the effects of temperature and humidity on the lipid film of the skin of the cartilaginous meatus

LITERATURE REVIEW

Some workers are convinced that the lipid film on the surface of the skin acts as an important barrier in preventing the extension of bacteria into or through the epidermis The lipid cover has been shown to have bactericidal and fungistatic properties[12-17] According to Rebell et al,[17] Gram-negative bacilli survived for much longer periods on skin from which the lipids were removed by thorough washing with organic solvents than on skin on which the lipid cover had been left intact Arnold and his co-workers[18] found that a coating of grease or dirt on the skin of hands allowed such bacilli to remain viable for long periods of time The findings of these two investigators are not necessarily contradictory since in one case the skin lipids are removed, and in the other case they are covered up so that they do not come in contact with the bacteria

The influence of environmental temperatures and skin moisture on the amount and distribution of lipids on the skin surface has been considered by many investigators[2-9] The theory has been advanced that at high temperatures and on moist skin the sebum may become fluid[6-9] and in this manner fail to provide a protective cover[3]

Mole[18] and Blank[19 20] have demonstrated that the stratum corneum will take up moisture from an environment having a high relative humidity Blank showed that cornified epithelium absorbed increasing amounts of moisture, particularly at relative humidities above 80 per cent It is conceivable, therefore, that when exposed to high humidities, the keratin in and around the orifice of the apo-pilosebaceous unit absorbs moisture, thereby swelling and causing a decreased flow of lipids to the skin surface[21-23]

METHODS AND TECHNIQUES

Animals. The cat and pig have been shown to have apocrine and sebaceous glands in the skin of the ear canal similar to those of the human.[26-28] The cat was chosen as the most suitable and available experimental animal. The difficulty of handling the cat, however, made it desirable to use in some of these experiments a more tractable animal, such as the rabbit, which has in the skin of its external ear canal numerous sebaceous but no apocrine glands. In two experiments cats and rabbits were used simultaneously, so that data from these two species could be compared.

Maintenance. Experimental animals were housed in individual metal cages, and all were offered a balanced diet.

Experimental Rooms. In the hot room the desired temperature was achieved by use of electric heaters controlled by thermostat,* which supplemented the centrally supplied steam heat. An automatically controlled humidifier† maintained humidities within the planned range. Conditions of low temperature and humidity were achieved in the cool room by use of a room air-conditioner‡ and a dehumidifier.§

Anesthesia. It was frequently necessary to anesthetize the cats. This was done by intrathoracic injection of pentobarbital sodium, approximately 12 mg. per pound of body weight. A few cats were anesthetized by intraperitoneal injection, but the intrathoracic route was found to be more satisfactory, in that the animals were subdued with less struggle and recovery was much faster, usually occurring within four to six hours. When no anesthetic was used, the cats were managed by wrapping them in a large square of heavy denim cloth, and the rabbits were restrained in a wooden box designed for that purpose.

Collection and Analysis of Specimens. Specimens for the determination of total ESS were obtained by wiping the cartilaginous meatus in a prescribed manner with two cotton swabs moistened with ether[11] The swabs were extracted with redistilled ether in a micro-Soxhlet apparatus and the amounts of ESS were determined by a colorimetric method adapted to micro-scale[29]

---

*Two Chromolon electric heaters thermostatically controlled by a Mercoid Switch.

†Walton Humidifier Model W.F.

‡General Electric Room Conditioner ¾-ton.

§Frigidaire portable dehumidifier.

Samples for the determination of the percentages of lipid and protein were collected and analyzed by methods previously described[30]

In all experiments a casual* specimen was taken from each ear to be studied For those experiments in which a zero-day† specimen was obtained, the order of the procedure was *a* Casual specimen taken, *b* ear canal and auricle cleansed with three cotton swabs moistened with ether, *c* zero-day specimen taken

EXPERIMENTAL PROCEDURES AND FINDINGS

Preliminary Experiments on Cats and Rabbits

Several pilot studies were conducted to examine the ear secretions of the animals without control of environmental temperature and humidity The normal (ambient) animal room temperatures and humidities were allowed to prevail

Experiment A

The percentage of protein and lipid in the cerumen of cats was investigated Casual specimens were collected from both ears of two cats and the ears were cleaned with ether-moistened swabs Fresh samples‡ were taken at two and 12 days after cleaning

As shown in Table I, the percentage of lipid in the first fresh samples (taken after cleaning) was higher than in the casual cerumen, while the percentage of protein was generally lower By the twelfth day the percentage composition of the cerumen of each cat ear tended to revert to the composition of the corresponding casual specimens In these characteristics, the findings in cats were similar to those for humans, as reported by Chiang et al.[31]

---

*Casual specimens are the samples obtained from the unprotected skin surfaces of the ear canal at the beginning of the period of observation without previous cleansing or treatment of the canal

†Zero-day refers to the initial day of any series of observations Specimens designated as zero day samples were collected immediately after cleansing the ear canal

‡A fresh sample is a specimen collected during the period of observation at any time after zero-day

Experiment B

The amounts of ESS obtained from the external auditory canals of cats and rabbits were compared. Casual and zero-day specimens were taken from one ear each of two cats and two rabbits. At intervals of four, eight and 15 days, specimens were obtained from the same ears.

The data in Table II indicate that one can expect the same order of magnitude in the amounts of ESS obtained from the ear canals of cats and rabbits. These amounts are generally larger than the amounts obtained from humans, as reported by Chiang et al.[11] As previously observed with humans, by the fifteenth day replacement totals (RT)* exceeded their respective casual amounts.[11]

TABLE I.—EXPERIMENT A

Percentages of Lipid and Protein in Cat Cerumen

		Casual Specimens		Day of Collection			
				2		12	
Cat	Ear	Lipid	Protein	L	P	L	P
2	R	46.9	22.9	54.8	14.9	41.3	15.1
2	L	47.5	30.6	56.2	15.8	46.8	19.9
3	R	32.1	32.7	53.0	20.6	32.4	24.3
3	L	36.3	41.8	44.3	38.1	28.4	39.1

Despite the histological differences of the skin of the cat and rabbit meatus, the findings here regarding average daily replacements (ADR)† and RT's are similar in these two species. The absence of apocrine glands in the skin of the rabbit did not appear to influence the amount of ESS recovered in these few ear canals.

Experiment C

Because the cleansing procedure used on zero-day might introduce an uncontrolled factor either by being traumatic to the skin of the ear canal or by influencing the delivery of lipids to the surface, this experiment was designed to determine whether or not the cleansing had any effect on the amounts of ESS subsequently obtained.

---

*Replacement total (RT) at any given time is the total amount of ESS that has been extracted from all the fresh specimens collected by that time from a single ear. This does not include zero-day amount.

†The average daily replacement (ADR) is a measure of the rate of lipid renewal on the skin surface during any interval between successive collections. It is calculated by dividing the amount of ESS in a fresh specimen by the number of days in the interval since the preceding collection.

In one ear of each of two rabbits a casual specimen was obtained, the canal was thoroughly cleansed, and a zero-day specimen was taken. In the contra-lateral ears casual specimens were taken, but no cleansing was performed and no zero-day specimens were obtained. At intervals of three seven and 14 days, specimens were taken from all ears (see Table III).

TABLE II.—EXPERIMENT B

Ether-soluble Substances in Cat and Rabbit Cerumen. A Comparison in Terms of Average Daily Replacements and Replacement Totals (Expressed in Milligrams)

Animal and Ear	Casual Amount	Zero-day Amount	Days After Cleaning 4		8		15	
			ADR*	RT†	ADR	RT	ADR	RT
Cat 90 L	15.3	1.3	1.4	5.4	1.3	10.5	1.0	17.8
Cat 91 R	10.8	1.2	1.3	5.0	1.0	8.9	0.9	15.1
Rabbit 59 R	11.8	0.4	1.7	6.8	2.3	15.9	1.6	27.1
Rabbit 60 L	10.2	1.2	1.4	5.7	3.0	12.1	2.4	29.0

*Average Daily Replacement
†Replacement Total (does not include zero day amount)

In the rabbit, thorough cleansing of the ear canal did not appear to influence the amounts of ESS which were obtained from the third day on. The technique for taking casual specimens evidently constituted a sufficient cleansing of the ear canal so that the additional cleansing had no effect.

Experiments on Cats and Rabbits Under Controlled Environmental Conditions

Experiment D

A comparison was made of the amount of ESS obtained from the ear canals of cats and rabbits kept under controlled environmental conditions.

Casual specimens were taken from both ears of two cats and two rabbits, the animals were kept in a cool, dry room for seven days, and then in a hot, humid room for seven days Specimens of ESS were taken on days 3, 5, 7 and 10, 12, 14 By measuring the amounts obtained on days 5, 7, 12, and 14,* it was possible to compare the data for two 2-day periods, under both environmental conditions (see Table IV)

Under the experimental conditions employed, the average amounts of ESS obtained from the ears of cats and of rabbits were somewhat greater when the animals were kept in the hot, humid room (12th and 14th days) than when they were in the cool, dehumidified room (5th and 7th days) †

TABLE III—EXPERIMENT C

Amounts of Ether soluble Substances (in Milligrams) Found in Rabbit Ear Canals, with or without a Cleansing Procedure

			Day of Collection			
Rabbit	Ear	Casual	Zero-day	3	7	14
65	R	6 0*	0 5	6 6	12 3	11 8
65	L	5 4		6 7	12 3	5 6
66	R	6 4		8 9	6 0	4 1
66	L	7 7*	2 3	8 5	4 2	4 3

*After casual specimen was taken ear was cleaned with 3 cotton swabs dipped in ether

As in Experiment B, no difference was observed between the average amount of ESS obtained from the ears of cats and rabbits when both groups were maintained in the same environmental conditions

Experiment E

In order to cancel any undetermined effects that order of exposure and the factor of time might have had on the data of Experiment D, it was decided to reverse the environments with half of the animals

Casual specimens were taken from one ear each of eight rabbits For a period of 11 days, half of the animals were kept in a hot, humid room and the other half in a cool, low-humidity room. Then the animals were interchanged for a similar period of time. Specimens for total ESS were taken on days 7, 9, 11 and 18, 20, 22. By determining the amounts of ESS obtained on days 9 and 11 in one environment, and on *days 20 and 22 in the other,* data were obtained for two 2-day* periods of accumulated secretions in both environments (see Table V).

---

*Specimens from days 3 and 10 were not determined as they represented 3-day intervals

†The significance of these differences was not evaluated statistically because of the limited number of animals

TABLE IV—EXPERIMENT D

The Amounts of Ether soluble Substances (in Milligrams) Obtained from the Ear Canals of Cats and Rabbits Kept in Environments of Controlled Temperature and Humidity*

Animal	Ear	Day of Collection 5 Cool dry room†	 7	 12 Hot, humid room‡	 14
Cat 1	R	6.7		5.8	6.1
Cat 1	L	5.0	5.7	5.6	7.4
Cat 2	R	5.7	7.1	6.6	9.1
Cat 2	L	8.0	6.5	8.0	11.8
Mean ESS		6.39		7.55	
Rabbit 3	R	6.3	6.1	9.2	7.1
Rabbit 3	L	4.8	5.2	7.6	6.6
Rabbit 4	R	4.4	4.4	6.4	5.3
Rabbit 4	L	5.1	7.3	7.5	5.7
Mean ESS		5.45		6.93	

*Dry and wet bulb temperatures were measured daily. Relative humidity was read from Relative Humidity Tables printed by Taylor Instrument Companies, Rochester, N. Y.

†Temperature Av. 71° F (range 69-74° F) Relative Humidity Av. 70% (range 64-74%)

‡Temperature Av. 85° F (range 84-88° F) Relative Humidity Av. 95% (range 93-98%)

A comparison was made between the data obtained from each rabbit ear during the time that the animal was in the hot, humid environment and that obtained from the same ear when the rabbit was in the cool, low-humidity room. When the data were compared, no significant difference was found between the amounts of ESS obtained in the two environments, under the experimental conditions employed.† The lack of a real difference in the amounts obtained was also reflected in the closeness of the means of 2-day accumulations in the two environments, *i.e.*, 6.29 and 6.53 (see Table V).

---

*Specimens on days 7 and 18 were not considered because they represented amounts accumulated for 7-day periods.

†Probability was much greater than 0.1 by the Wilcoxon signed-rank test for matched samples.[22]

Experiment F

Since it seemed possible that the effect of a particular environment might not be immediately apparent, it was considered desirable to expose the animals to each environment for a longer period of time than had been done in Experiment E

Cats were used in this study, whereas rabbits had been used in Experiment E Casual specimens were taken from both

TABLE V—EXPERIMENT E

ears of each of six cats, which were divided into two equal groups, one being placed in a hot, humid room and the other in a cool, low-humidity room Fresh specimens were taken at the end of each week for three weeks, then the two groups of cats were interchanged, and specimens were taken weekly for another three weeks The data which were obtained on the amounts of ESS in all fresh specimens are shown in Table VI

The data were examined in two ways In one test, the data from only one ear of each of the six animals were considered and in the other the data from both ears were added and used together. As in Experiment E the hot, humid room data for each animal were compared with the cool, dry room data for the same animal. The overall means of the amounts of ESS obtained per ear in the period of a week were 14.5 mg in the cool dry room and 13.1 mg in the hot, humid room. In both methods of examining the data, no significant difference was found between the amounts of ESS obtained in the two environments under the experimental conditions employed.*

Experiment F

Since it seemed possible that the effect of a particular environment might not be immediately apparent, it was considered desirable to expose the animals to each environment for a longer period of time than had been done in Experiment E

Cats were used in this study, whereas rabbits had been used in Experiment E Casual specimens were taken from both ears of each of six cats, which were divided into two equal groups, one being placed in a hot, humid room and the other in a cool, low-humidity room Fresh specimens were taken at the end of each week for three weeks, then the two groups of cats were interchanged, and specimens were taken weekly for another three weeks The data which were obtained on the amounts of ESS in all fresh specimens are shown in Table VI

The data were examined in two ways In one test, the data coating which is present on the skin surface in the external ear canals of the rabbit and cat

It is of interest that the average amounts of ESS that were obtained from the external ear canals of cats and rabbits which were kept in the same environment did not appear to differ, even though there are notable histological differences in the skin of the ear canals of the two species The presence of apocrine glands in the skin of the cat meatus and their absence in the rabbit had no measurable effect on the quantities of ESS found

CONCLUSION

The quantity of lipid material (measured as ESS) which is found in the ear canal of the cat or rabbit is not significantly different whether the animal is kept in a hot, humid environment, or in a relatively cool, low-humidity room

ACKNOWLEDGMENTS

The authors express appreciation to Charles D Carr for technical assistance and advice and to Dorothy L Baldwin and Nancy Hellman for secretarial and editorial aid

DISCUSSION

A completely satisfactory method for collecting specimens which contain all of the ether-soluble matter that is present in an ear canal at a given time has not yet been devised In view of the variation in size and anatomical configuration of the external auditory canal that prevails from one animal to another, there is, very likely, some variation in the degree of completeness with which the total ESS present in a meatus are collected with our ether-moistened swab technique

Tests have been made to determine the *feasibility of* collecting the lipid matter by instilling several successive, measured portions of organic solvent, *i e*, ether and ethanol, into the ear canal, recovering the solvent solution with a syringe and a small piece of flexible tubing, then measuring the lipid in these solutions It was found, however, that in the cat, ether used in this manner acted as a strong irritant, whereas ethanol was unsatisfactory as a solvent Although the swab method of collecting specimens of ESS was far from being ideal, it seemed to be the more satisfactory for the purposes of these studies

The amount of lipid (ESS) which was found in the meatus in both cats and rabbits revealed neither an increase nor decrease when the animals were kept in a hot, humid environment, as compared with a cool, low-humidity environment The protected position of the external auditory canal may afford a degree of insulation sufficient to prevent any large fluctuations in air temperature in the meatus, and, therefore, also may prevent any change in the physical characteristics of the skin surface film It is also conceivable that even though the viscosity of the skin surface lipids may be lowered by an increased temperature, the anatomical configuration of the cartilaginous meatus would prevent the lipids from flowing to the perimeatal regions

It is still possible that environmental temperature and humidity do have an important role in determining susceptibility of the skin of the auditory canal to infection It appears, however, from our data, that these factors do not exert their influence through a regulation of the amount of lipid

THE GOULD AWARD

The Gould Award is presented annually for outstanding research in laryngology to encourage and reward fundamental investigations in this field

The International Committee for the Gould Award announces the selection of the recipient for the year 1958 Prof FumioNakamura, M D, Kyoto Prefectural Medical College, Kyoto, Japan, for his electrophysiologic studies of laryngeal function

The International Committee for the Gould Award for 1959 will consist of Sir Victor Negus, 149 Harley St, London, W 1, Prof Cotoji Satta, No 111 Morikawa-cho, Bunkyo-ku, Tokyo, and Hans von Leden, M D, Medical Director, The William and Harriet Gould Foundation, 30 North Michigan Avenue, Chicago 2, Illinois

The amount of the Award has been increased to $300 00

At home the mother was required to suction the nose every four hours For the next four months the infant would feed, breathe and sleep well for one week at a time As a result the patient was seen regularly at the office for thorough suctioning and dilatation of the choanal openings At eight months of age a revision was done by the intranasal route using a small biting forcep gouge and chisel The edges of the opening were removed by this means resulting in a good sized passage Following this the child has been breathing solely through the nose and suctioning was necessary only once daily in the morning Feeding proceeded normally and the infant slept through the night with quiet respirations

When last seen at the age of two years the child was completely normal in all habits feeding sleeping and breathing through the nose The breathing was quiet and the choanal openings were unchanged Examination of the ears pharynx sinuses and nasal cavity showed no abnormalities

A further revision may be done in the future, (the time will depend upon the progress of the child, whereby the remainder of the choanal bony plate will be removed) A transpalatine approach as advocated by Owens, etc, will probably be used The easier surgical approach employed in this case was thought advisable because of the age of the infant

ANNOUNCEMENT

The Annual Spring Meeting of the Alumni Association of the New York Eye and Ear Infirmary will take place April 20-23, 1959, at the Infirmary

Symposia will be offered on Headache, Allergy and Immunology in Otolaryngology, Diagnosis and Treatment of Laryngeal Conditions, Hearing Rehabilitation, and Rhinoplasty In addition, there will be a closed circuit television demonstration of Head and Neck Surgery

Additional information may be obtained by writing to Dr John R Finley, Secretary, Alumni Association, 218 Second Avenue, New York 3, N Y

CONGENITAL BILATERAL COMPLETE BONY CHOANAL ATRESIA

JACK A. RUBIN, M.D.,

Winnipeg, Manitoba

The following case of choanal atresia as an emergency in the newborn, is reported.

CASE REPORT

K.V., a white female, newborn, was noted to have respiratory distress after a spontaneous delivery. Birth weight 6 lbs., 14 ozs. The pre-natal course had been uneventful. Direct laryngoscopy and chest examination revealed no abnormalities. An attempt to pass a nasal catheter via both sides of the nose was unsuccessful. A diagnosis of congenital bilateral choanal atresia was made.

The infant was placed in an incubator and given oxygen. Repeated nasal suctioning was necessary to remove the thick mucoid discharge, which kept reappearing at the anterior nares. It was noted that the child's color was good, and the respiratory difficulty disappeared when the patient cried; however, while feeding or lying quietly in its crib, definitely labored breathing, blue spells and indrawing of the intercostal and supraclavicular spaces would occur. The breathing was "noisy" and labored at all times, except when crying. X-rays of the skull did not show air in the nasal cavities, and for some reason contrast media was not instilled into the nasal cavities.

The infant was treated with oxygen and repeated nasal suctioning for the first 48 hours. Feeding was poor, and the infant began to show signs of dehydration and progressive asphyxia.

Otolaryngological consultation at age two days confirmed the diagnosis of bilateral complete bony choanal atresia. Neither catheter nor metal probe could be passed through the thick bony partition, via the anterior nares. Considering the state of the infant an emergency procedure was done as follows: After unsuccessfully attempting to push a trocar through the partitions a small gouge and mallet was used to punch an opening through both bony choanal walls. The results immediately following this were dramatic. The child fell asleep with no respiratory distress for the first time, and breathing through the nose was possible.

Following this, feeding and sleeping were normal; however, because of noisy nasal breathing, both choanal openings were enlarged slightly intranasally five days later. A polyethylene tube was placed in the nose through the choanal opening; however, the tubing had to be removed within 24 hours, as it interfered with nasal breathing. Because of a very shallow nasopharynx, the inner opening of the tube was partially obstructed.

The infant was discharged from the hospital at two weeks of age.

Editor's Note: This manuscript received in The Laryngoscope Office and accepted for publication June 16, 1958.

controlled the convulsions but the patient immediately stopped breathing He was kept on controlled respirations for approximately one hour when spontaneous respirations returned During the prolonged period of respiratory paralysis the patient s pulse rate went up a little and on occasions became somewhat irregular His general condition however remained very good He was given 4 cc of Coramine intravenously after 30 minutes of apnea and this was repeated about 15 minutes later It appeared to have little effect One hour later he was able to answer questions but was still quite drowsy When seen later that day he was fully conscious and felt quite well He was discharged from the hospital next day and I hope to do a tonsillectomy with a general anesthetic soon

This man was a healthy farmer Neither he nor his family had any previous history of epilepsy He had a local anesthetic for a dental extraction two years ago with no reaction

SUMMARY

A case of convulsions after infiltrating the peri-tonsillar tissues with 25 cc of 1 00 per cent procaine with two drops of epinephrine, 1/1000, is reported Although the convulsions were controlled with Pentothal they returned when its effect began to wear off, approximately one-and-a-half hours later They were again controlled by Pentothal, and after a period of apnea of one hour's duration the patient made an uneventful recovery

PROCAINE CONVULSIONS

JOHN KEOHANE, M D ,

Stettler, Alta, Canada

Toxic reactions to local anesthetic drugs may be of a cardio-vascular system depressant, or a central nervous system stimulating type The latter may also be followed by the former more serious type of reaction

The entire subject of toxic reactions to local anesthetics, whether used by topical application or infiltration of tissues, has been very well reviewed in two recent publications[1,2] The following report is, however, of interest since it concerns a toxic reaction to procaine in a dose about one-quarter of the generally accepted maximum safe dose Procaine is also thought to be one of the safest local anesthetics

N D , a 26 year-old man, was admitted to the hospital on May 13, 1958 for a tonsillectomy under local anesthesia the following morning At 10 00 P M the evening before his operation, he was given Seconal, 1½ gr orally Next morning he had Seconal 1½ gr two hours preoperatively, followed by ¼ gr morphine and 1/200 gr atropine one hour preoperatively A few minutes after spraying his throat with a small amount of 2 per cent pontocaine solution, both peri tonsillar regions were infiltrated with a total of 25 cc of 1 00 per cent procaine with two drops of epinephrine, 1/1000 solution, added About two minutes after the last of the local anesthetic had been injected the patient became restless and excitable He was immediately put into a horizontal position and directions given to the operating room nurse to get a solution of Pentothal ready About 30 seconds later his face began to twitch and this was soon followed by a severe generalized convulsion

As soon as the Pentothal was available (approximately one minute after it was requested) the patient was given 10 cc of a 2 5 per cent solution intravenously (250 mg) Meanwhile oxygen was given from an anesthetic machine The convulsions were quickly controlled Pulse respiration blood pressure and color were soon within normal limits An intravenous drip of 5 per cent glucose in water was started, to have ready access to a vein After observing the patient for a little longer the oxygen was discontinued and he was transferred back to bed A solution of Pentothal in a syringe and the anesthetic machine was brought to the patient's bedside in case of further trouble

A little over an hour and a half later I was urgently called to see the patient. It took me approximately two minutes to get to his bedside He was having a severe convulsion, which had commenced two minutes previously (when he began to recover from the effects of the Pentothal) and showed no sign of abating A further 8 cc of Pentothal (2 5 per cent)

Editor s Note This manuscript received in The Laryngoscope Office and accepted for publication June 2 1958

concept of alteration of nasal pH to the alkaline side in nasal infection may be a defense mechanism and, therefore, the effect of the early stage of infection rather than the cause

DISCUSSION

Dr Aubrey G Rawlins brought out some of the relationships between the corticosteroids and the ground substance whose density is regulated by the pituitary adrenal axis The efficiency of this axis may be one determining factor in the invasiveness of certain organisms Dr Hopp has furnished good evidence that hyaluronidase-producing bacteria are often more invasive than non producers and this would be an important factor in many nose and throat infections The authors have shown how the spreading factor loosens the basement membrane under the epithelium resulting in easier invasion by organisms

Not much is known as to whether or not there is any spreading factor in the normal nose and throat mucosa however it must be assumed that its precursor is there since the existence of hyaluronidase and mucolytic enzymes in the connective cells has to be postulated if equilibrium of the ground substance is to be explained

Dr Hopp mentioned the anti spreading factor of which there are two types the antibody which is specific and the heparin like substance which is non specific and is high in the blood stream in many diseases of a serious nature

The authors have well emphasized the dual features of infection namely the virulence and characteristics of the infecting organism and the quality of the ground substance of the host.

Dr George Kelemen showed several electron microscopic slides of tonsil tissue which at high magnification (30 000) depict the elements in the collagenous material the fibrillar structures and the relationship of the epithelial cells to each other Since these are joined together by intercellular bridges it can be seen how the lymphocytes have to push their way through by breaking down these bridges

Electron microscopy can contribute much of our knowledge of tissue reaction to infection by bringing out the finer anatomic details of the various elements under varying conditions

Dr Hopp in closing stated in response to Dr Rawlins' query that in 1931 filtrates were taken from the normal nose as well as from individuals having a cold and it was demonstrated that there were spreading factors in the normal noses and interestingly enough there was an increase in the spreading factor in the patients with colds at that time

Dr Kelemen's slides are most interesting and suggest the possibility of applying some of these histochemical staining techniques to the study of tonsil material

ABSTRACT OF THE PROCEEDINGS

GROUND SUBSTANCE IN THE NOSE IN HEALTH AND INFECTION

EUGENE S HOPP, M D,
and
HELEN F BURN, M S (By Invitation)

These authors present the evidence thus far accumulated by themselves and others relating to the permeability of the ground substance in nasal tissues under varying conditions and the factors which permit certain bacteria to penetrate and spread Spreading factors, notably hyaluronidase, seem to be more abundant in staphylococci than in most streptococci, which enhances their invasive potentialities The hyaluronidase possesses the ability to depolymerize the hyaluronic acid in connective tissue, thus favoring the spread of infection These findings resulted from comparative multiple stain techniques of serially sectioned biopsies of turbinates from normal individuals and from patients with infection The authors conclude that since hyaluronidase is most active in the range of normal, slightly acidic nasal pH, the accepted concept of alteration of nasal pH to the alkaline side in nasal infection may be a defense mechanism and, therefore, the effect of the early stage of infection rather than the cause

DISCUSSION

Dr Aubrey G Rawlins brought out some of the relationships between the corticosteroids and the ground substance whose density is regulated by the pituitary adrenal axis The efficiency of this axis may be one determining factor in the invasiveness of certain organisms Dr Hopp has furnished good evidence that hyaluronidase-producing bacteria are often more invasive than non producers and this would be an important factor in many nose and throat infections The authors have shown how the spreading factor loosens the basement membrane under the epithelium, resulting in easier invasion by organisms

Not much is known as to whether or not there is any spreading factor in the normal nose and throat mucosa however it must be assumed that its precursor is there since the existence of hyaluronidase and mucolytic enzymes in the connective cells has to be postulated if equilibrium of the ground substance is to be explained

Dr Hopp mentioned the anti spreading factor of which there are two types the antibody which is specific and the heparin like substance which is non specific and is high in the blood stream in many diseases of a serious nature

The authors have well emphasized the dual features of infection namely the virulence and characteristics of the infecting organism and the quality of the ground substance of the host.

Dr George Kelemen showed several electron microscopic slides of tonsil tissue which at high magnification (30 000) depict the elements in the collagenous material the fibrillar structures and the relationship of the epithelial cells to each other Since these are joined together by intercellular bridges it can be seen how the lymphocytes have to push their way through by breaking down these bridges

Electron microscopy can contribute much of our knowledge of tissue reaction to infection by bringing out the finer anatomic details of the various elements under varying conditions

Dr Hopp in closing stated in response to Dr Rawlins query that in 1931 filtrates were taken from the normal nose as well as from individuals having a cold and it was demonstrated that there were spreading factors in the normal noses and interestingly enough there was an increase in the spreading factor in the patients with colds at that time

Dr Kelemen's slides are most interesting and suggest the possibility of applying some of these histochemical staining techniques to the study of tonsil material

VOCAL REST IN LARYNGEAL DISEASE

MERVIN C MYERSON, M D

Vocal rest must be intelligently applied and varies with the pathology in each case It is of greatest value in acute cases where inflammation and edema predominate, and less useful in chronic cases characterized by fibrosis and irreversible changes, therefore, it is of no value in the treatment of vocal nodules or in the chronic stages of contact ulcer It is useful in the preoperative days before removal of tumors and should not be prolonged postoperatively Delay in permitting the patient to speak in some cases may lead to psychologic trauma Within a very few days after surgery the voice may be used for moderate conversation, avoiding undue strain

DISCUSSION

Dr Louis H Clerf agreed in the main with Dr Myerson's conception of the role of vocal rest in laryngeal therapy Contact ulcers will not disappear under this plan except when they are of very recent origin In both vocal nodules and contact ulcer, speech therapy may be of some value, in addition to surgery when indicated Pre- and postoperative vocal rest, particularly the latter, should not be prolonged Voice use after operation should be permitted, since it prevents the piling up of exudate and granulations and tends to a better anatomical and functional result

Dr C L Jackson favored moderate rest of the voice in the conditions mentioned by Dr Myerson, but cautions the patient not to attempt talking against noises such as in traffic or busy offices In the treatment of contact ulcer he believes there is a time and place for cautious use of the voice but also it is important that the patient have the benefit of guidance under a speech therapist Like Dr Clerf, Dr Jackson encourages patients who have undergone partial laryngectomy to begin using the voice as soon as it can be done without discomfort

Dr Hans Von Leden said that electronic synchrostrobic examinations with high speed photography can furnish much valuable information about the action of the vocal cords under varying conditions On the basis of such observations he felt impelled to challenge Dr Myerson's statement that certain lesions disappear in 24 hours To the naked eye they may appear to shrink but "one must consider the effect of the Bernoulli phenomenon on the lesions of the vocal cords before one draws any clinical conclusions"

Dr Paul J Moses pointed out that voice rest is often advised in the expectation of curing a disorder, but frequently fails because of an underlying psychological problem which is the chief cause Voice rest will not cure a vocal disorder that is due to emotional causes It is therefore important in many cases that a psychiatric evaluation be obtained before any type of therapy is proposed

Dr Myerson closed the discussion with the following comments Bi opsies are usually not necessary in contact ulcers since it is known that carcinoma rarely occurs on the medial aspect of the arytenoid cartilage As for raising the voice in the presence of noise mentioned by Dr Jackson, this can be avoided by using ear plugs as advised by Mr Cantor Since the electronic synchrostroboscope is not available universally the laryngologist must depend on his clinical observations, and he personally can attest to a number of edematous lesions which have disappeared within 24 hours and with return of perfect function

Dr Moses remarks are well taken and bring up the point as to what constitutes a qualified voice therapist Many who claim this distinction have been found to be woefully deficient Psychotherapy may well be the answer in many cases but there are some patients of the exhibitionist type such as a night club singer upon whom he had operated to remove some vocal nodules who refused to undergo proper voice therapy and with the recurrence of the nodules blamed the surgeon

PANEL DISCUSSION

REHABILITATION OF THE POST-LARYNGECTOMIZED PATIENT

JOHN J CONLEY M D, *Moderator*

Rehabilitation of the Post-Laryngectomized Patient—
Charles M Norris, M D

Vocal Therapist Place and Contribution to the Rehabilitation Program .... Paul J Moses, M D

Rehabilitation of the Post-Laryngectomized Patient—
F Johnson Putney, M D

Psychological Factors Determining the Success or Failure of the Rehabilitation Program of Laryngectomized Patients—
Bernard Stoll, M D

Discussion of Some Technical Aspects of Speech Aids for Post-Laryngectomized Patients .... Harold L Barney, M D

A New Surgical Technique for the Vocal Rehabilitation of the Laryngectomized Patient .... John J Conley, M D,
Felix DeAmesti, M D,* and
Max K Pierce, M D *

---

*By invitation.

John J Conley, M D, Moderator, introduced the members of the panel who were to discuss various aspects of the problems of rehabilitating the laryngectomized patient These were to include surgical aspects, electrical equipment for voice production and speech therapy Some of these aspects have to some degree been overlooked in the past, and although some progress has been achieved, further study may prove fruitful in resolving the problems which confront these patients

Dr Charles M Norris lists the deformities and disabilities likely to be encountered following extensive laryngeal and accompanying pharyngeal and neck resection These are considered in two groups first, are those resulting inevitably from the surgery itself, such as permanent tracheostomy and loss of sensation due to section of branches of the cervical plexus and of function of the trapezius from section of the spinal accessory

The second group comprises deformities which may or may not be avoided, depending upon the technique These include stenosis of the stoma, stenosis of the hypopharynx, and paralysis of the mandibular, lingual or hypoglossal nerve, also the effects of sectioning the jugular vein

Dr Conley commented on the clear orientation of the operated area, the relative sizes of the wound, the demands on the local tissues and the resultant deformities This demonstration should be valuable in assessing the surgical damage inherent in various procedures

Dr Paul J Moses discussed the emotional status of the patient prior to a laryngectomy and its influence on the postoperative rehabilitation Restoring the ability to produce audible speech fails to compensate for the inability to transmit the nuances of feeling which no form of esophageal speech can duplicate It is, therefore, important that the speech therapist be properly trained in the field of psychology and psychiatry in order to obtain the full background of the patient's personality and to be able to adjust him properly to the altered status of voice production Placing him under the guidance of a laryngectomized patient who has mastered the technique of esophageal speech may fail unless the latter is qualified to understand and cope with a neurotic or psychiatric patient It is also important that the surgeon keep in close contact with the patient during the postoperative period while under tuition of the speech therapist, since it is he who is responsible for having taken away the speech, and who must display the keenest interest in seeing that it is restored

Dr Conley, hearing this paper for the first time, found it stimulating, provocative and humanistic The symbolism he attached to the "Adam's apple" as an attribute of virilism in the male may well explain the differing attitudes of the male and female when anticipating removal of the larynx The high artistic and esthetic quality of Dr Moses' presentation should be fully appreciated by all who are interested in the subject

Dr F Johnson Putney, reviewing the postoperative records of 440 patients subjected to a laryngectomy at the Jefferson Hospital, found that 38 per cent failed to develop a useful voice The percentage of failures was higher in the female patients than the male, due to psychologic factors The various techniques employed seemed to have but little influence on the ability to develop a voice, even when extensive removal of pharyngeal tissues, including the cricopharyngeus, was necessary, however, it was found that disturbance in the range of activity of the tongue and muscles of the floor of the mouth interfered with the ability to produce a voice as well as with the act of swallowing

It would appear, therefore, from the analysis of this group of patients, that failure to develop a voice could not be attributed to extent of the surgery or the amount of tissue removed, with the exception of the item just mentioned

Dr Conley called attention to figures presented by Dr Putney, where only 5 7 per cent of 440 patients elected to use an artificial larynx Comparing this with 38 per cent of the cases that failed to become rehabilitated vocally, this is pretty much in line with the figures obtained at the National School for Speech Disorders in New York It is interesting to note that no matter how much neck tissue is removed, rehabilitation is possible as long as you reconstitute the pharyn-

Dr F Johnson Putney, reviewing the postoperative records of 440 patients subjected to a laryngectomy at the Jefferson Hospital, found that 38 per cent failed to develop a useful voice The percentage of failures was higher in the female patients than the male, due to psychologic factors The various techniques employed seemed to have but little influence on the ability to develop a voice, even when extensive removal of pharyngeal tissues, including the cricopharyngeus, was necessary, however, it was found that disturbance in the range of activity of the tongue and muscles of the floor of the mouth interfered with the ability to produce a voice as well as with the act of swallowing

It would appear, therefore, from the analysis of this group of patients, that failure to develop a voice could not be attributed to extent of the surgery or the amount of tissue removed, with the exception of the item just mentioned

Dr Conley called attention to figures presented by Dr Putney, where only 5 7 per cent of 440 patients elected to use an artificial larynx Comparing this with 38 per cent of the cases that failed to become rehabilitated vocally, this is pretty much in line with the figures obtained at the National *School for Speech Disorders in New York* It is interesting to note that no matter how much neck tissue is removed, rehabilitation is possible as long as you reconstitute the pharyngeal tube and preserve the muscles of the floor of the mouth and tongue

Dr Bernard Stoll, in attempting to evaluate the patient's attitude toward rehabilitation, enumerated the fears that beset most patients prior and subsequent to operation The degree of anxiety varies with the temperament of the patient, his vocation, position in society and interpersonal relationship Preoperative counselling by the physician will remove many of these fears and the presence of an intelligent, psychologically astute person, who has undergone a laryngectomy and has acquired a good esophageal speech is very helpful Instruction within a group of laryngectomy patients lends psychologic support through the competitive element

Necessity and willingness to learn are most essential, and as a rule, it has been found that the extrovert type of individual adapts himself to the new regimen better than the introvert It is important during the periods of instruction to avoid the use of the word "belch" because of its disagreeable connotations

Psychologic conditioning whereby the patient acquires confidence in the ready acceptance by the public of his newly acquired speech is most helpful in instilling the necessary confidence

Dr Conley stated that Dr Stoll's paper illustrates very well the necessity for adaptation on the part of the patient in order to master the technique successfully One can regard the patient as standing on a ladder, you either push him up into an area of greater success, if he has the adaptive capacity and necessary motivating principles, plus the support of proper schooling, or he will slip backward into failure to achieve adequate rehabilitation If the speaking phenomenon can be made technically easier the stratum is lowered thereby putting it within reach of the patient's adaptive capacity

Dr Conley apologized for the absence of the film which was scheduled to be shown, due to an error on the part of the Phillips Company, who sent a film of the palate instead of the esophagus

Mr Harold L Barney, of the Bell Telephone Laboratories, analyzed the problem of constructing an artificial larynx that will meet certain mechanical acoustic and commercial requirements Improvements have been achieved with the introduction of transistors and miniature batteries, however, the ideal has not yet been attained insofar as being able to produce speech patterns which will more closely simulate the normal In order to obtain the full advantage of tongue, lip and palate movements, as well as the resonating chambers above, it would be necessary to introduce an air column as low down in the pharynx as possible If this could be achieved *through an artificial opening in the neck, it would be ideal*, but there are certain hygienic and cosmetic considerations, which are objectionable

The author showed graphs which demonstrated the sound spectograms for certain vowels and consonants with the tube at different locations as compared with the normal

It is anticipated that the Western Electric Model 2 device, improved with proper acoustic and electronic circuit design, should provide sufficient drive when applied to the outside of the throat to produce adequate intelligibility which will result in more natural sounding speech

Dr Conley and associates describe a new technical procedure whereby air can be conducted from the trachea to the esophagus for the production of controlled sound It is accomplished by the construction of a mucosal-lined tube derived from the esophageal mucosa supported by one of the neck muscles and so directed as to be closed during the passage of food The operation was performed on 11 patients, eight as primary procedures following the laryngectomy, and three as secondary procedures Of the eight primary, three were technical failures (two of stenosis and one through fistula formation) The stenosis may have been due to removal of the catheter stent too soon The fistula formation was in a patient who had had irradiation prior to laryngectomy

In the successful cases the patients were able to speak with the first effort, and the quality of the voice was that of pharyngeal or esophageal speech but with better air control and supply and greater ease

DISCUSSION

Dr Julius McCall called attention to his paper on "Preliminary Voice Training for Laryngectomy" of 18 years ago, which set in motion the development of what was termed "The Lost Chord Club" It is his contention that training for the esophageal voice should begin before and not after surgery, also he disagreed with Drs Moses and Stoll, who deny that the expulsion of air is not a burp or a belch He could recall only two patients who were able to belch after laryngectomy who failed to develop a good esophageal speech He agreed with Dr Putney that the amount of tissue removed had little to do with the subsequent development of the speech

Dr Joseph H Ogura had little to add, expressing his agreement with everything that had been said

Dr McNaught echoed the same sentiments

Dr Louis H Clerf felt that while the opinions expressed were in many respects admirable, he could not agree with everything, since some of them were diametrically opposed It is generally agreed that the problem is one from which the surgeon cannot divorce himself It is he who must take the initiative in getting the patient started since it is he in whom the patient has the greatest confidence He agreed with Dr McCall to the extent that whether you call it belching or burping you have to get air into the lower pharynx Where the dividing line is located is difficult to say He does not have the patient deliberately swallow but encourages him to relax during inspiration so that air may accumulate in the lower passages He himself has been able to relax his cricopharyngeus sufficiently to fill the stomach with air

Dr Paul H Holinger agreed with Dr Putney that the type of operation has little to do with the subsequent development of a speech pattern He believed that the most important factors are the motivation by the patient and intelligent co operation of therapist and surgeon Often it is a question of persisting too long in efforts to produce esophageal speech in some cases to the point of frustration when such individuals can more readily be made to accept an artificial larynx With improved models of prothesis this medium may become more acceptable As to preoperative training he disagreed with Dr McCall because it is so often an individual problem In some cases it only adds to the burden on the patient, who has many other things to attend to before undergoing surgery Rehabilitation and inspiration to learn can begin before the patient leaves the hospital through association with others who have acquired speech and instruction by the therapist

Dr Conley agreed with Dr Holinger that one of the most important psychological points is the compulsion of the patient to speak It may be a good idea to give the patient a speaking apparatus at the outset as a means of encouraging adaptation

Dr Walter H Hoover could not entirely agree that the type of operative procedure played no role in subsequent speech development. Certainly a flexible pharynx will adapt itself to voice production better than one which is hampered by deep neck scars

Dr Conley closed the discussion by stating that the purpose of the panel was not so much for medification as for a stimulus to all laryngologists and allied specialists to apply themselves toward the development of new techniques which may further the advancement of knowledge in this most important field

---

THE CHANGING YEARS THEIR IMPACT UPON THE MANAGEMENT OF PARANASAL SINUS DISEASE

FREDERICK T HILL, M D

Dr Hill reviewed the changes that have taken place during the past 40 years in the management of sinus disease, showing how increasing knowledge of the physiology of the nose and sinuses and a better understanding of constitutional and environmental factors has led to a saner and safer attitude He mentioned the excellent research and contributions of many members of this association which were responsible for the advances we have witnessed He discussed the impact of allergy, endocrines and other constitutional factors as they were developed within and without our specialty, whose influence on the course and development of sinus conditions was studied by our colleagues, resulting in a more intelligent understanding of the pathogenic processes Surgical procedures have as a result tended more and more to conservatism, as demonstrated in his analysis of the treatment of frontal, ethmoid and antrum disease Comparing the widespread and often indiscriminate surgery of the sinuses formerly practiced on fallacious indications, with the modern conception of the sinuses as part of a total organism, it is easy to see why we are doing less surgery and obtaining better results under a comprehensive regimen which takes into account all of the contributing factors

DISCUSSION

Dr Samuel Salinger confessed to an emotional reaction to Dr Hill's presentation which was primarily a response to the realization that he was older than he had thought and secondarily to an amazing change in perspective

Recalling for instance a meeting some years ago at which a colleague reported having done 300 intranasal frontal operations with a rasp and with only one fatality, he is now shocked to think that at the time he was only impressed by the great skill of the surgeon without having given any thought to the question of why these operations were done

To comment on the numerous items so ably assembled by Dr Hill would be superfluous, but one or two personal observations are submitted One should always be suspicious of any unilateral clouding of a sinus that is more than transitory, and should never be guilty of overlooking the possibility of a malignancy, which is so difficult to diagnose in the early stage It is for this reason that he is a firm believer in the value of laminagraphs and X rays with contrast media in every case that fails to yield promptly to conservative treatment

Another conclusion to which he has been forced is that the only way to insure against recurrence after frontal sinus surgery is to obliterate the cavity He was impressed with the work of Bergara, who uses abdominal fat to fill the sinus and has presented evidence of subsequent development of fibro-osteoid tissue completely filling the space In two recent cases Salinger has used Gelfoam instead and in following the cases with X rays for several months, has been able to observe a gradual obliteration of all bony landmarks This may or may not mean a permanent filling, but only time will tell

Dr Francis L Weille believed that the role of allergy has been overemphasized Many people believe that the allergist can cure recurring polyposis with anti allergic therapy He recalled a report by Dr Schenck and Dr Kern on a series of 700 cases a third of which had polypi in which only four were cured by anti allergic therapy He would like an expression from Dr Hill on this point

Dr Hill closed the discussion by stating first, that he agreed with Dr Weille as to over-emphasis on the allergic factor although he had seen a number of cases in which this cannot be denied Yet he doubts that polypi will disappear under allergic therapy except under the most unusual circumstances

The subject of malignancies as well as complications was not presented, although both are included in the full paper to be published As for Dr Salinger's opening remark regarding the passing of time, he could say only that one thing worse than growing old is not having a chance to do so!

SURGERY TO THE NASAL LOBULE

HENRY L WILLIAMS, M D

Dr Williams described in detail the anatomy of the nasal structure with special emphasis on the relationship of the septum to the lateral and alar cartilages Variations in the nasal apertures are responsible for varying effects on the degree of resistance to the inspired air which produce symptoms of hyper- or hypoventilation He pointed out that in most patients it is impossible to demonstrate the physiologic effects of these variations, and that from a practical point of view operations are indicated for the relief of subjective symptoms He described the symptoms caused by nostrils that are too narrow deformities of the lobule, deviations of the lower portion of the septal cartilage, variations in the size and placement of the lateral cartilages and nasolabial angles

The procedures for correcting these manifold conditions involve a combination of techniques which may embrace the septum, upper lateral cartilages and the lobule The septum is dealt with through a modified resection with replacement of excised cartilage, and the lateral and lobular cartilage resected in part or cross-hatched as indicated These techniques were given along with appropriate illustrations Good functional results can be obtained only through careful study of the individual case, applying only those remedial measures which are strictly indicated

DISCUSSION

Dr G Edward Tremble described the anatomic differences between the nares of the Caucasian as compared with the Negro and Filipino which account for differences in the direction of the air flow within the nasal passages These are to be taken into account when surgery is to be undertaken which involves changes in the contour of the nares and vestibule so that the normal pattern of air flow is not to be altered The shape of the nares must conform to the normal Caucasian, when operating on a white individual and the vestibule must retain the normal valve of Mink so that the air current is properly directed

Frequently after a properly performed submucous resection nasal blockage will be complained of which can easily be corrected by a simple procedure on the lobule

Dr Samuel Salinger felt that, since Dr Williams had introduced the subject of the septum in his consideration of deformities about the lobule he would like to comment on that aspect of the problem He has long been an advocate of a conservative type of operation in which the deformity is corrected with removal of a minimum of cartilage and bone Others have had the same idea and a variety of procedures have been described by Stevenson Dingman Becker and Maliniak In all these techniques the Metzenbaum procedure has been more or less modified the objective being the straightening of bends curves and cartilage The point is that no single technique is applicable to all cases and that success depends on the ingenuity and technical skill of the individual operator

Dr Irving Goldman called attention to the varying shapes of the nares to be found in different races and the question as to how much influence they exert on the respiratory function Changing the shape of the lobule may be applicable in one type and disastrous in another In the combined septum rhinoplasty with surgery of the lobule he is convinced that the causative factor is most generally to be found in the septum and he agrees with Dr Salinger that conservative procedures will yield the best results

Dr Juergen Tonndorf disagreed with Dr Tremble in the statement that there is a substantial difference between the currents of inspired and expired air Experiment of older authors did make this claim, but it was found that the difference was due to the use of too heavy material It was disproven 20 years ago in Dr Proetz's experiments He also may have misunderstood Dr Tremble as saying the current slows down as it goes through the vestibule On the contrary, when a current of air passes through a narrow opening, its velocity must increase The third point refers to the eddy motion of the air which through the nose is more laminary and unstable If you calculate the Reynolds' number which indicates whether the motion will be laminary or eddying it develops that the Reynolds number for the nose is about 1,000 in eddying It starts at 1,100 or 1,200 This means that you are just short of eddying, and if surgery does anything to speed up the flow of air you will produce an eddying current

Dr Wilson stated that we are led to believe that the Caucasian nose is narrower than the Negroid type because of living in colder and drier climates Could Dr Williams offer any explanation of the shape of the Eskimo's nose?

Dr Williams closed the discussion by first answering Dr Wilson's query to the effect that not being privy to the designs of the Lord, he was unable to offer any explanation, nor did he believe the anthropologists could

As to the remarks of Drs Salinger and Goldman, the technique he has described here offers great flexibility and permits surgery on the lobule at the same time He agrees that there is no set technique

The question as to whether the various types of noses have to do with varieties of obstruction is beyond the point Patients come to the surgeon because of obstruction, and in many instances the submucous resection is inadequate, and better results can be obtained by additional surgery on the lobule

What the mechanism of obstruction from lobular deformities is, he would leave to mathematicians such as Dr Tonndorf, but the fact remains that patients are relieved of their complaint when the deformities are properly corrected

CARCINOMA IN SITU OF THE LARYNX A TEN-YEAR STUDY OF ITS HISTOPATHOLOGICAL CLASSIFICATION, PROGNOSIS AND TREATMENT

ALDEN H MILLER, M D,

and

H RUSSELL FISHER, M D

Drs Miller and Fisher, analyzing a series of 48 patients with carcinoma *in situ* of the larynx, observed during a ten-year period, certain data pertaining to classification, local characterists, invasive potential and results of therapy Of the three histologic types encountered, basal cell, squamous cell and Bowmanoid, the most common was the squamous cell, which appeared to be associated with leukoplakia Ten patients developed invasive carcinoma, most of them originating from the squamous type Treatment by stripping, laryngofissure or X-rays was individualized on the basis of extent of the lesion, original diagnosis and development of recurrence Laryngofissure was successful for the small lesions More extensive lesions, especially the bilateral, received X-ray therapy, which obviated the need for laryngectomy in 17 of 23 patients

There was only one death following laryngectomy with subsequent invasion of the lymphatics and a radical neck dissection

DISCUSSION

Dr Francis E LeJeune brought out the point that the clinical picture of carcinoma *in situ* was not characteristic and that its differentiation from invasive carcinoma could be determined only by the pathologist. The question as to whether the lesion has penetrated the basal membrane can be resolved only through serial sections and since it is impractical to examine all the sections in a given specimen it is possible that some invasive cases may escape detection and thus account for recurrences

He has found carcinoma *in situ* ideal for removal by suspension laryngoscopy with wide excision followed by electric coagulation of the base Dr LeJeune inquired of Dr Fisher as to why he found it necessary to use the words without invasion in referring to these growths since penetration of this barrier changes the picture and one is now dealing with an invasive carcinoma and not a carcinoma *in situ* He would also like Dr Miller to explain why he was impelled to do laryngofissure in some of these cases

As to statistics he has not had an opportunity to review his own but is under the impression that he had seen very few recurrences

Dr Eugene S Hopp suggested a possible explanation for invasion which might reconcile the points of view of Drs LeJeune and Fisher namely that invasion and even metastasis depends on the integrity of the ground substance Some excellent work has been done showing that metastases develop where depolymerization of ground substance has taken place It would be interesting and profitable to do histochemical stains on these carcinomas with the idea of ascertaining whether those which subsequently developed extension or invasion showed this depolymerization in the sections and whether those which did not develop showed intact ground substance

Dr Julius McCall would view carcinoma *in situ* as an unpredictable lesion As stated by Dr LeJeune much depends on the area from which a biopsy is taken since a distance of a few millimeters may produce an entirely different picture This was illustrated in pictures shown by Dr

McCall of a case where one section showed intact basement membrane, whereas another showed a break through

Dr Miller closed the clinical side of the discussion by stating that he had attempted to make the distinction between the strictly intraepithelial growths and those showing invasion, the latter being excluded from the series, if *recognized*

Regarding the potentially malignant character of these lesions Dr Miller agreed with Dr LeJeune that *every case is potentially invasive* although in many cases the invasive character is not manifested until years later Initially a clinical diagnosis cannot be made from the appearance of the lesion, many of them being leukoplakia cases on the surface

Dr Fisher explained his terminology "without invasive carcinoma" to emphasize that all parts of the tissue had been examined He may perhaps have been too redundant for this audience but has so often been asked "was there not invasion in some other part" that as a result it has been his habit to add the words "without invasive features"

The point brought up by Dr Hopp is an important one and it must be conceded that the character of the ground substance has much to do with the chance of invasion He has made *studies in a few cases but not* systematically Alterations in the ground substance have been observed in simple keratosis, chronic laryngitis as well as carcinoma *in situ* without however revealing any specific change characteristic of carcinoma *in situ* Dr McCall's case brings to mind the studies on carcinoma *in situ of the cervix in which a potential to invasion has been more or less* fixed By comparison the cases involving the larynx occupy a place midway between the peak age of cervix lesions and keratosis being estimated at about eight years Dr McCall's slides demonstrate the difficulty that arises when only one section is examined One slide appeared to be simple metaplasia another showed carcinoma *in situ* at one spot, and another showed it with invasion

BRONCHOSCOPIC FINDINGS IN TUBERCULOUS CHILDREN (A FIFTEEN YEAR STUDY) *

Dr Whaley described the results of their bronchoscopic examinations of 144 children with bronchial tuberculosis *Many of these had bronchograms as well, and a total of 273* examinations was made They give the details of the procedure, which is carried out under general anesthesia in a properly ventilated room with shock and explosion-proof apparatus

Primary bronchial tuberculosis was found in a limited number of cases, the result of direct infection of the mucosa, which revealed redness and swelling over a limited area Most commonly the upper lobe bronchi and the lingula were affected

---

*Due to the untimely death of Dr Wishart this paper was presented by Dr Whaley

Secondary tuberculous bronchitis was found more frequently and often called for emergency treatment Compression of a bronchus due to pressure of enlarged glands was a common finding, and frequently there was an accumulation of caseous material and granulations, due to rupture of a caseous gland into the lumen These called for bronchoscopic removal Other findings were bronchiectatic lesions of the "flagellate" type

Following unsuccessful trials with streptomycin, para-amino-salicylic acid (PAS) and isotonic acid hydrozide (INH) proved more successful Repeated bronchoscopic aspiration with removal of granulations was helpful in many cases In a few it was necessary to resort to lobectomy and occasionally to pneumonectomy

Numerous pictures showing bronchograms illuminated the presentation

DISCUSSION

Dr Mervin C Myerson found that the age group below two years is the worst from the standpoint of prognosis In the group between the age of 4 and 14 about 15 to 20 per cent present the type of lesion seen in adults In the infant and young child the glands cause the most trouble often to the point of obstructing the bronchi These glands may develop in two directions one erosion into a bronchus the other by lymphatic extension to the bronchial mucosa This may be either a submucous infiltration or an open ulceration Dr Myerson showed slides depicting lesions in the parenchyma and showing the manner of extension to the bronchi Generally speaking one may safely attempt to remove a granuloma but if the lesion is caseous surgical trauma might precipitate a miliary spread to other parts of the body also he would not recommend dilating a bronchial stenosis because of a hematogenous spread

Dr J P Atkins has found that it is safe to remove endobronchial caseation debris without danger of dissemination probably due to the effectiveness of the antibiotics and the improved ventilation is certainly beneficial

Dr Whaley in closing agreed with Dr Myerson that many cases do not respond to endobronchial therapy and have to submit to surgery As for the caseous lesions he agreed that cautious removal of the debris is desirable while on the other hand as Dr Myerson pointed out dilatation is risky

THE CLINICAL SIGNIFICANCE OF THE ANATOMICAL ARRANGEMENT OF THE PARANASAL SINUSES

FRED W DIXON, M D

A study of 200 wet specimens by Dr Dixon yielded a number of observations which have proven of value in surgery of these areas These include the accessibility of the middle meatus for irrigation of the antrum, the variations in size and disposition of the ethmoid cells, the variations in size and relative positions of the two frontal sinuses and the extreme variability of the sphenoid sinuses Dr Dixon pointed out the value of closely observing the fovea ethmoidalis, which is an excellent landmark when performing surgery on the ethmoids via the intranasal approach Preserving as much as possible of its mucosa, plus that which covers the superior and supreme turbinals, and as much as possible of the middle turbinate will prove valuable in avoiding complications

Recurrence of polypi can be expected if the surgery is incomplete and in allergic individuals A resume of 200 intranasal ethmoidectomies showed 25 per cent with recurrences, mostly in allergic cases and in individuals who rejected complete removal

DISCUSSION

Dr Walter P Work stressed the points brought out by Dr Dixon relating to the variations of the frontal sinuses In narrow frontal sinuses it is extremely difficult to preserve a functional frontal duct The chances are better in cases where the anterior dimension of the sinus is greater Surgical treatment of the frontal sinuses must of necessity include associated surgery of at least a portion of the ethmoid labyrinth and here a knowledge of the disposition of the cells is of great value

Dr Work has found that serious complications were most frequently encountered in the allergic cases and inquired of Dr Dixon whether this had been his experience also

Dr Barry J Anson, as an anatomist expressed his appreciation in having been able to hear two papers dealing with the morphology of the sinuses At the onset of the antibiotic era he had been led to believe that the mention of sinusitis would be an anachronistic act Now that it appears that sinusitis still exists despite antibiotics he fears curricular encroachment by clinical courses on the time formerly available for preclinical courses In his department he has already lost 30 per cent of previously allotted time Since it is apparent that hours must be recaptured for teaching anatomy the pressure and influence must come from the clinicians Meanwhile postgraduate lectures of the type presented here are refreshing and helpful additions to make up for deficiencies in the undergraduate instruction

Dr W Likely Simpson described his approach to the frontal sinus through the floor with complete removal of all mucosa and all septa between the frontal and the ethmoids Visualization of all parts of the large sinus is accomplished with the use of small mirrors No irrigation is practical and only a small gauze is left under the middle turbinate which is removed on the third day No further drainage is employed since there is no nasofrontal duct left, the fronto-ethmoid cavity being all in one

Dr Francis W Davison complimented Dr Dixon on his paper and called attention to a previous presentation of his which was given at the meeting of the American Laryngological Association which he considers a classic He inquired as to when and where this was to be published

Dr Kinsey M Simonton called attention to Dr Dixon s reference to removal of the middle turbinate which has been invaded by a cell He has found it practicable to remove only one wall thus leaving the other for physiologic functioning

Dr Dixon closed the discussion by first replying to Dr Simonton It is his practice to leave as much of the turbinal structure as possible on the side facing the septum This has proven helpful in preserving the olfactory sense

The article mentioned by Dr Davison will appear in the *Annals* He agrees that the operation for removal of polypi should be done in the hospital where a more thorough job can be accomplished and also agrees with Dr Simpson that thorough removal of all the tissue will yield the best results

Dr Anson s point is well taken We need more teaching of anatomy and pathology at the undergraduate level

About swimming like all rhinologists he feels that it should be interdicted for all patients having chronic sinus trouble

As to indications for the operation it should be required in all cases where ventilation and drainage has failed and where irreversible changes have taken place

ORBITAL APEX SYNDROME

AUSTIN A SMITH, M D

Dr Smith described the orbital apex syndrome as the clinical manifestation of a lesion which affects the nerves and vessels that pass through the optic foramen and sphenoid fissure The chief symptoms are severe temporoparietal pain, impairment or loss of vision, ptosis and ophthalmoplegia It may be due to infection, neoplasm or trauma, and can originate either in the retro-orbital region or in the posterior sinuses

Five cases are cited one being due to a severe upper respiratory infection, one to a posterior sinus infection, a third to a carcinoma originating in the ethmosphenoid area The fourth was a complicated case which, after careful study and radical surgery, proved to be an extensive involvement of all the sinuses in a gangrenous destructive process with necrosis apparently due to endarteritis and thrombophlebitis The last case was due to trauma resulting from a fall from a ladder

The clinical history of these cases affords an interesting study in diagnosis and therapy

DISCUSSION

Dr Oliver E Van Alyea pointed out some of the anatomic features of the orbital apex, explaining the symptomatology

The complete syndrome as described by Dr Smith is, fortunately, quite rare, but an uncomplete syndrome may be more common Two cases are cited one due to an aneurysm of the internal carotid artery, the other, to a retrobulbar cyst This latter patient, a girl of 13, after drainage of the cyst still persisted in having severe headaches and a mild ptosis Surgery on the affected ethmoid was advised, but was rejected by the parents on religious grounds Dr Van Alyea asked Dr Smith how he would proceed in such a case

Dr Smith replied to Dr Van Alyea's question by calling attention to the necessity of having the cooperation of the neurologist, ophthalmologist, neurosurgeon and X ray man Too often, however, the case goes from internist to ophthalmologist and neurologist and X ray man without consultation with the rhinologist, because the possibility of a sinus involvement is overlooked This may be due to the fact that antibiotics have often been considered as having eliminated sinus disease This is indeed a grievous error In the particular case mentioned by Dr Van Alyea, every effort should be made to at least explore the ethmoids cautiously

PHYSIOLOGY OF THE LARYNX UNDER DAILY STRESS

PAUL G MOORE, M D ,[*]
and
HANS VON LEDEN, M D [*]

Drs Moore and Von Leden demonstrated the action of the vocal cords in a slow motion film which reveals their responses under daily stress Numerous subjects were checked and rechecked to insure the accuracy of their interpretations Two new ideas ensued following a study of the film which seemed to alter previous concepts of the physiology of the larynx

---

[*] By invitation.

1 The old concept that the cords open faster than they close is not true Opening and closing phases are related to the intensity of the voice

2 The larynx is capable of biphasic movements, which to date had been considered impossible

It is hoped that these studies will lead to a better understanding of the frequently observed disparity between the degree of hoarseness and the objective findings in the larynx, and point the way toward a more rational treatment of early larynx disorders

DISCUSSION

Dr John A. Murtagh expressed his admiration for the film just shown which he appreciated all the more because of some experience with a highspeed Fairchild industrial motion analysis camera which he had been using in an effort to evaluate the basic physiology of the larynx in animals He confessed that his film could not compare with the one just shown This type of work should be encouraged because so much can be learned which was previously unexplained

Dr Von Leden stated that it is at first difficult to accustom oneself to viewing these pictures but that after seeing them frequently many new factors can be seen and understood

---

THE MANAGEMENT OF CHRONIC LARYNGEAL STENOSIS

PAUL H HOLINGER, M D,
and
KENNETH C JOHNSTON M D*

Drs Holinger and Johnston reviewed their experiences in 163 cases of chronic laryngeal stenosis over a period of ten years Sixty-one *of these were congenital in origin, 43 were* inflammatory and 57 were traumatic Each of these types is described and illustrated by a typical case The authors have noted recently a decline in the percentage of cases due to inflammatory processes, and an increase in the number of post-traumatic lesions They point out the importance of early attention to fractures of the larynx in the prevention of subsequent stenosis from scarring and maladjusted cartilage *Tracheotomies were performed in 138 of the 163 cases* and dilatations were carried out in 123

---

*By invitation

They also call attention to the value of voice therapy in the development of proper phonation and respiratory control

DISCUSSION

Dr Daniel C Baker, Jr, has found that long-continued bougienage in children is frequently disappointing In adults it is difficult because of the pain and discomfort which cannot always be avoided, even with local anesthesia or nerve block Rubber core molds as suggested by Jackson are irritating and cause considerable laryngeal reaction Mc Naught's keel is excellent for web stenoses especially the acquired type This is frequently the result of using the cautery, and he is in agreement with Dr Holinger, who advises against it. The stent graft as described by Figi, has been most useful when followed by the acrylic mold

Dr Holinger's experience with traffic injuries is most valuable, and his suggestions for their management are extremely important

Indwelling catheters for feeding in some tracheotomy cases will often delay decannulization because of reaction in the larynx due to the tube

Four cases of necrosis of the thyroid cartilage with resulting draining fistulae over a period of years were cured only after surgical removal of the diseased cartilage

Dr Holinger's presentation may well serve as a proper guide in the management of laryngeal stenosis of the chronic form

EVIDENCE OF LARYNGEAL PARTICIPATION IN EMOTIONAL EXPRESSION ITS RELATION TO HYSTERICAL APHONIA

A C FURSTENBERG, M D

Experimental electrical stimulation of various cerebral areas in the monkey have demonstrated secondary motor areas which may activate laryngeal movements These have separate and distinct pathways to the nucleus ambiguus and can carry impulses eliciting laryngeal movements even in cases of supranuclear laryngeal paralysis The secondary motor areas are in fields which, on stimulation, result in homolateral movements of the facial muscles, jaw and tongue Theoretically, therefore, it should be possible to train the larynx to function in patients with supranuclear lesions which have produced bilateral laryngeal paralysis

It was also found that some of the additional motor areas are in fields which have to do with emotional responses This has been demonstrated in a case of hysterical aphonia The patient, when aroused, may scream loudly and even speak audibly

It is also probable that the additional motor areas of the larynx, like those of other types of movements, serve as centers for automatic associated movements, as illustrated by unaware whistling, humming and talking to oneself

It is assumed on the phylogenetic basis that these experimental findings in monkeys represent a similar pattern in the human

DISCUSSION

Dr Stanton Friedberg recalled some of Dr Furstenberg s previous papers on the subject of laryngeal innervation in which the role of supranuclear lesions in the production of laryngeal paralysis were demonstrated His present contribution gives strong experimental evidence of secondary motor areas supplying pathways to the nuclei which can activate laryngeal movements While Penfield and Rasmussen demonstrated laryngeal movements through stimulation of the human cortex at surgery it remained for Dr Furstenberg to demonstrate and record them photographically and then study the postmortem specimens of cortical areas stimulated

The emotional connotations of hysterical aphonia as explained by Dr Furstenberg may not be the only factors since Jackson hinted long ago that an ephemeral adductor paralysis may be due to sudden anemia of the anterior cerebral cortex as in syncope or fainting however this has not been proven by anatomic or physiologic studies

Dr Furstenberg's suggestion that stimulation or inhibition of hypothalmic areas concerned with emotional expression may stem from certain definite regions of the brain it could supply the physiologic evidence to explain hysterical aphonia is described and illustrated by a typical case The authors have noted recently a decline in the percentage of cases due to inflammatory processes, and an increase in the number of post-traumatic lesions They point out the importance of early attention to fractures of the larynx in the prevention of subsequent stenosis from scarring and maladjusted cartilage Tracheotomies were performed in 138 of the 163 cases and dilatations were carried out in 123

They also call attention to the value of voice therapy in the development of proper phonation and respiratory control

Chevalier Jackson, M D , Sc D ,
LL D , L H D , F A C S

In Memoriam

CHEVALIER JACKSON, M D , Sc D , LL D , L H D , F A C S

1865-1958

Like a Hick'ry cog,
In the old mill wheel,
He did his part,
As his turn came 'round

With these words as a postscript, Chevalier Jackson closed his autobiography He considered his life's work and responsibilities in this vein and with determination, persistence and singleness of purpose fulfilled his role in life as he saw it, in spite of hardship, adversity, discouragement and even ridicule It is gratifying to know that he lived to see his accomplishments appreciated at their full worth, and to know that many of his pioneering procedures became standard, routine techniques in both the diagnostic and therapeutic aspects of diseases of the air and food passages

Chevalier Jackson was born in Pittsburgh, Pa , on November 4, 1865 His mother and father were natives of the State French ancestry gave him his name, and a love of the French language, the culture and the country itself, throughout his life His early years in Pittsburgh, in a coal mining and farming community were rough, but habits of early rising, long hours of work and a keen interest in drawing, painting and making things with his hands were developed at this formative stage At 12 years of age he had his first experience in retrieving a foreign body—tools used in drilling for oil, lost down a 1500-foot test well The successful solution of this mechanical problem further molded his later career, the achievement of a task previously considered "impossible" continued to stimulate him throughout his life the speculum made it a practical instrument, the basic design of which has been retained in most of the present day esophagoscopes A vast experience in intubation and tracheotomy for diphtheria, and experience in the management of post-diphtheritic laryngeal stenosis acquired during the last decade of the Nineteenth Century, served as a background for subsequent work in bronchoscopy Foreign body extraction proved an absorbing challenge in the years that followed This necessitated the development of new instruments, techniques and procedures Jackson insisted on perfecting the solution of a mechanical problem of foreign body extraction by trial, first on a manikin board, then in the cadaver and finally in the anesthetized dog Constant research, self-training and discipline permitted him to achieve perfection, utilizing these progressive steps Jackson stressed the principle of education of the eye and the fingers through practical experience gained by extracting foreign bodies from the air and food passages of anesthetized dogs Physicians from every country in the world participated in the courses which he conducted in Pittsburgh, later in Philadelphia and in Paris

In 1899 Chevalier Jackson married Alice White of Pittsburgh She accepted and understood his devotion to the development of his special field of medicine She encouraged him and sheltered him from what they both considered unnecessary social obligations that might take time from study or writing, she preceded him in death by only a few months

By the turn of the Century, Jackson was receiving increasing recognition in the field of laryngology and in the new fields of bronchoscopy and esophagoscopy In 1911 he was President of the American Laryngological, Rhinological and Otological Society, and in the following year was elected Professor of Laryngology at the University of Pittsburgh, however, a change in activity was necessitated at this time by an attack of pulmonary tuberculosis Enforced rest was mandatory, but the time was far from lost Characteristically rest periods became an opportunity to write, and the first complete text on "Peroral Endoscopy and Laryngeal Surgery"

Early schooling was most difficult, not because of schoolwork, but because of the bullying by the larger, rough, miners' boys in the country school The study of medicine, as was customary at that time, was begun under a preceptor In 1884, after working for a year painting glass and china to obtain funds, Jackson entered Jefferson Medical College The medical curriculum consisted of two Winter courses of lectures and clinics from October through March At the conclusion of the first Winter course he became a salesman of medical books This took him to New England and gave him the opportunity to study his texts while waiting in doctors' offices, unfortunately the physicians usually claimed they were too busy to read books and sales were few Completing the coverage of his territory in Gloucester, Mass, Jackson shipped on a *Gloucester fishing schooner for the remainder* of the summer at $10 00 a month, plus a share in the catch Taking over as ship's cook improved his income This and his earnings from another month's work in a decorating shop painting china, enabled him to return for his second year of medical school His medical degree was conferred in 1886 when he was but 21 years of age

Specialization in a limited field was rare at that time, but interest in the field of laryngology, stimulated by the work of J Solis Cohen and the writings of Sir Morell Mackenzie led to a trip to England to visit Mackenzie's clinic Returning from Europe as a specialist at the age of 22, Jackson began his work in laryngology in Pittsburgh He demonstrated the value of tonsillectomy and adenoidectomy in children, and tried to establish a health program of throat inspection in the public school system Although this effort was unsuccessful, the experience in dealing with government agencies was of value later in pressing legislation concerning the labeling of lye as poison

His interest in endoscopy began in 1890 when he developed an esophagoscope with which he removed a dental plate from the esophagus of an adult, and a coin from a child's esophagus Adoption of Einhorn's suggestion of using a light carrier on societies throughout Europe, North, South and Central America and all parts of the United States In 1926 he was President of the American Laryngological Society and received the DeRoaldes Award in Laryngology He was a recipient of the Philadelphia Bok Award, was made a Chevalier de la Legion d' Honneur (France) and Chevalier de l'Ordre de Leopold (Belgium) in 1927 He was the recipient of the Henry Bigelow Medal awarded by the Boston Surgical Society in 1928, the Cresson Medal of the Franklin Institute in 1929, the I P Strittmatter Award in 1932, and in 1933 received the Gold Medal of the Radiological Society of North America The highest honor in American Medicine, the Distinguished Service Medal of the American Medical Association was conferred on him in 1940 The award of the American College of Chest Physicians, for meritous Services in Diseases of the Chest was given him in 1952

Jackson was the first to point out that the field of peroral endoscopy had broadened to justify considering it as an "-ology" rather than an "-oscopy", a "study of" rather than merely a "looking into" He coined the word "broncho-esophagology" to indicate this advance, and it has come into common usage Those who stumbled over its pronunciation were gently reminded of the similar term, "gastroenterology"

One of the achievements accomplished through the dogged determination so characteristic of Dr Jackson was the passage of the Federal Caustic Act by Congress in 1927 He effected this through personal appearances before numerous senators, congressmen and committees He used the many children under his care at that time as a living demonstration of the need for this legislation This law made mandatory the labeling of caustics as poisons, and required the printing of the antidote on the label Jackson obtained great personal satisfaction from this triumph The pen with which President Coolidge signed this bill was presented to him by the President

Holding five chairs of Bronchoscopy and Esophagoscopy in as many separate medical schools was a unique achieve-was prepared and published in 1914 This and an earlier text in 1907 were richly illustrated by Jackson, who stressed this form of teaching in lectures as well as texts No one who ever saw him sketch with both hands while lecturing will forget the drawings or the points they illustrated He used his line and chalk drawings, as well as oil paintings of endoscopic pathology in the texts, and they became the basic works in this new field of medicine

Foreign body work became Chevalier Jackson's greatest interest, and his skill in the management of the difficult case and his success in safely removing a foreign body after others had failed were soon recognized, however, more than anyone else, he demonstrated the value of bronchoscopy and esophagoscopy in the diagnosis and treatment of other diseases of the chest, and the safety with which these procedures could be done in infants as well as adults Peptic esophagitis, the upper and lower pinch-cock of the esophagus, bronchial adenoma, post-operative atelectasis and other phenomena he described were received with skepticism, but later were accepted as definite clinical entities In 1916 Jackson was offered the Professorship of Laryngology at Jefferson Medical College and moved to Philadelphia to accept this position Here he became recognized as the world's leading laryngologist and bronchoscopist In 1917 he was instrumental in founding the American Bronchoscopic Society and served as its first president He had been a Founder Member of the American College of Surgeons in 1913 In 1919 he was elected to fill the new chair of Bronchoscopy and Esophagoscopy created for him at the University of Pennsylvania Graduate School of Medicine He later received similar appointments at Temple University and Women's Medical College He became President of the Women's Medical College in 1935

During these years Jackson received innumerable medical honors in this country and abroad He traveled widely to give papers on bronchoscopy and allied subjects and visited all parts of the world to teach the principles and techniques of peroral endoscopy He was an honorary member of medical

Dr Jackson experienced great personal satisfaction in the establishment and subsequent development of the Chevalier Jackson Bronchoscopic Clinic of Temple University Hospital and Medical School Here, his son, Chevalier L Jackson, joined him in the clinical work and teaching program in bronchoesophagology and laryngeal surgery The quiet, friendly guidance, the teaching of technical skill and medical judgment, and finally the transfer of authority from one generation to the next, was one of the ways in which the character and wisdom of this great man were most beautifully revealed Under the son's guidance, the father's work continues

In all medical achievements the beginning can never be defined, nor the end envisioned Chevalier Jackson's influence in medicine will continue to be felt far beyond the borders of his country and the span of his life Modern medicine, as well as his individual patients, pay great homage to this man who did so much more than his part "as his turn came 'round " ment It attested to Jackson's constant drive to teach and to broaden the field of bronchoscopy In the separate clinics he developed individuals who carried on his work in strictest adherence to his principles Dr Ellen J Patterson of Pittsburgh continued his work there when he moved to Philadelphia Dr Louis Clerf continued at Jefferson Medical School, maintaining the international reputation of that world famous clinic Dr Gabriel Tucker carried on in like manner at the Graduate School as did Dr Emily Van Loon at the Women's Medical College

The great modesty, sincerity and singleness of purpose of this man, who lived through almost a century of medicine can hardly be realized He developed a specialty through keen observation, consummate skill and great perseverance He discussed its problems and their solutions with his colleagues, but his wealth of clinical experience kept him far in the lead in any consultation He gave his opinion when it was asked, but often with the disarming statemnet, "But of course, I have just one vote, you know" His kindness, gentleness, and courtesy pervaded all his actions, and these basic attitudes commanded the greatest respect from his patients and the colleagues who worked with him, yet his strict formality gave only a very few an opportunity to know him, except through medical discussions Those few who had the privilege of a visit to "The Mill" where he lived in the beautiful countryside outside of Philadelphia, saw a man keenly interested in nature and humble in his appreciation of the beauty of his surroundings He was fascinated by the mechanics of the mill wheels, the electric boat he used on the mill pond and the wood and metal tools he could use so well Even carving a roast at dinner was a task requiring a host of intruments, all laid out before him with precision and in exact order At Old Sunrise Mills he cherished the warmth of the family circle He derived great pleasure, for example, working with his granddaughter preparing the drawings for one of his last papers, illustrating the types and action of grassheads as foreign bodies in the bronchi

AMERICAN MEDICAL ASSOCIATION, SECTION ON LARYNGOLOGY, OTOLOGY AND RHINOLOGY

President Dr Van D Rathgeber
Vice-President Dr William Skokan
Secretary Treasurer Dr Paul Rockwell

GREATER MIAMI EYE, EAR, NOSE AND THROAT SOCIETY

President Dr William B Steinman
President Elect Dr James H Mendel, Jr
Secretary-Treasurer Dr H Carlton Howard
Meeting quarterly (March , May, October and December), on the second Thursday of the month, 6 30 P M , at Urmey Hotel, Miami

INTERNATIONAL BRONCHOESOPHAGOLOGICAL SOCIETY

President Dr Jo Ono, Tokyo, Japan
Secretary Dr Chevalier L Jackson, 3401 N Broad St , Philadelphia 40, Pa , U S A
Meeting

KANSAS CITY SOCIETY OF OTOLARYNGOLOGY AND OPHTHALMOLOGY

President Dr Clarence H Steele
President Elect Dr Dick H Underwood
Secretary Dr James T Robison, 4620 J C Nichols Parkway, Kansas City, Mo
Meeting Third Thursday of November, January, February and April

LOS ANGELES SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Max E Pohlman
Secretary Treasurer Dr Wendell C Irvine
Chairman of Ophthalmology Section Dr Carroll A McCoy
Secretary of Ophthalmology Section Dr Philip D Shanedling
Chairman of Otolaryngology Section Dr Robert W Godwin
Secretary of Otolaryngology Section Dr Francis O'N Morris
Place Los Angeles County Medical Association Bldg , 1925 Wilshire Blvd , Los Angeles Calif
Time 6 30 P M last Monday of each month from September to June, inclusive—Otolaryngology Section 6 30, first Thursday of each month from September to June inclusive—Ophthalmology Section

LOUISIANA MISSISSIPPI OPHTHALMOLOGICAL AND OTOLARYNGOLOGICAL SOCIETY

President Dr Fred D Hollowell, Lamar Life Bldg , Jackson, Miss
Secretary Dr Edley H Jones 1301 Washington St Vicksburg, Miss
Meeting Edgewater Gulf Hotel, Edgewater Park Miss , May 15 16, 1959

RESEARCH STUDY CLUB OF LOS ANGELES, INC

Chairman Dr Orrie E Ghrist, 210 N Central Ave., Glendale, Calif
Treasurer Dr Norman Jesberg, 500 So Lucas Ave , Los Angeles 17, Calif
Otolaryngology Dr Russell M Decker, 65 N Madison Ave., Pasadena 1, Calif
Ophthalmology Dr Warren A. Wilson, 1930 Wilshire Blvd , Los Angeles 57, Calif
Mid Winter Clinical Convention annually, the last two weeks in January at Los Angeles, Calif

SECTION OF OTOLARYNGOLOGY OF THE MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA

Chairman Dr J L Levine
Vice-Chairman Dr Russell Page
Secretary Dr James J McFarland
Treasurer Dr Edward M O'Brien
Meetings are held the second Tuesday of September, November January, March and May at 6 30 P M
Place Army and Navy Club Washington D C

SCOTTISH OTOLARYNGOLOGICAL SOCIETY

President Dr F T Land 13 Newton Place, Glasgow C 3
Secretary Treasurer Dr J F Birrell 14 Moray Place, Edinburgh
Assistant Secretary Dr H D Brown Kelly, 11 Sandyford Place, Glasgow, C 3

SOCIEDAD COLUMBIANA DE OFTALMOLOGIA Y OTORRINOLARINGOLOGIA (BOGOTA, COLUMBIA)

Presidente Dr Alfonso Tribin P
Secretario Dr Felix E Lozano
Tesorero Dr Mario Arenas A.

SOCIEDAD CUBANA DE OTO LARINGOLOGIA

President Dr Reinaldo de Villiers
Vice-President Dr Jorge de Cárdenas
Secretary Dr Pablo Hernandez

SOCIEDAD DE ESTUDIOS CLINICOS DE LA HABANA

Presidente Dr Frank Canosa Lorenzo
Vice-Presidente Dr Julio Sanguily
Secretario Dr Juan Portuondo de Castro
Tesorero Dr Luis Ortega Verdes

SOCIEDAD DE OTORRINOLARINGOLOGIA Y BRONCOESOFAGOSCOPIA DE CORDOBA

Presidente Dr Aldo Remorino
Vice-Presidente Dr Luis E Olsen
Secretario Dr Eugenio Romero Diaz
Tesorero Dr Juan Manuel Pradales
Vocales Dr Osvaldo Suárez Dr Nondier Asis R , Dr Jorge Bergallo Yofre

OTOSCLEROSIS STUDY GROUP

President Dr E P Fowler, Jr, 180 Fort Washington Ave, New York 32, New York
Secretary Treasurer Dr Arthur L Juers, 1018 Brown Building, Louisville 2, Ky
Meeting Palmer House, Chicago, Ill, October 11, 1959

PACIFIC COAST OTO OPHTHALMOLOGICAL SOCIETY

President Dr H Leroy Goss, 620 Cobb Bldg, Seattle 1, Washington
Secretary Treasurer Dr Homer E Smith, 508 East South Temple, Salt Lake City, Utah
Meeting

PAN AMERICAN ASSOCIATION OF OTO RHINO-LARYNGOLOGY AND BRONCHO ESOPHAGOLOGY

President Dr Paul Holinger, 700 No Michigan Blvd, Chicago, Ill
Executive Secretary Dr Chevalier L Jackson, 3401 N Broad St, Philadelphia 40, Pa, U S A.
Meeting Seventh Pan American Congress of Oto Rhino Laryngology and Broncho-Esophagology
Time and Place Miami, Fla, March, 1960

PHILADELPHIA LARYNGOLOGICAL SOCIETY

President Dr John J O'Keefe
Vice-President Dr Joseph P Atkins
Secretary Dr William A. Lell
Executive Committee Dr Harry P Schenck, Dr Benjamin H Shuster, Dr William A Lell, Dr William J Hitschler, and Dr Chevalier L Jackson

PITTSBURGH OTOLOGICAL SOCIETY

President Dr Bernard L Silverblatt, 3500 Fifth Avenue, Pittsburgh, Pa
Vice-President Dr Emory A Rittenhouse, 203 Masonic Bldg, McKeesport, Pa.
Secretary Treasurer Dr John T Dickinson Mercy Hospital, Pittsburgh 19, Pa

PORTUGUESE OTORHINOLARYNGOLOGICAL SOCIETY

President Dr Albert Luis de Mendonca
Secretary Dr Antonio da Costa Quinta Avenida, de Liberdale 65 1° Lisbon

PUGET SOUND ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Clifton E Benson, Bremerton, Wash
President Elect Dr Carl D F Jensen, Seattle Wash
Secretary Dr Willard F Goff 1215 Fourth Ave, Seattle, Wash

SOCIEDAD PANAMENA DE OTORRINOLARINGOLOGIA

Presidente Dr Manuel Preciado
First Vice-Presidente Dr Alonso Roy
Second Vice Presidente Dr Carlos Arango Carbone
Secretario Dr María Esther Villalaz
Tesorero Dr Ramòn Crespo

SOCIEDADE PORTUGUESA DE OTORRINOLARINGOLOGIA E DE BRONCO ESOFAGOLOGIA

Presidente Dr Alberto Luis De Mendonca
Vice-Presidente Dr Jaime de Magalhaes
1° Secretario Dr Antonio da Costa Quinta
2° Secretario Dr Albano Coelho
Tesoureiro Dr Jose Antonio de Campos Henriques
Vogais Dr Teofilo Esquivel
Dr Antonio Cancela de Amorim
Sede Avenida da Liberdade 65 1° Lisboa

SOCIETY OF MILITARY OTOLARYNGOLOGISTS

President Lt. Col Stanley H Bear, USAF (MC), USAF Hospital, Maxwell (Air University) Maxwell Air Force Base Ala
Secretary Treasurer Capt Maurice Schiff, MC USN U S Naval Hospital Oakland Calif
Meeting

SOUTH CAROLINA SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr James H Gressette Orangeburg S C
Vice-President Dr Robert P Jeanes Easley S C
Secretary Treasurer Dr Roderick Macdonald 333 East Main St, Rock Hill S C
Meeting

SOUTHERN MEDICAL ASSOCIATION, SECTION ON OPHTHALMOLOGY AND OTOLARYNGOLOGY

Chairman Dr V Eugene Holcombe Charleston W Va
Chairman Elect Dr G Slaughter Fitz Hugh Charlottesville, Va
Vice-Chairman Dr George M Haik New Orleans, La.
Secretary Dr Mercer G Lynch, New Orleans La.

VIRGINIA SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr Benjamin Sheppard 301 Medical Arts Building Richmond Va
President Elect Dr Emanuel U Wallerstein Professional Building Richmond Va
Vice-President Dr Calvin T Burton Medical Arts Building Roanoke Va
Secretary Treasurer Dr Maynard P Smith 600 Professional Building Richmond Va

WEST VIRGINIA ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

President Dr James K Stewart Wheeling W Va.
Secretary Treasurer Dr Frederick C Reel Charleston W Va
Annual Meeting

SOCIEDAD DE OTO RINO LARINGOLOGIA, COLEGIO MEDIO DE EL SALVADOR, SAN SALVADOR, C A

President Dr Salvador Mixco Pinto
Secretary Dr Daniel Alfredo Alfaro
Treasurer Dr Antonio Pineda M

SOCIEDAD ESPANOLA DE OTORRINOLARINGOLOGIA

Presidente Dr D Adolfo Hinojar Pons
Vice Presidente Dr D Jose Perez Mateos
Secretario General Dr D Francisco Marañés
Tesorero Dr D Ernesto Alonso Ferrer

SOCIEDAD MEXICANA DE OTORRINOLARINGOLOGIA

Monterrey 47-201
Mexico 7, D F

President Dr Rafael Giorgana
Secretary Dr Carlos Valenzuela
Treasurer Dr Benito Madariaga
First Vocal Dr Rafael González
Second Vocal Dr Juan Oberhauser

SOCIEDAD NACIONAL DE CIRUGIA OF CUBA

Presidente Dr Reinaldo de Villers
Vice Presidente Dr César Cabrera Calderin
Secretario Dr José Xirau
Tesorero Dr Alfredo M Petit
Vocal Dr José Gross
Vocal Dr Pedro Hernández Gonzalo

SOCIEDAD OTO-RINO LARINGOLOGIA DE LOS HOSPITALES DE MADRID

Presidente Dr Don Fernando Beltrán Castillo
Secretario General Dr Don Alfonso Vassallo de Mumbert.
Tesorero Dr Don Rafael Garcia Tapia

SOCIEDAD VENEZOLANA DE OTORRINOLARINGOLOGIA

Presidente Dr Gabriel Briceño Romero
Vice-Presidente Dr Silvestre Rincón Fuenmayor
Secretario General Dr Oscar Bustamante Miranda
Tesorero Dr Arturo Marrero Gómez
Vocales Dr Miguel Octávio Russa, Dr Benjamin Briceño, Dr Oscar Gonzalez Castillo

SOCIEDADE DE OFTALMOLOGIA E OTORRINOLARINGOLOGIA DO RIO GRANDE DO SUL

President Dr Paulo Fernando Esteves
Vice-President Dr Jayme Schilling
First Secretary Dr Carlos Buede
Second Secretary Dr Moizés Sabani
First Treasurer Dr Israel Scherman
Second Treasurer Dr Rivadávia C Meyer
Librarian Dr Carlos M Carrion

Nichols NASAL SYPHON

In acute and chronic

Sinusitis

If inflammatory exudates are periodically removed by instituting a strict regimen of cleansing, it is now known that the membrane of the sinuses has far greater recuperative powers than was once realized Even in treating sinus infections with antibiotics, complications are being seen and reported in increasing numbers due to the mutations of bacteria which can easily resist them This has brought safe SYPHONAGE nasal irrigations to the fore in the conservative management of nasal pathologies

NICHOLS NASAL SYPHON has been widely prescribed by leading rhinologists for FORTY years and has proven its efficacy in the treatment of nasal infections Its systematic use inhibits rapid growth of pathogenic organisms as it prevents stagnation of mucopurulent pus—thereby reducing the engorgement of the nasal mucosa Quickly reestablishes VENTILATION and DRAINAGE and promotes regeneration of healthy tissue

Try this TIME TESTED method Just send coupon!

NOTICE TO CONTRIBUTORS

THE LARYNGOSCOPE reserves the right of exclusive publication of all articles submitted This does not preclude their publication in Transactions of various Societies

Manuscripts should be typewritten, double spaced, on one side of paper only and with sufficient margins to allow for corrections

Author's name and city should appear directly under title on first page, street address at end of article

All prints or photographs to be submitted in black and white, in good sharp contrast Good halftones depend upon clear photographs Line drawings for zincs to be in black and white Colored inks or red or blue quadrille rulings will not reproduce

References should be complete author's surname, initials, title of article, Journal, volume, page, month, year

Six illustrations will be furnished for each article without cost to author Authors will please limit illustrations to six or assume the expense of additional illustrations

Proofs will be submitted to authors for corrections If these are not returned, articles will be published as corrected in this office

Reprints will be furnished at the following prices

WITHOUT COVER

	250 Copies	500 Copies	1000 Copies	2000 Copies

PERMANENT
Courses in Microsurgery
of the Ear
(Stapesmobilisation)

In the First Clinic for Ear, Nose and Throat Diseases, in Vienna, Austria Personal work on specimen

Apply Directly to
DR F NEUBERGER,
I Ohrenklinik, Wien, IX,
Alserstr 4
for further details The cost of the course is $6 per hour

INDEX

SUBJECTS

A

Abstract of the Proceedings of the Seventy Ninth Annual Meeting of the American Laryngological Association 2098

A Case of Unusual Congenital Fistula of the Auricle—Keohane, J [illegible]

Acetylcholinesterase and the Olivo Cochlear Tract of Rasmussen (Abstract)—Schuknecht H F 627

A Clinical Look at Progress in Evaluation of Hearing Function—Guilford F R and Haug Olaf 1313

A Comparison of Picture Response and Hand Raising Techniques for Pure Tone Audiometry with Young Children—Siegenthaler B M and Kaplan Harriett 548

Addenda—Guilford F R, and Haug Olaf 1313

Adenoidectomy A Technical Aid in—Obregon G 73

A Device for Intra Esophageal and Other Intra Lumen Pressure Recording—Field, A S Jr 1160

A Guide for Stapes Surgery Based on a New Surgical Classification of Otosclerosis—Bellucci R J 741

A Laboratory Method for the Study of Acoustic Trauma—Eldredge D H and Covell W P 465

American Laryngological Association Abstract of the Proceedings of the Seventy Ninth Annual Meeting of the 2098

Anatomical Discussion of the Paper Given by Dr R Galambos on Neural Mechanism in Audition—Rasmussen G L 404

Anatomical Observations for Rhinoplastic Surgery—Luongo R and Luongo R A Jr 1076

Attempted Synthesis of Psychoacoustic Test Data in the Audiology Clinic—Harris J D 527

Electrophysiologic Procedure for Determination of Auditory Threshold in Children—Goldstein R and Withrow F B Jr 1674

Anesthesia Methods for Bronchoscopy and Their Usefulness in Practice—Knudsen E J, Rasmussen H Ruben H and Thaun Pedersen P 133

Anesthesia Topical for Bronchoscopy—McKinney J R 1814

An Objective Approach to the Complaint Lump in the Throat—Henry G A 1257

Applications and Limitations of Auditory Tests in Surgery of the Stapes—Rosen S and Bergman Moe 629

A Study of the Relationship of Air Pressure to Myringorupture—Keller A P Jr 2015

A Technique of Tympanoplasty (Tympanomalleolar Stapediopexy)—Bell H L 883

Atticomastoidectomy in Chronic Otitis Media with Central Perforation—Henner R and Jeantet Colette 780

Aural Harmonic and Bone Conduction Thresholds in the Evaluation of Cochlear Reserve in Clinical Otosclerosis—Yantis P A and Magielski J E 159

A Technical Aid in Adenoidectomy—Obregon G 73

Audiologic Findings in Central Nerve Deafness—De Sa Geraldo 309

Audiology International Conference on 209

CENTRAL INSTITUTE
FOR THE DEAF

Founded by
Dr Max A Goldstein

ORAL SCHOOL for deaf children —Day and Residential—Preschool to High School—

SPEECH CORRECTION—Classes for Children with Aphasia and other defects of speech

Modern dormitories and equipment

INSTRUCTION and CLINICS for hearing assessment, deafness prevention, auditory training, lipreading, speech defects, including aphasia, cleft palate, laryngectomy, stuttering, articulatory defects, voice disorders—children and adults

TEACHERS COLLEGE — affiliated with Washington University—leads to B S and M.A degrees and Ph D research degree—outstanding opportunities for practice

MODERN LABORATORIES FOR RESEARCH IN SPEECH AND HEARING

S Richard Silverman, Ph D ,
Director

Helen S Lane, Ph D ,
Principal

For further information address the Principal

and Bone Conduction Thresholds in the Evaluation of, in Clinical Otosclerosis —Yantis, P, and Magielski J E [illegible]

Cochlear vs Retrocochlear Lesions —Palva T 289

Combined Nutritional and Psychosomatic Management of Mucosal Disease The Stress Concept Applied to the Treatment of Ear Nose and Throat Diseases —Currier W D 1819

Comments on a Fourth Year of Training for Certification in Otolaryngology —Hoople, G D 1579

Congenital Bilateral Complete Bony Choanal Atresia —Rubin J A 2094

Congenital Stapes Footplate Fixation A Preliminary Report of Twenty Three Operated Cases —House H P, House W F, and Hildyard V H 1389

Controversial Aspects of the Treat of Laryngeal Keratosis —Priest R E 766

Convulsions Procaine —Keohane John 2096

Craniocerebral Injury Difference Limen of Intensity in Hearing Impairment Due to —Hormia A. L 808

Cysts Dermoid of the Nasal Dorsum Rhinoplastic Approach for Report of Three Cases —Riggs R. H 699

Cytologic Diagnosis and Prognosis in Carcinoma of the Mouth Pharynx and Nasopharynx —Hopp E S 1281

D

DC Potentials of the Membranous Labyrinth (Abstract) —Smith C A. Davis Hallowell and Gessert, C F 595

Dermatoses of External Auditory Canal Preliminary Report on the Pathogenesis —Jones E H and Norman T D 839

Developmental Anatomy of the Temporal Bone and Auditory Ossicles in Relation to Some Problems in Endaural Surgery —Anson B J, and Bast, T H 1383

Diagnosis and Management of Chemical Burns of the Esophagus —Waggoner L. G 1790

Difference Limen of Intensity in Hearing Impairment Due to Craniocerebral Injury —Hormia A. L 808

Differential Salpingoscope A New Device for Tubal Auscultation, —Arnold G E 1978

Direct Audiometry in Audiosurgery (Abstract) —Antoli Candela Francisco Antoli Candela Fernando Olaizola F and Saft L 635

Discussion of Function of Auditory Cortex by W D Neff —Tunturi A R 419

Discussion of Dr Lawrence s Paper on Process of Sound Conduction —von Gierke H E 347

Disease Mucosal Combined Nutritional and Psychosomatic Management of The Stress Concept Applied to the Treatment of Ear Nose and Throat Diseases —Currier, W D 1819

Diseases Rhinologic Rhinomanometry in Some —Ogura J H and Stokstead Poul 2001

Disease Temporal Bone Four Unusual Cases of —DeWeese D D 1028

Does Irradiation in Children Cause Cancer of the Thyroid? —Baron S H 1267

Drugs The Wonder a Psychosocial Phenomenon —Coleman L L 907

Dysphonia Dysplastic Minor Anomalies of the Vocal Cords Causing Persistent Hoarseness —Arnold G E 142

Dysplastic Dysphonia Minor Anomalies of the Vocal Cords

Audiometry in Diagnosis,—Carhart Raymond 253

Auditory Canal, Osteoma of the External,—Sheehy, J L 1667

Auditory Fatigue and Occupational Deafness,—Van Dishoeck, H A E, and Spoor, A 645

Auditory Threshold in Children, An Electrophysiologic Procedure for Determination of,—Withrow, F B, Jr, and Goldstein, R 1674

Auricle, A Case of Congenital Fistula of the,—Keohane, J 63

B

Basic Techniques in Myringoplasty and Tympanoplasty,—Guilford, F R, and Wright, W K 825

Behavior of the Neuroglia of the Acoustic Nuclei, Subcortical Centers and Auditory Cortex of Cats Intoxicated with Dihydrostreptomycin,—De Sa, Geraldo 571

Bell's Palsy, Medical and Surgical Treatment of,—Fowler, E P, Jr 1655

Bleeding and Clotting Time Tests, The Routine Their Medicolegal Status,—Fletcher, R 1087

Bronchoscopy Anesthesia Methods for, and Their Usefulness in Practice—Knudsen, E J, Rasmussen, H, Ruben, H, and Traun Pederson, P 133

C

Cancer of the Larynx and Pharynx—Work, W P 1544

Cancer of the Larynx. Report of an Advanced Case Surviving 22 Years—Hammond A E 876

Cancer of the Nasopharynx and Oropharynx,—Hilger, J A 1532

Cannula Eustachian Tube Biopsy—Muftic, M K 131

Case of Tracheo Malacia Following Removal of Adenoma of Thyroid Gland—Kassay, Dezso 1451

Carcinoma of the Epiglottis, Supraglottic Subtotal Laryngectomy and Radical Neck Dissection for,—Ogura, J H 983

Carcinoma of External Ear Canal Transitional Cell Type Squamous Cell,—Mehra, Y N 1983

Carcinoma of the Larynx Contralateral Metastasis in Lesions Approaching the Midline,—Jesberg, Norman 1251

Carcinoma of Mouth, Pharynx and Nasopharynx, Cytologic Diagnosis and Prognosis in,—Hopp, E S 1281

Cancer of the Thyroid, Does Irradiation of Infants and Children Cause?—Baron, S H 1267

Carotid Body Tumors Report of One Case—Montreuil, Fernand 1191

Chisels in Stapes Mobilization, Results with,—Schuknecht, H F, Graham A B, and Costello, Mary R 726

Choanal Atresia, Congenital Bilateral Complete,—Rubin, J A 2094

Cholesteatoma of the Skull Pseudo Vertigo from,—Baron, S H 1104

Cleft Palate Patients Otologic Evaluation in,—Skolnik, E M 1908

Clinical Aspects of Cortical Deafness,—Bocca, Ettore 301

Clinical Bone Conduction Audiometry at the Frontal Bone (Abstract),—Naunton, R F 671

Clinical Discussion of the Paper "Neural Mechanism in Audition" by Dr R Galambos,—Riesco, J S MacClure 406

Clinical Discussion (Neurosurgery) of Paper on the Function of the Auditory Cortex by Dr W D Neff—King R B 424

Clinical Experiences in Tympanoplasty Results of Sixty One Cases—House L R 1481

Cochlea Pendulums, Traveling Waves and the,—v Bekesy, G 317

Cochlear Reserve, Aural Harmonic

geal Surgery Employing the Emerson "Raincoat" Spirator—Shane S M, Ashr an H Welfield, A Synder J Michelson, E and Navratil D 25

Hearing Function A Clinical Look at Progress in Evaluation of—Guilford F R, and Haug Olaf 1313

Hearing in Children—Panel Discussion 2[illegible]8

Hearing Loss in Industry,—Glorig Aram, Grings W and Summerfield Anne 447

Histologically Malignant Glomus Jugulare Tumor (Case Report)—Hoople G D Bradley W H Stoner, L R and Brewer, D W 760

Hoarseness Minor Anomalies of the Vocal Cords Causing Persistent Dysplastic Dysphonia,—Arnold G E 142

Hormones Effect of on Hypogammaglobulinemia—Dolowitz D A Dougherty T F, and Higginbotham R D 1182

How Do You Go About Making a Diagnosis in Some of the More Important Rhinologic Deformities?—Owens Harold 1515

Hypogammaglobulinemia Effect of Hormones on—Dolowitz D A, Dougherty, T F, and Higginbotham R D 1182

I

Intermittent Parotid Swelling Due to Ill Fitting Dentures An Entity Its Diagnosis and Treatment—Furstenberg A C and Blatt I M 1165

International Conference on Audiology 209

Intra Aural Muscle Contraction in Man Examined by Measuring Acoustic Impedance of the Ear—Moller A R 48

Irradiation of Infants and Children Cause Cancer of the Thyroid Does—Baron, S H 1267

Irrigation of the Maxillary Sinus Through the Middle Meatus,—Myerson, M C 1555

J

Julius Caesar and the Falling Sickness—Cawthorne Terence 1442

K

Keratosis Controversial Aspects of the Treatment of Laryngeal,—Priest R E 766

L

Laryngectomy Supraglottic Subtotal and Radical Neck Dissection for Carcinoma of the Epiglottis—Ogura, J H 983

Laryngectomy Technique of Extended Fronto Lateral Parietal—Norris C M 1240

Laryngitis Polypoid The Treatment of—Lowenthal, G 1095

Laryngologic Experience in Bulbar Poliomyelitis—Lebo C P 2030

Larynx Cancer of the Report of an Advanced Case Surviving 22 Years—Hammond A E 876

Larynx Carcinoma of the, Contralateral Metastasis in Lesions Approaching the Midline—Jesberg, Norman 1251

Larynx Review of Available Literature on for 1957—LeJeune F E and Lynch, Mercer 1841

Larynx The Management of Hyperkeratosis of the—Cracovaner A J 1494

Lesions Benign of the Vocal Cords Pathology of Three Hundred Clinically,—Fitz Hugh G S Smith D E, and Chiong A. T 855

Lesions Paraorbital—Harbert F 907

Lump in the Throat An Objective Approach to the Complaint—Henry, G A. M. 1257

Malformations and Anatomical

Causing Persistent Hoarseness,—Arnold, G E 142

E

Ear, External, Studies of Factors Considered Responsible for Diseases of the I Survival of Exogenous Bacteria in the External Auditory Canal Under Varied Conditions — Senturia, B H, and Carr, C D 2052

Ear, Intra Aural Muscle Contraction in Man Examined by Measuring Impedance of the Ear,—Moller, A R 48

Ear Protection,—Zwislocki, J 486

Early Experience with Tympanoplasty (Wullstein Technique),—Lewis, M L 900

Effect of Hormones on Hypogammaglobulinemia, — Dolowitz, D A Dougherty, T F, and Higginbotham R D 1182

Effects of Ambient Noise on Speaker Intelligibility of Words and Phrases,—Dreher, J J, and O'Neill, J J 539

Effusion, Middle Ear Systemic Factors,—Davison, F W 1228

Electromyographic Study on Respiratory Movements of the Intrinsic Laryngeal Muscles —Nakamura F Uyeda, Y, and Sonoda, Y 109

Endaural Surgery, Developmental Anatomy of the Temporal Bone and Auditory Ossicles in Relation to Some Problems in,—Anson B J, and Bast T H 1380

Epithelioma of Malherbe Mummified Epidermal Cyst Calcified Report of a Case —Greenberg, S D and LeJeune F E Jr 1706

Esophagus Diagnosis and Management of Chemical Burns of the —Waggoner, L G 1790

Establishment of Criteria Based on the Concept of Noise Exposure,—Rosenblith W A 497

Evaluation of the Orthopedic Septo Columellar Suture in Rhinoplasty,—Fred, G B 1700

Eustachian Tube Biopsy Cannula,—Muftic, M K 131

Experiences in the Treatment of the Allergic Nasal Polyp by the Intrapolyp Injection of Prednisolone T B A,—Myers, David 1

Experimental Observations on Squamous Metaplasia of the Trachea —Correll, N O and Beattie, E J Jr 1036

Experimental Studies in Fixation of the Stapes and Fenestra Ovalis,—Fernandez, Cesar, Allen, G W and Lindsay, J R 1881

External Auditory Canal, Studies of Factors Considered Responsible for Diseases of the II Evaluation of Temperature and Humidity as They Influence the Amount of Ether Soluble Substances in the External Auditory Canal,—Baumann, Elizabeth S, Gessert, C F, and Senturia B H 2080

F

Falling Sickness Julius Caesar and the,—Cawthorne, Terence 1442

Fistula, Congenital, of Auricle A Case of Unusual,—Keohane, J 63

Fixation of Fractures in the Middle Third of the Face, with Kirschner Wires,—Harris H H 95

Fractures in Middle Third of the Face, with Kirschner Wires, Fixation of —Harris H H 95

Four Unusual Cases of Temporal Bone Disease,—DeWeese, D D 1028

Functions of the Auditory Cortex —Neff, W D 413

Further Contributions to the E E G Method of Evaluating Auditory Function,—Derbyshire, A J and McDermott M 558

G

General Anesthesia in Bronchoscopy Esophagoscopy and Laryn

Otologic Evaluation in Cleft Palate Patients—Skolnik, E I 1908

Ototoxicity, Report of a Recent Study on Dihydrostreptomycin—Glorig Aram 1013

P

Panel Discussion—Hearing in Children 218

Paralysis Facial Nerve A Test of Chorda Tympani Nerve Function as an Aid in Diagnosis and Prognosis of—Magielski J E and Blatt, I M 1770

Paraorbital Lesions—Harbert F 907

Paresis Problems in the Diagnosis of Pharyngeal—Kirchner J A 1641

Parotid Swelling Intermittent Due to Ill Fitting Dentures An Entity Its Diagnosis and Treatment—Furstenberg A C and Blatt I M 1165

Pathology of Three Hundred Clinically Benign Lesions of the Vocal Cords—FitzHugh G S Smith D E and Chiong, A. T 855

Perceptive Hearing Loss—Schuknecht H F 429

Pendulums Traveling Waves and the Cochlea—v Bekesy G. 317

Perforations Tympanic Office Closure of—Juers A L 1207
